Together for Science and Conservation

WMMC'19
World Marine Mammal Conference
Barcelona 2019

BOOK OF ABSTRACTS

WORKSHOPS // DECEMBER 7-8, 2019
MAIN CONFERENCE // DECEMBER 9-12, 2019

Centre de Convencions Internacional de Barcelona
Barcelona, Catalonia, Spain

OUR HOLA!

This adventure began in 2015 when the Society for Marine Mammalogy and the European Cetacean Society decided to join forces to host a World Conference. Barcelona was chosen by membership vote that year as the venue for the conference, to be co-organized by SUBMON and the University of Barcelona.

The World Marine Mammal Conference was full of new and exciting research! We were delighted to welcome a community of over 2700 people from 95 countries involved in marine mammal science and conservation, who shared an intense and rewarding week at the WMMC'19. There will be three global plenary sessions, 627 talks and 1077 posters that presented cutting-edge and thought-provoking research that will help lay the foundation for our work into the future.

A total of 1,952 abstracts were submitted for WMMC'19; however, the Program schedule allowed for only 1,652 abstracts to be presented. A panel of 451 experts (listed below) volunteered their time to review and score abstracts on a scale of 1 to 5 for criteria of originality, quality, importance, and presentation. In an effort to minimize reviewer bias, all authors and affiliations were removed from the abstracts before review. Most abstracts were reviewed by 3 experts.

After normalizing scores to correct for inter-reviewer variability, abstracts were ranked on the basis of overall score. Authors of the highest-scoring abstracts were given their first preference for presentation, whether poster, speed, or oral. Given this rigorous process and the excellence of the abstracts selected for the conference, we are confident the quality of work presented at this meeting will be unparalleled.

In closing, we wish to thank the magnificent group of very passionate and committed people who have voluntarily worked hard over the last two years to create the best program for the WMMC. Please see the very long list of these fine individuals on the next page!

Carla and Manel
Conference Co-chairs

Frances and Joan
Scientific Co-chairs

Ann and Mario
SMM and ECS

CONFERENCE HOSTS

EUROPEAN CETACEAN SOCIETY

The European Cetacean Society (ECS) was established in January 1987 and aims to promote and advance the scientific studies and conservation efforts of marine mammals and to gather and disseminate information about them to members of the Society and the public at large. The ECS is coordinated by a Council of 11 members and each year organizes an Annual Conferences in a European country.

THE SOCIETY FOR MARINE MAMMALOGY

The mission of the Society for Marine Mammalogy (SMM) is to promote the global advancement of marine mammal science and contribute to its relevance and impact in education, conservation and management.

CONFERENCE ORGANIZERS

SUBMON is a marine environmental organization born in 2008 with the aim to conserve, study and educate about the marine environment. It works to preserve marine biodiversity and to reach a sustainable use of the marine environment through promoting a change in the relationship between society and the ocean, conducting in situ actions and sharing knowledge. Its core team has more than 20 years of experience working with marine mammals, sea turtles, sharks and marine habitats. SUBMON is part of the Marine Mammal Expert Group for the implementation of the EU Marine Strategy Framework Directive and of the National Underwater Noise Expert Group.

Founded in 1450, the University of Barcelona is the major public university in Catalonia and the only Spanish university member of the League of European Research Universities (LERU). According to the Center for World University Rankings (CWUR), the UB is listed among the top 100 universities worldwide, and according to The Times Higher Education, the University of Barcelona is listed among the top 25 universities with more than 400 years of history. As WMMC19 Co-organizator, the Large Marine Vertebrates Research Group of the University of Barcelona focuses its research activities on conservation-related aspects of the biology and ecology of large marine vertebrates and its activity spans four main lines of action: conservation-oriented research, training of researchers and technicians, technical implementation of specific actions of conservation, and public awareness on the environmental challenges affecting large marine vertebrates.

WMMC'19 CONFERENCE COMMITTEE

This conference would not have been possible without the hard work and dedication from our conference committees and volunteers!

ORGANIZING COMMITTEE

Manel Gazo - Conference Co-Chair
Carla A. Chicote - Conference Co-Chair
Ann Pabst - President SMM
Mario Aqcuarone - Chair ECS

Frank Cipriano - Workshops Co-Chair
Juanita Zorrilla - Workshops Co-Chair
Eva Flores - Financial Manager
Odei Garcia-Garin - Registration Coordinator
Alba Tojeiro Formoso - Volunteer Coordinator
Irene Cervera - Sponsor/Exhibit/Coordinator & Communication
Natalia Subirà - Exhibit & Sponsorship
Angela Olvera - Exhibit & Sponsorship
Eva van den Berg - Media Coordinator
Mireia Peris - Communication Coordinator
Jonas Teilmann - Posters Coordinator
Eva Hidalgo - Visa Coordinator
Raquel García-Vernet - Student Events Coordinator
Diego Rita - BCN_Pods Coordinator & Travel Grants
Carmen Andrés - Posters & Icebreaker Coordinator
Luis Freitas - Video Night Coordinator
Mariluz Parga - LGTB Event Coordinator
Alicia Cardona - Media Event Coordinator
Sara Fernández - Graphic Design & Media support
Tecla Maggioni- Conference Committee Assistant
Tonya Wimmer - Advisor
Hillary Moors-Murphy - Advisor
Giuseppe Notarbartolo di Sciara - Int. Travel Grants Coordinator
Lindsay Porter - Award Committee Co-Chair
Aviad Scheinin - Award Committee Co-Chair

With special assistance from:
Jarrett Corke - SMM Conference Information and Technology Manager
Katherina Audley - SMM Information and Technology Manager

STUDENT AFFAIRS COMMITTEE

Raquel García-Vernet, SMM
Serena Lagoria, ECS
Courtney Smith, SMM
Rebecca Boys, ECS
Eric Ramos, SMM

SCIENTIFIC PROGRAM COMMITTEE

Joan Gonzalvo - Scientific Committee Co-chair
Frances Gulland - Scientific Committee Co-chair

Peter Tyack - Acoustics and Communication
Ari Friedlaender - Foraging Ecology
Lars Bejder - New Technology
Jaume Forcada - Polar Ecology
Phil Hammond - Population Biology and Abundance
Yara Bernaldo de Quirós - Physiology
Heli Routti - Toxicology
Marcela Uhart - Health
Bruno Cozzi - Anatomy and Morphology
Lucy Keith-Diagne - Education and Outreach
Scott Baker - Phylogeny, Systematics and Genetics
Randy Wells - Behavioural Ecology
Charles Littnan - Conservation
Andy Read - Fisheries Interaction
Peter Thomas - Policy and Management

CONFERENCE SUPPORT COMMITTEE

Silvia Frey, ECS
Katie Moore, SMM
Joan Gonzalvo, ECS
Tara Cox, SMM
Luis Freitas, ECS
JonasTeilmann, ECS
Michael Dähne, ECS

CONFERENCE CONSULTANTS

Kim Rhodes - Experient Conference Planner
Michael Smith - Experient Account Manager

WMMC'19 REVIEWERS

WMMC'19 ABSTRACTS:
ORAL, SPEEDTALKS AND POSTER PRESENTATIONS

The following is a list of all accepted abstracts for oral, speedtalks and poster presentations that were presented at WMMC'19. They are in alphebetical order based on the first author.

Marine stewardship strategy as conservation tool of common bottlenose dolphin (Tursiops truncatus) population in the Cap de Creus Canyon MPA, North-western Mediterranean basin: Habitat use and fishery interaction.

A. Chicote, Carla[1]; Auladell Quintana, Clàudia; Álvarez de Quevedo, Irene[1]; Gazo, Manel[2]
(1) SUBMON, Barcelona, Spain
(2) SUBMON & University of Barcelona
Corresponding Author: carlachicote@submon.org

Populations of Common Bottlenose dolphins (CBD) (*Tursiops truncatus*) have a very wide distribution in the Mediterranean Sea, although, most of the studies has been conducted in the northern part. It is more abundant in coastal waters above the continental shelf and the habitat use is extremely related with feeding behavior and diet preferences and depends on prey availability and specific conditions in each area. Total abundance for the Mediterranean Sea Common Bottlenose Dolphin subpopulation, listed as Vulnerable on the IUCN Red List, is unknown but thought to be in the low 10,000's and decreasing. The present study shows the results of a marine stewardship strategy implemented as a conservation tool within the Sites of Community Importance (EU-SCIs) of Cap de Creus and Lacaze-Duthiers area and the Natural Park of Cap de Creus MPA. The main objective was to determine habitat use and asses fishing interaction impact on a CBD population in the study area. A two-year based photo-id monitoring program was started in 2017. Visual transects and photo-identification surveys were conducted on the MPA using a 6 meter long RIB. A total of 3112 nm of effective effort was carried out with a total of 48 CBD sightings. Model prediction of occurrence probability has been implemented showing that distribution is related with depth and that there are two important areas of presence for the CBD population. Besides, most of CBD sightings (64%) were associated with trawl-fishing activities suggesting an dolphin-trawling interaction. stressing the need for further research to better determine the impact of the activity on the population and vice versa. With the aim of a bottom-up approach to minimize this interaction a marine governance strategy is being implemented among fishermen community in order to establish conservation measures such a ecolabel for best practices fish products when best practices of fishing are used.

Reproduction and survival of Svalbard polar bears

Aars, Jon; Andersen, Magnus
Norwegian Polar Institute, Tromsø, Norway
Corresponding Author: jon.aars@npolar.no

Capture-recapture data is frequently used to gain estimates on reproduction and survival of wild animal populations. Frequently, these estimates may be biased, e.g. when capture probability varies with life history stages. Among polar bears in Svalbard, live capture is opportunistic, and areas are not covered evenly. Many bears travel between Svalbard and Russian Arctic, and distribution of female bears that have been denning and are with cubs in spring will to a large degree depend on which maternity denning areas were available in fall the year before. For bears to reach denning areas, the actual islands need to be connected to hunting areas by sea ice. Proportions of females with cubs captured may thus not be representative of the population.

Capture data provides information on reproduction (presence or absence of cubs) and survival up to the capture date. Satellite telemetry data provides data also in the period after, up to several years. The signature of the data reveal if a bear is alive, and also if she is reproducing (as only females giving birth stay in dens for prolonged periods in winter). We employed from 10-20 collars the last 15 years on adult females, most working more than a year. From 2011, we also employed small data loggers in one ear on each female captured (geolocation tags, Migrate Technology). These tags have a battery life from 5-10 years. Most years, we have recovered 10-20 tags upon recapture, with one to several years of data. Light and temperature reveal maternity denning events, and thus a combination of data from collars and ear tags made it possible for us to construct denning (reproduction) and survival history of many females, and compare estimates with those from capture-recapture data. Results show a high frequency of failed breeding, or early loss of cubs.

Strandings of Longman's beaked whale (Indopacetus pacificus) in the Philippines

Acebes, Jo Marie[1]; Bautista-Barcelona, Andrea Leonor[2]; Yamada, Tadasu K.[3]; Santos, Mudjekeewis[4]; Dolar, Louella[5]; Tan, Jose Ma. Lorenzo[6]

Longman's beaked whale, *Indopacetus pacificus*, is one of the least known of all cetacean species. Its

external appearance was only first described in the 21st century. Prior to 2004, the species was known from only six specimens. Although at least twenty more specimens were recovered from strandings since then, knowledge on the species is still very limited. In the Philippines, the first record of the species was confirmed through a stranding in Davao in 2004. Sightings of *Indopacetus pacificus* alive at sea in the Philippines remain unconfirmed. Herein we account for all the strandings of the species in the Philippines and describe the specimens collected and their status based on examined stranding reports and actual examination of the specimens conducted by one or more co-authors. To date, there are four confirmed strandings of the species, all sub-adult individuals, which occurred at four different sites: 1.) 5.73m male at Matina-Aplaya, Davao in 2004; 2.) 5.02m male at General Nakar, Quezon in 2016; 3.) 5.4m male at Gonzaga and 4.) 5.6m male at Sta. Ana, both in Cagayan Province in 2018. Three of the strandings occurred at northern Luzon, while one in southern Mindanao. Two out of four stranded alive but died shortly after. From three of these the skeleton, stomach contents and tissue samples were examined and collected. Squid beaks and lenses were found in the stomach. Skin samples are pending genetic analysis. The skeletal specimen collected from Sta. Ana, Cagayan is by far the most complete in the country and is probably in one of the best conditions in the world. For a cetacean species that is poorly known examination of stranded specimens offers a rare opportunity to collect information. Hence, the importance of standardizing necropsy and stranding data collection protocols, training stranding first-responders and establishing a database are emphasized.

Do bigger bodies require bigger radiators? Insights into thermal ecology from closely related marine mammal species and implications for ecogeographic rules.

Adamczak, Stephanie[1]; Pabst, Ann[2]; McLellan, William[3]; Thorne, Lesley[4]

Ecogeographic rules, which aim to describe latitudinal variation in morphology within and between species, have seldom been examined in marine mammals. Bergmann's and Allen's rules, based upon thermoregulatory concepts for terrestrial mammals, describe an increase in body size [and concomitant decrease in surface area to volume (SA:V)] and decrease in appendage size (decrease in SA) with latitude. However, the unique thermoregulatory challenges of life in an aquatic environment may result in alterations or exceptions to these rules in marine mammals. Short- and long-finned pilot whales (*Globicephala macrorhynchus* and *G. melas*, respectively) provide an ideal opportunity to examine these ecogeographic rules in marine mammals because of their contrasting latitudinal distributions, morphological differences, and associations with varying temperature regimes. We applied 3D models, scaled using morphometric data from stranding networks, to examine interspecific differences in core body SA:V and appendage SA normalized by total length (SA:TL). In addition, we examined intraspecific trends between core body heat retention and appendage heat dissipation. Interspecific differences in body size supported Bergmann's rule: the more temperate long-finned pilot whale had a larger body size and lower core body SA:V than the more warm-water short-finned pilot whale. However, Allen's rule was not supported; long-finned pilot whales had larger overall appendage SA:TL than short-finned pilot whales. In addition, for both species we observed a strong and highly significant negative relationship between SA:V (heat conservation) and appendage SA (heat dissipation). Marine mammals have thinly insulated appendages that can be used to dissipate heat as the core warms. We found that both within and between species, the low overall SA:V of larger individuals was apparently balanced by a larger surface area of appendages over which to dissipate heat. Our results provide novel insight into ecogeographic rules and suggest that thermoregulatory adaptations have profound effects on morphological patterns in marine mammals.

Vessel activity trends in the Arctic, 2015-2018

Adams, Jeff[1]; Silber, Gregory K.[2]
(1) NOAA, Fisheries, Silver Spring, Maryland
(2) Smultea Environmental Sciences, Washington Grove
Corresponding Author: jeff.adams@noaa.gov

Arctic systems are among the most rapidly-changing on the globe. The increase in the extent and duration of seasonal ice-free waters is creating new opportunities for high-latitude maritime trade and marine resource utilization activities in historically inaccessible areas such as the Northern Sea Route and Northwest Passage. Associated degradation of Arctic marine ecosystems may accompany growing vessel operations through elevated levels of underwater noise, air-borne emissions, and introduction of non-native species. In addition, potential for large oil spills, among other things; and may compound stressors already

effecting biological populations as a result of climate change. Therefore, ongoing Arctic-wide, multi-year assessments of vessel traffic are needed. We analyzed 2015-2018 global satellite Automatic Information System vessel data to quantify the existing volume and spatial distribution of vessel operations, assess possible changes in these operations, and establish a baseline for ongoing monitoring. Several metrics, including hours of operation, amount of sea surface exposed to vessel traffic, and number of trips, were used to assess operations. Maritime activities in the Arctic (an area defined by the Arctic Research and Policy Act) were extensive and diverse. Fishing vessels accounted for nearly 50% of the total transits each year. Inter-year fluctuations in different locations throughout the region complicate the identification of simple, single-factor explanations (e.g., ice cover levels) regarding trends. Instead, variables such as abundance and distribution of fisheries resources, market forces (*e.g.*, global oil/gas demand), and economic feasibility as weighed against inherent risks of high Arctic marine travel appeared to influence regional activities. While measures (e.g., the Polar Code) have been established to protect Arctic marine ecosystems from vessel activities, the potential risks associated with expanding commercial and industrial activities in the region will likely warrant their expansion.

Bioenergetic requirements of grey whales in the face of prey shortages

Agbayani, Selina[1]; Trites, Andrew W.[2]
(1) University of British Columbia
(2) UBC Marine Mammal Research Unit, Vancouver
Corresponding Author: s.agbayani@oceans.ubc.ca

Eastern North Pacific grey whales (*Eschrichtius robustus*) rely heavily on energy reserves obtained on their northern feeding grounds to complete their annual 17,000 km round trip between the Arctic and Mexico. Unusually high mortalities of grey whales observed in 1999 and 2000 during their northward migration were attributed to starvation caused by reduced prey availability (likely due to climate change) or competition from increased numbers of whales on the feeding grounds. However, the role that decreased prey intake had on the observed mortalities cannot be evaluated without knowing the minimum amounts of prey required to sustain the annual migration. We addressed this knowledge gap by constructing an age-structured bioenergetics model to predict the energy requirements of each migrating cohort of grey whales and estimated the minimum threshold of daily prey consumption needed during the summer to avoid nutritional stress during the annual migration. Inputs included a comprehensive growth model describing mass-at-age for females and males, and refined estimates of energetic expenditure for different activity states based on field measurements of respiration rates at each life stage or reproductive state. Our model thereby derived daily food requirements (e.g., kg of amphipods, mysid shrimp, etc.) for all age classes of grey whales and also incorporated a range of annual energetic requirement thresholds that has specific life history consequences. Thus, we related death and reproductive failure to the amounts of prey consumed (i.e., expressed as a proportion of daily energy requirements met) to predict future mortality rates of grey whales as a function of varying prey densities. Our results, when combined with measured densities of benthic prey, can be used to assess and anticipate the likelihood of starvation-related mortality events occurring, due to either population or environmental changes.

Population parameters of southern right whales (Eubalaena australis) off Península Valdés, Argentina, for the period 1971-2015

Agrelo, Macarena[1]; Rowntree, Vicky[2]; Daura-Jorge, Fábio G.[3]; Sironi, Mariano[4]; Marón, Carina F.[5]; Vilches, Florencia O.[6]; Payne, Roger[7]; Simões-Lopes, Paulo C.[8]

Long-term studies can generate key information on the life histories and dynamics of wild populations. Southern right whales at Península Valdés, Argentina, have been monitored since 1971 through aerial photographic surveys. A 45-year dataset (1971–2015) of individuals life histories was used to estimate apparent survival, capture probability, abundance and population growth rate using capture-recapture methods. A total of 8951 sightings were used to create a photo-identification-based encounter history for 3487 individuals identified in the sampling area: 1319 females, 98 males and 2070 individuals of unknown sex. Of all individuals identified, 37.5% (n=1307) were re-

sighted over subsequent years and 21.3% (n=742) were identified in their year of birth. The Cormark-Jolly-Seber models estimated a constant apparent sex-specific survival of 0.995 (95% CI 0.993–0.997) for females and 0.951 (95% CI 0.938–0.961) for males. The recapture probabilities were not affected by variation in the survey effort but differed between adults and newborns and were time-dependent. The POPAN super-population approach estimated a varied abundance from 615 (CI 504-752) in 1980 to 4669 (CI 4176–5226) in 2014, totalizing 9197 (IC 8548–9898) different whales present in the population between 1971 and 2015. The Pradel formulation approach estimated constant population growth of 5.6% (IC 5.3–5.9) for the period 1971-2015, similar to the estimates from theoretical models previously developed for this population. In the early years (1975–1985), resightings were higher than the sightings of new whales (32.1%), however, in the last decade (2005–2015), 59.8% of the sightings corresponded to new whales (n= 1323). Southern right whales at Península Valdés have experienced high calf mortality events since 2003. Considering Península Valdés as the largest calving ground in the Western South Atlantic Ocean, these estimates are essential when assessing the conservation status of this whale population.

Fear of killer whale predation drives extreme collective behaviour in beaked whales

Fear of predation risk is a strong evolutionary pressure for prey species. Here we use animal borne DTAGs to investigate the evolution of anti-predatory behaviour in beaked whales for which fear of predation drives mass mortalities related to naval sonar exposure. Beaked whales play a predator-prey arms race against killer whales mediated by acoustic detection of prey and predators. Here, beaked whales are obligated vocalisers, as they need to use echolocation to forage at 200-3000 m depth. In contrast, killer whales reduce acoustic emission when hunting mammals sensitive to the frequencies of their calls, meaning that beaked whales need to be alert at all times, as they can be unaware of the presence of killer whales. We show that groups of Cuvier´s and Blainville´s beaked whales reduce to <25% their temporal availability for acoustic detection by killer whales thanks to closely coordinated diving and vocal behaviour. Their extreme synchronicity is not for cooperative foraging as group members spread at depth to hunt. This foraging footprint and their long dives limit their group size and metabolism, reducing their defences from predators. Instead, beaked whales resort to acoustic hiding to minimise predator encounter rate: full groups diving in synchrony are free to ascend silently in a random direction from deep dives, covering >1 km horizontal distance. These long ascents have physiological and foraging costs, but reduce by an order of magnitude the risk of post-detection interception by stalking killer whales. The idiosyncratic behaviour of beaked whales has enabled them to thrive in most oceans by exploiting a specialised deep water niche while reducing predation from killer whales. However, this fear-driven behaviour turns maladaptive when beaked whales are confronted with novel predator-like human stimuli such as sonar.

Wetlands sedimentation as a major threat to manatee survival: An analysis of Antillean manatee stranding cases in the Magdalena River (Colombia).

Corresponding Author: belkisaguilar@gmail.com

Antillean manatees (Trichechus manatus manatus) are considered Endangered. In Colombia the threats to the species include hunting, entanglement, and habitat loss. Particularly, the rapid increase of wetlands sedimentation in the Magdalena River Basin (MRB) could represent a major risk factor during the dry season. We reviewed social media and newspapers to obtain information of incidents involving manatees in the MRB, occurring between 2014 and 2019. For each event, we gathered information on date, locality, size, sex, and probable cause of death. We compiled 49 records of stranded manatees along the Middle (24.4%) and Lower (75.5%) Magdalena River (30.6% females; 24.4% males; 44.8% unknown), with 85.7% of casualties occurring during the dry season. In 27 cases the manatee was found dead, and the causes of decease were poaching (7.4%), stranding

(11.1%), killed after stranding alive (37.0%), perinatal (animals that were less than 150 cm in total length that did not die from human related causes) (3.7%) and unknown (29.6%). Twenty-two manatees were found alive and either relocated (63.6%) or released in situ (36.3%). Our records indicate that dry season represents the time of highest vulnerability and signal the sedimentation as a major threat for manatees. The MRB have undergone dramatic changes in land cover and further forest loss during the last three decades, causing an increasing sedimentation and a significant reduction of the water column of floodplain lakes and associated wetlands. Manatees in the MRB migrate forced by pronounced seasonal hydrologic fluctuations. Their migratory routes encompass shallower segments, some of which dry out during the most lowering-water seasons due to sedimentation, blocking the passage to refuge areas and increasing the chances of isolation, stranding, vulnerability to illegal hunters, and/or death. An effective strategy for protecting manatees will require socioecologic and community-based conservation approaches, which guarantee the preservation at a landscape scale.

"I don't want to go Mrs. Mom"… Survival rates for mothers and calves in common bottlenose dolphins from the southwestern Gulf of Mexico.

Demographic parameters are hard to estimate in many cetaceans, due to their large home ranges and population sizes; furthermore, they are exposed to natural selective pressures and anthropogenic impacts, which consequently influence their mortality. Negative effects may be reflected on top predators, such as the common bottlenose dolphin, as it faces natural and artificial alterations in their ecosystem. The coastal waters off Alvarado in Veracruz, Mexico, sustains a highly productivite artisanal fishery, which competes with dolphins for common food resources. Thus, we estimated the (apparent) survival rate for mothers and their calves using mark-recovery information from 98 dorsal fin photo-id surveys (2002-2010) using the Cormack-Jolly-Serber model. We used individual records on 28 well-known females (678 records) and their calves (589 records for the first and up the third calf). We also estimated the nursing period through a half-weight coefficient of association (COA) in SocProg. Mothers' survival was 0.99 ±0.14 s.d., and we found slight differences in average calf survival depending on their birth order (first 0.74±0.53; second 0.83±0.46; there was not enough reliable data for the third calf). Also, mother-calf COA values showed a monotonical decrease, which was not different from the null model at 2.9 years, and thus was assumed as the nursing period. Mother survival is within the reported values for the species, and the higher (apparent) mortality rate for calves may involve both natural (predation) and anthropic causes related to direct (wounds and entanglements) or indirect (stress and lower feeding opportunities) interactions. The difference between survival rates of the first and second calf may suggest a learning process for the mothers. Finally, the estimated nursing period is on the lower limit for the species, suggesting earlier independence for calves inhabiting this area, probably derived from competition for food resources.

Blubber cortisol concentrations as a bioindicator of stress response and overall health status in stranded striped dolphins (Stenella coeruleoalba)

There is a growing concern about the impacts of environmental changes and anthropogenic threats in marine mammals. In recent years, efforts have been directed to understand how marine mammals cope with stressors and to validate stress biomarkers, mainly through analysis of glucocorticoid hormones (e.g. cortisol). In this study, we correlated blubber and serum cortisol levels in response to cause of death in striped dolphins (*Stenella coeruleoalba*). Samples were obtained post-mortem from 52 individuals stranded on the Mediterranean coast between 2012 and 2018. A steroid hormone extraction method was performed and cortisol was analysed by enzymeimmunoassay. Individuals were divided in two groups according the cause of death, which was determined through veterinary necropsies and anatomopathologic studies: (1) Stranding,

including alive and dead stranded animals which were euthanized or died due to a disease or condition that impeded survival; and (2) Bycatch, i.e. dead stranded animals suspected to be discarded by fishermen after being incidentally captured. Cortisol concentrations (mean ± SD) were six times higher in stranded animals (35.3 ± 23 ng cortisol/g blubber; 66.3 ± 32.2 mg cortisol/ml serum) compared to the bycaught group (6.2 ± 4.3 ng cortisol/g blubber; 11.5 ± 15.1 mg cortisol/ml serum). Further, high correlation was found between circulating and blubber cortisol concentrations ($R2 = 0.73$, $p < 0.01$), providing the first evidence of this relationship in free-ranging animals. Both serum and blubber cortisol concentrations appeared to reflect a physiological state of chronic stress response in stranded striped dolphins. However, further research should address the kinetics of blubber cortisol incorporation and removal. The present study provides evidence that serum and blubber cortisol concentrations have the potential to be used as biomarkers of stress response in stranded striped dolphins, and of overall health status in free-ranging cetaceans. Moreover, it could have applicability in the study of cetacean stranding causes.

DNA collection from free-ranging Hector's dolphin and its environment

Ahn, JiYe[1]; Roe, Wendi[2]; Gedye, Kristene[3]; Weir, Jody[4]

Background:

Genetic sampling has been widely adapted for conservation and wildlife management. Obtaining DNA from free-ranging wild cetaceans is challenging, with collecting dart biopsies being commonly used. However, interest in less invasive methods has been arising, particularly when collecting from endangered species. Recent studies have shown that DNA can be collected using the exhaled air, or blow, of cetaceans. Furthermore, a study has demonstrated that species identification could be possible by collection of environmental DNA (eDNA). While larger Delphinidae (*Orcinus orca*) have had samples collected in this manner, we report here on the first DNA collection from blow in the small Hector's dolphin (*Cephalorhynchus hectori*).

Methodology/Principle findings:

In this study, we investigated if valid blow samples could be retrieved from the free-ranging Hector's dolphins in Kaikoura (New Zealand), one of the smallest cetacean species in the world. Seawater was also collected concurrently with the blow for eDNA analysis. Our methodology involves 62 blow samples that had been taken from Hector's dolphin, using petri dish on an extendable pole, and 32 water samples collected from the sea surface. To optimize detection, multiple displacement amplification, and purification steps were applied before PCR amplification of a Hector's dolphin specific mitochondrial sequence. Sanger sequencing of amplicons identified DNA from Hector's dolphins, from both the blow and the seawater samples.

Conclusions/Significance:

Here we show that the DNA were retrievable from the blow of wild dolphin, and the surrounding seawater. This study adds support that blow sampling and collection of eDNA are viable and less invasive genetic sampling methods. This study also indicates the possibility of the application of the blow sampling to any cetacean species, as the Hector's dolphin, being the one of the smallest of its order, potentially could demonstrate the lowest exhalation airflow rates.

Monitoring population trends of Baltic ringed seals in changing ice conditions

Ahola, Markus[1]; Carlsson, Anja[2]

Corresponding Author: markus.ahola@nrm.se

The Baltic ringed seal (*Pusa hispida ssp. botnica*) is one of the five subspecies of strongly ice-dependent ringed seals. During early 1900's hunting and environmental contaminants caused a massive population decline from approximately 200 000 to only 5 000 individuals. Its breeding distribution is today limited to the Bothnian Bay and to small remnants further South.

Ringed seals primarily give birth in lairs which they dig in snow drifts on sea ice to protect their pups against harsh weather and predators. Their breeding success and breeding distribution is strongly associated with ice-conditions. Population monitoring of the ringed seals in Bothnian Bay is based on aerial line-transect methodology over ice

during moult in April. Surveys have been carried out on an annual basis since 1988, constituting a unique long-term data-set.

Here we show how the Baltic ringed seal population in Bothnian Bay, where sufficient ice-conditions have been common until recently, has increased by average rate of 5 %/year to a total population size of over 20 000 animals during 1988-2019. The more Southern stocks have been affected by poor ice-conditions in most years which have likely impeded their recovery. Today climate warming is also diminishing the extent and quality of the breeding habitat for the Baltic ringed seals in the Bothnian Bay.

During the ongoing decade, warm winters have even compromised the monitoring method. In years with limited extent and early breakup of sea-ice, the results have been exceptionally high, not comparable with the results from years with stable ice-conditions, possibly due to changes in seal behavior in response to sea-ice cover. With current projections of climate warming the future for the Baltic ringed seal population is uncertain and the population development may be hard to follow since the quality of the population monitoring will be jeopardized.

Inter-annual variability in acoustic detection of blue (Balaenoptera musculus) and fin whale (B. physalus) 20 Hz calls in the Northeast Atlantic High Arctic.

Ahonen, Heidi[1]; Stafford, Kate[2]; Lydersen, Christian[3]; Kovacs, Kit M.[3]

Corresponding Author: heidi.ahonen@npolar.no

Blue whales and fin whales are regular seasonal migrants to the High Arctic. They are thought to feed throughout the summer months, taking advantage of the intense pulse of summer productivity in the High North, before returning to temperate areas at lower latitudes for the winter. Trends in distribution and habitat use of these species are not well known in the Northeast Atlantic but given that the Arctic is undergoing profound changes in sea ice dynamics associated with global warming a change in habitat use and movement behaviour of these migrating species is predicted. In this study, passive acoustic monitoring was used to investigate the spatial and temporal occurrence of these species in the Northeast Atlantic sector of the High Arctic. Two AURAL recorders were deployed on oceanographic moorings, one in the Fram Strait at about 79˚N and another situated north of the Svalbard Archipelago at about 81˚N (ATWAIN). Acoustic data were available for seven years for Fram Strait (in the period 2008-2018), and three years for Atwain (in the period 2012-2016). In the Fram Strait, most blue whale 20 Hz call detections occurred August through October, though recently (2015-2018) an increase in blue whale calls was detected in July. At this site, fin whale 20 Hz calls were detected from September through March, documenting their acoustic presence throughout the winter months. At Atwain, both species were recorded in September and October, with fin whales extending into November. Intra- and inter-annual variation in vocal presence of both species, at both locations, were detected (partly related to ice cover), providing novel long-term baseline information for the occurrence of these species in a region where traditional survey methods are seasonally limited. Such data will be valuable for investigating how environmental change impacts the phenology of seasonally resident cetaceans in the High Arctic.

Sudden decline of sperm whale sightings may be related to decay of giant squid landings in the Eastern Midriff Island Region in the Gulf of California, Mexico.

daniela.ahuatzingo@udlap.mx

Sperm whales (*Physeter macrocephalus*) are one of the toothed whale populations known in the Gulf of California, a priority site for conservation where the marine mammal diversity overlaps with the abundance of the largest marine fisheries in Mexico. Even though their presence in the Gulf has been known for centuries, there is little information on sperm whale population dynamics in this site. We conducted a study with monitoring data from 2010 to 2018, in which we recorded sperm whale sightings in the Eastern Midriff Island Region of the Gulf of California, and then applied photo-identification techniques to identify individuals. From our surveys, we found that between 2015 and 2018, the individuals' occurrence dropped to zero, leading us to analyse what could be influencing this trend. We found a strong positive correlation (r^2 = 0.8) between each season's sperm whale encounter rate, measured in whales per effort hour, and yearly landings of jumbo squid (*Dosidicus gigas*), a major fishery in the Gulf and the sperm whale's main

prey in the area. Additionally, we applied an open-population Jolly-Seber (POPAN) mark-recapture model to estimate the population size for sperm whales (2010-2015), which resulted in a negative trend. These results seem to confirm that sperm whale occurrence is strongly affected by food availability, even in habitats were site fidelity was once high. The sperm whale's relationship with jumbo squid is complex and might be influenced by oceanographic conditions such as El Niño and La Niña. Detailed studies on this trophic relationship in the region could be useful to better understand sperm whale population dynamics in the Gulf of California.

High frequency vocalizations of Amazon river dolphins (Inia geoffrensis), potential function of acoustic communication in shallow water systems.

Yamamoto, Yukiko[1]; Vera, M. F. da Silva[2]; Koshima, Shiro[1]; Akamatsu, Tomonari[3]

Amazon river dolphin has been known to produce high frequency vocalizations, which are different from echolocation signals. The function of this vocalization has been not well known. Behavioral and acoustic biologging was conducted on 8 botos in Mamirauá Sustainable Development Reserve, Brazil. Three-dimensional body accelerations, swimming depth and sounds from 20 Hz to 24 kHz were recorded during 13 to 147 minutes after release. The high frequency sounds having dominant frequency between 9-13 kHz were recorded in three dolphins. They dove regularly with two minutes periodical dives up to 4-6 m in maximum depth followed by one or two surfacing. Vocalizations were recorded in the middle of each dive, not nearby the surface. Most frequent sound production was observed just before changing the behavioral phase turned to the active swimming with non-periodic respiration and depth profiles. No high frequency vocalization was recorded in the rest of 5 individuals except for clicks. All the 5 dolphins kept active swimming during entire recording periods. Because of the Lloyd's mirror effect, low frequency sound does not travel long distance in shallow water. The sound source and the receiver should be much deeper than the sound wavelength. As the result of the mirror effect, Amazon river dolphins should avoided surface from acoustic communication. Assuming the minimum frequency of vocalization at 9 kHz and 2 m depth of the phonating and receiver dolphins, the range limit of sound traveling is calculated as 301 m, which is the physical constrain of communication distance. To communicate each other in the shallow water systems, the sound producer and the receiver should be deeper in the water column for a prolonged duration. The regular periodic dive pattern could be for effective sound propagation and eavesdropping to communicate among conspecifics. Funded by SATREPS (JST-JICA).

Distribution of common dolphins (Delphinus delphis) off São Miguel Island, Azores: Using "Highly Identifiable Individuals" to determine a potential residency pattern.

Al Abbar, Fadia[1]; cabo ibarzabal, iñaki[2]; Balibrea, Carmen[2]; Ventura Catalão, Rita Isabel[2]; Huamán Benítez, Maria Eulalia; González García, Laura[3]

Corresponding Author: fadia.alabbar@gmail.com

Short-beaked common dolphins (*Delphinus delphis*) are the most sighted species in the Azores archipelago. Yet, little is known about their spatial and temporal distribution, seasonal variation and residency patterns in this region. In order to better understand the common dolphins sighted off São Miguel Island, Azores, a 10-year sightings dataset (2009-2018), collected by opportunistic observations on board whale-watching vessels, has been used to analyse the temporal and spatial distribution, and seasonal variation.

As common dolphins occur in large numbers in the study area, and photo-identification can be extremely time consuming in terms of data collection and processing, no public catalogue has been created for the Azores archipelago yet. However, several studies in New Zealand, Australia and Greece have shown that photo-identification of common dolphins, using pigmentation and markings on dorsal fins, is reliable. In this study, a selection of "highly identifiable individuals" (HIIs) has been used to build a catalogue and determine the re-sighting rate of marked common dolphins. HIIs have been defined as dolphins with highly distinctive nicks/notches and/or extensive pigmentation of the left side of the dorsal fin. The research focus on HIIs aims to facilitate the data collection from a platform of opportunity, such as whale-watching vessels, as the time spent with the species is limited.

Pictures have been collected between 2018 and 2019.The initial results show the presence of common dolphins year-round, with larger groups in summer months. Several HIIs have been re-sighted in the months of July and August 2018. These findings may indicate the presence of certain individuals within the same season around São Miguel. Further comparisons between seasons and the two years of the study will allow to determine if some individuals are resident off the coast of São Miguel Island.

Modelling the bioaccumulation of microplastics in a marine mammalian food web of the Northeastern Pacific

Alava, Juan José
Institute for the Oceans and Fisheries, University fo British Columbia, Vancouver, British Columbia, Canada
Corresponding Author: j.alava@oceans.ubc.ca

Microplastics (MPs) are emerging pollutants of concern in the oceans and given their small size (<5mm), they can be directly or indirectly ingested by zooplankton, fish, and marine mammals. Bioaccumulation of MPs is scarcely known in marine mammalian foodwebs. To understand whether MPs bioaccumulate in cetaceans, a bioaccumulation model for microplastics was developed for the southern resident killer whale (SRKW) foodweb of the Northeastern Pacific with documented dietary uptake rates. MP concentrations of 0.66 and 3.20 particles/L in seawater and of 66 and 100 particles/kg in sediment observed around SRKW critical habitats, were used as abiotic concentrations to project simulation of high and low MP concentration scenarios. Elimination rates were calculated from documented retention time of MPs observed in some invertebrates and planktivorous fish. The response of the organisms to the abiotic exposure was projected by a plausible species-specific bioaccumulation potential of MPs. Both SRKW and its main prey (Chinook salmon) accumulated MPs from the diet, but the level of bioaccumulation in SRKW was relatively lower compared to that projected in prey in the short- or long-terms, as indicated by the biomagnification factor (BMF = predator[SRKW]/prey[Chinook salmon], where BMF<1 =no biomagnification; BMF>1 =biomagnification), ranging 0.30−0.90, except at 10 or 50 days of simulation when the BMF values ranged 1.0−1.1 and 1.2−1.5, under each scenario, respectively. The model projected that SRKW can retain 0.30−1.0 MP at 35 and 45 days to 2.5−4.0 MPs at 55 days, but with total elimination of MPs projected at 60 or 70 days. Moderate to high MP accumulation (i.e. >27 to 700 MPs) at 65 and 75 days was also projected in SRKW due to re-exposure to contaminated prey. This model can be applied as a practical tool to assess MP bioaccumulation in marine mammal species.

Habitat use of minke whales in Skjálfandi Bay, North Iceland.

The focus of this study are distribution and habitat use of minke whales (*Balaenoptera acutorostrata*) from 2005 - 2018 in Skjálfandi Bay, North Iceland. The data was set up through a continuous sighting surveys by trained volunteer using whale watching vessels as research platform. Interannual and seasonal distribution changes were investigated. Seasonal changes seem to be according to prey distributions: fish distribution obtained from fishermen interviews and Chlorophyll-a densities from satellite images. Annual changes might originate from dynamics in the whale community and a humpback whale (*Megaptera novaeangliae*) abundance increase through the years. Investigating dynamics of the minke population itself the sightings per unit effort were calculated. Less SPUE seemed to occur during the years 2006 - 2009, followed by a strong increase to similar values than found in 2005. Variations and a slowly declining trend were found for the years after 2010. A GLM will be performed to assess significant changes in SPUE between years and months. Significant declines will be discussed on conservational context regarding Iceland's commercial whaling activities. Additionally, we aim to test for small scale site fidelity and spatial group clustering using the R-package wildlifeDI. Therefore, the sighting data is currently being joined with a Photo-ID catalogue. As outcome of this research we expect site fidelity to occur for single individuals over years and to find spatial group clustering in adjacent ranges as found previously in other areas for minke whales. Results as not an infinite number of individuals sharing space equally, but groups occupying adjacent ranges would lead to important implications for conservation of the species and management of protected areas without whaling.

A whale bio-echosounder tell-tale of niche diversification in deep-diving beaked and pilot whales

Deep-diving whales must meet their energetic requirements by foraging efficiently in time-limited dives. Pilot whales are active hunters that sprint to catch few prey items while beaked whales target more low-caloric prey. Within depth-stratified pelagic habitats, the mesopelagic deep scattering layer constitutes the highest biomass concentration in the oceans, followed by the Benthic Boundary Layer (BBL). In order to investigate if there is a niche diversification between similar-sized deep-diving odontoceti with different hunting tactics via segregation within the water-column, we analyzed acoustic and movement data recorded by suction-cup attached DTAGs deployed on 28 short-finned pilot whales (121 dives) and 14 Blainville´s beaked whales (60) in the Canary Islands, and 10 Cuvier´s beaked whales (34) in the Ligurian Sea (Italy). Using echolocation clicks as bio-echosounders, we measured the time delay between the tagged whale clicks and their echoes reflected by the seafloor to calculate the altitude of the whales when attempting to capture prey (i.e: emitting buzzes). We show that pilot whales prey almost equally between the epipelagic and mesopelagic (46 and 53%), with few buzzes within the BBL (1%). Cuvier´s and Blainville´s beaked whales bypass epipelagic prey and forage within the mesopelagic (67 and 80%) and bathypelagic (29 and 5%). The BBL is exploited by Cuvier's (4% of the buzzes), which even physically probe the seafloor, and by Blainville's while following the seafloor slope (15%). Pilot whales presented diel patterns, foraging more in the epipelagic than in the mesopelagic during the night. Cuvier's beaked whales increased their bathypelagic buzzes (from 11 to 47%) at night, while Blainville's become slightly more mesopelagic. Our data supports previous findings regarding these species foraging strategies: pilot whales would target at night the more active migrant organisms of the DSL while beaked whales forage on low-caloric non-migrant meso-, bathy- and benthopelagic organisms, presenting a niche diversification.

Predictive habitat models of bottlenose dolphins (Tursiops truncatus) in the Sicilian Channel (Mediterranean Sea).

Corresponding Author: alessijessica@gmail.com

Bottlenose dolphin (*Tursiops truncatus*) is a species listed in Annex II of the Habitat Directive which require to select, designate and protect sites that support these species in order to create a network of marine protected areas. To meet these requirements, knowledge on distribution and habitat preferences of species is fundamental. Predictive habitat models can provide critical information that is necessary for species conservation. In this study, using Maximum Entropy modelling (MAXENT), we generated spatial predictions of bottlenose dolphins in the waters along Agrigento's coast in the Sicilian Channel (Mediterranean Sea). According to previous studies conducted in the area, bottlenose dolphins were frequently encountered with a rate of 72% and often interact with professional fisheries, 56% of the sightings. In this work was analyzed data collected during summer seasons from 2016 to 2018, 60 pods of bottlenose dolphins were sighted, 48 of this were feeding beyond fisheries boats. To run MAXENT model four predictive variables were considered: average depth, bottom slope, distance from the shoreline, and the number of professional fishing boat. The goodness of the model is demonstrated by AUC greater than 0.9, meaning an outstanding discrimination. The proximity to the coast was the variable that best predicts dolphins distribution, followed by the average depth, slope of the sea bottom and lastly the number of fishing boat. According to the model, this species prefers water from 3 to 7 nautical miles far from the shoreline with depth ranged from 30 to 100 m. Despite the strong interaction with fisheries, it contributes to the model for just 0.2%, even if a reduction in probability presence of bottlenose dolphins results when numbers of fishing boat increase. This study provides an example of a presence-only habitat model used to inform the management of a species for which habitat preferences are poorly understood.

Hologenomics for conservation: A first test of utility using New Zealand's endemic Māui and Hector's dolphins.

In the face of the current biodiversity crisis, conservation genetics has been quick to adopt the latest genomic approaches to improve detection of demographic bottlenecks, inbreeding, selection leading to local adaptation, and the spread of maladapted genes. A new approach that has not yet been used in conservation genetics is hologenomics, where the genome of a host organism is considered in tandem with the microbes that naturally occur throughout the host's body (the microbiome). The New Zealand endemic Māui dolphin (*Cephalorhynchus hectori maui*), thought to number only ~63 individuals, and Hector's dolphin (*C. h. hectori*), thought to number a total of ~24,000 individuals but subdivided into several regional populations, provide a compelling test case of the utility of hologenomics, as significant uncertainty remains about: (i) the potential for genetic interchange between these two subspecies; (ii) changes in their population sizes through time, (iii) the risks of inbreeding within each subspecies, and (iv) individual susceptibility to pathogens e.g. toxoplasmosis. Using an extensive database of individual Hector's and Māui dolphins collected throughout their ranges, we are sequencing both host and microbial genomes to elucidate the hologenomic basis of disease susceptibility; assess the presence (or absence) of defining hologenomic characteristics between these subspecies; and use the increased resolution of the hologenome to describe more precisely anthropogenic impacts, such as fisheries related mortality, on population sizes and connectivity. This will provide a first 'proof-of-concept' with the potential to revolutionise conservation biology on a global scale, as well as improve management of New Zealand's only endemic cetacean.

Stomach content analysis of stranded small cetaceans from Abu Dhabi and Dubai, United Arab Emirates (UAE).

The United Arab Emirates (UAE) coastal waters host a number of small cetacean species including the Indian Ocean humpback dolphin (*Sousa plumbea*) and the Indo-Pacific bottlenose dolphin (*Tursiops aduncus*). Little is known about the ecology of these small cetaceans in the Arabian/Persian Gulf (Gulf). Further studies to better understand their current status are paramount to support their conservation needs, especially considering their coastal habits and the semi-enclosed feature of the Gulf. Dietary investigations provide valuable information on cetacean feeding behavior and predator-prey relationships. This study reports on the stomach contents of one Indian Ocean humpback dolphin and three Indo-Pacific bottlenose dolphins found stranded along the shores of Dubai and Abu Dhabi. Stomach Content Analysis was used to identify prey items in cetacean stomachs. Otolith analysis was used to identify fish, and fish bones were used for secondary confirmation. Cephalopods were identified through beak analysis. A total of 137 fish, representing 11 families and 14 genera, were counted in the four stomachs. Four families of fish were found in more than one stomach: jacks (Carangidae), snappers (Lutjanidae), seabream (Sparidae) and goatfish (Mullidae). The family with the highest number of fish was mojarras (Gerreidae), however were all found in one of the three *Tursiops* stomachs, followed by Carangidae and Sparidae. A total of six cephalopod beaks were found in one stomach and classified as squid (Teuthoidae). Comparison with published data from Oman revealed five overlapping fish genera for the same two dolphin species. Additionally, 80% of the identified prey items belonged to species regularly sold in fish markets throughout the UAE. This shows a significant overlap between cetacean diet and local commercial fishery species deemed as being over exploited.

Modelling the habitat preferences of sperm whales off the north-west coast of Scotland

The distribution and habitat preferences of male sperm whales (*Physeter macrocephalus*) off the north-west coast of Scotland are poorly understood. Understanding the factors which drive distribution is critical in understanding the species ecology and has important conservation implications. The habitat preferences of sperm whales were modelled in relation to environmental variables to determine distribution and habitat preferences and define critical areas for sperm whales in the waters off the north-west coast of Scotland. This study used acoustic data collected on Extended Ellet Line (EEL) hydrographic survey in June 2016. Sperm whales make loud, near-continuous echolocation clicks, making passive acoustics the most reliable method of detecting animals. A Generalised Additive Model (GAM) was used to model sperm whale acoustic occurrence with Generalised Estimating Equations (GEEs) to account for temporal autocorrelation, resulting from the large distances over which sperm whales could be heard. A range of bathymetric and oceanographic variables including: depth, slope, sea surface temperature (SST) and the distance to, strength and persistence of thermal fronts, were available for inclusion in the model. Results suggest that sperm whales off the north-west coast of Scotland are most likely to be encountered in depths between 1500-2500m and temperatures between 10-14°C. Highest aggregations were also associated with areas of high internal wave activity around Anton Dorhn seamount and north of Rockall Bank as determined by numerical models that are likely to aggregate their squid prey. These areas were also associated with deep scattering layers around 500m depth identified from concurrent fisheries echosounder data. These results suggest that the deep waters off NW Scotland provide an important foraging habitat for sperm whales, with implications for conservation.

Locomotive response of narwhal (Monodon monoceros) to large vessel traffic in Milne Inlet, Nunavut.

Narwhal (*Monodon monoceros*) in the Eastern Canadian Arctic may be subject to a changing environment as a result of increased commercial shipping activity. To assess the potential effects of commercial shipping on narwhal, behavioral response to large vessels (≥ 100 m) transiting along an active shipping route in Milne Inlet, Nunavut was investigated by comparing animal-borne tag data with ship-tracking data collected during the 2017 open-water season. High resolution horizontal and vertical (dive) movement data were obtained for four narwhal outfitted with a combination of Argos satellite biologging tags (SPLASH-10 backpack tag and MiniPAT tow tag; Wildlife Computers) over a period of 27 to 38 days. Concurrently, vessel traffic data were obtained using a combination of shore-based and satellite-based Automated Identification System (AIS) data. A total of 67 encounters were identified in which the closest point of approach (CPA) between individual narwhal and a given vessel was within 3km and no narwhal travelled within 0.1 km of a vessel over the course of the study (mean 1.3 km; SD = 0.8 km). For each vessel-whale encounter, behavioral responses analyzed included changes in narwhal surface movement (e.g. horizontal avoidance) and changes in subsurface movement (i.e. dive behavior); with the latter component including potential changes in dive rate, dive duration, bottom time, descent velocity, and proportional time spent at surface during encounters with large vessels. Although measurable changes in surface behavior (e.g. increased turning rate in the presence of vessels) and certain dive behaviors (e.g. increased likelihood of deep dives in the presence of vessels) were observed, the response of narwhal to vessel encounters with vessels varied among individuals and among encounters by the same individual.

OK Google: Where are the humpback whales? Identification of trends in Hawaiian Island humpback whale occurrence using machine learning on passive acoustic data.

High inter-call variability in humpback whale song provides a unique challenge to the development of accurate and precise automated detection and classification algorithms for use in passive acoustic monitoring data. While relatively simple spectral or

temporal detectors work well for other baleen whales, humpback whale calls require a more adaptive approach. The Pacific Islands Fisheries Science Center (PIFSC) partnered with Google AI to develop a machine learning (ML) model capable of recognizing humpback song with high precision and recall despite the large variability between calls, through time, and across vast geographic regions. PIFSC maintains a network of seafloor-mounted long-term autonomous recording sites to listen for sounds produced by cetaceans, including humpback whales. Of particular interest are the trends in the distribution and movements of humpback whales throughout the Pacific, and particularly within the Hawaiian Archipelago, as sighting rates in the main Hawaiian Islands have declined in recent years. The acoustic network is well-suited to investigating these types of changing trends with 13 monitoring sites extending from Hawaii to the Mariana Archipelago and data reaching back more than a decade at several sites. The Google ML model was used to successfully annotate humpback whale calls within 75 second chunks of acoustic data for the entire data archive, which totals more than 170,000 hours of recordings. We used the annotated data to identify patterns of humpback whale occurrence within the Hawaiian Islands over the past decade. The ML model combined with our long term acoustic dataset provides a comprehensive and consistent metric of the occurrence of singing humpback whales between sites and over long-time periods. The success of our collaboration with Google AI demonstrates the powerful possibilities achievable when science agencies and industry partner together to address conservation questions using large data sets and cutting-edge industry tools.

Development of a fine-scale activity proxy to estimate the energetic cost of swimming in common bottlenose dolphins

The rapid advancement of bio-logging tools has led to significant interest in developing tag-based activity proxies of energy expenditure for marine mammals. The use of activity as a proxy for energetics has demonstrated mixed results; in some cases, diving, gliding, and details of tag attachment can confound the relationship between activity and energy expenditure. It is becoming clear that we need species-specific calibrations to understand the feasibility and limitations of these proxies. Therefore, to develop and calibrate an activity-energetics proxy in common bottlenose dolphins, *Tursiops truncatus*, we conducted 37 swim trials with five male dolphins at Dolphin Quest Oahu. In each trial, dolphins swam 8-12 60-meter laps while wearing suction-cup attached tri-axial accelerometry tags. We measured all breaths using novel breath-by-breath respirometry between laps which permitted fine scale resolution of respiratory flow, expired O_2 and CO_2 composition, and O_2 consumption ($\dot{V}O_2$) and CO_2 production ($\dot{V}CO_2$) rates. We calculated Overall Dynamic Body Acceleration (ODBA) for every dolphin in each trial. Inter-trial swim speeds varied, and after steady-state $\dot{V}O_2$ was reached at lap 5, activity (ODBA) and energy expenditure ($\dot{V}O_2$) were assessed as average rates of the remaining laps. The metabolic cost of locomotion was estimated by subtracting the resting $\dot{V}O_2$ measurements from the steady state $\dot{V}O_2$. Generalized Linear Models, with individual as a random effect, showed a significant relationship ($p<0.01$, $R^2=0.6$) between ODBA and $\dot{V}O_2$. The highest $\dot{V}O_2$ rates were below values associated with the onset of lactate production in other studies, indicating that these trials were primarily aerobic. This calibrated proxy substantially improves current methods for estimating locomotion costs and provides an opportunity to quantify the energetic effects of natural and anthropogenic disturbance in wild dolphins.

Skeletal injuries provide insight into the cryptic lives of beaked whales

Allen, Dee[1]; Mead, James G.; Meshida, Keiko[2]; Potter, Charles[3]

Beaked whales exhibit extreme morphology, including aspects of their bone structure and design. Osteological structure and composition within a single animal can range from highly porous osseous tissue, as in post-cranial skeletal elements, to extremely dense hypermineralized components, such as the rostra of certain species. As a living tissue, bone not only serves a structural role, but also contributes to the overall physiological function of various systems and the organism as a whole. When an injury occurs to

bone tissue, its function may be compromised, resulting in negative impacts to the health of the animal. We examined cranial and post-cranial bones of five North Atlantic beaked whale species (*Mesoplodon bidens, M. densirostris, M. mirus, M. europaeus*, and *Ziphius cavirostris*) available in institutional research collections and documented signs of antemortem bone injury. We summarized anatomical locations of osteological trauma for only those cases showing evidence of healing prior to death in order to exclude observations of damage to the bones that may have occurred postmortem; this likely resulted in underestimates of injuries that occurred perimortem. Mandibular fractures were observed more often in males than females for all species examined. Given the heavy conspecific tooth-rake scarring often observed externally on males, this finding fits with our hypothesis that males would exhibit increased incidence of associated mandibular trauma. However, post-cranial fractures were observed near-equally in both sexes for all species examined. Post-cranial fractures were observed primarily in spinous processes of the thoracic, lumbar, and caudal vertebrae and ribs, with some fractures also observed in vertebral transverse processes, rostra, and cervical vertebrae. Observations on the prevalence, anatomical location, and severity of injury between sexes, age classes, and among species are providing valuable insights into beaked whale life history, behavior, bone physiology, and physiological response to antemortem injury.

Experimental evaluation of two computer-assisted dorsal fin identification systems

Photographic-identification of bottlenose dolphins using features on the dorsal fin is a well-established and useful tool for tracking individuals over time; however, this method can be labor-intensive especially when dealing with large catalogs and/or infrequently surveyed populations. Algorithms have been developed that can find a fin in an image, characterize the features of the trailing edge of the fin, and compare the fin to a catalog of known individuals to generate a ranking based on dorsal fin similarity. We tested the performance of two platforms that have integrated fin-matching algorithms for bottlenose dolphin photo-ID: finFindR and FlukeBook TM. A test data set comprised of 604 images of 194 unique individuals was compared to a catalog of 26,706 images of 888 known individuals within each platform. Images tested included all quality levels (excellent – Q1, average – Q2, poor – Q3) of all fin distinctiveness levels (very distinct – D1, average level of distinctiveness – D2, low distinctiveness – D3, non-distinct – D4). Both algorithms performed well with 96.92 % and 95.90 % of Q1, Q2 and D1, D2 fins matched, respectively. Each platform made matches that the other platform missed. When matches between platforms were combined, 98.97 % of Q1, Q2 and D1, D2 images were matched and 95.55% of all images (regardless of image quality or fin distinctiveness) were matched. Efforts are underway to incorporate the algorithms used by both platforms into a single system to improve overall match performance and streamline the user interface so that it can be easily incorporated into the photo-ID workflow. These platforms provide reliable and accurate computer vision ranking of potential matches to marked individuals based on dorsal fin photographs within a few minutes, greatly reducing the time required to search manually for potential matches.

Syntactic features in humpback whale song revealed through network analysis facilitate population-wide cultural learning.

The arrangement of acoustic signals into vocal displays is typically governed by a set of syntactic rules. However, there is a limited understanding of which syntactic rules might be shared by the complex arrangements of vocal displays in different taxa. Recent work, focused on the complex repertoires and syntax of songbirds, has taken a new approach to investigating syntax. Network-based modelling quantifies song features such as the connectivity between signals (adjacent signals in a sequence) and other patterns in their arrangements. These features indicate structural complexity and are often the basis of syntax. Here, we apply similar network-based modelling to a mammalian display, the complex, hierarchically structured songs of eastern Australian humpback whales (*Megaptera novaeangliae*) over 13 consecutive years. Given the song's evolving pattern each year and the cultural conformity of

males in a population to learning that pattern, network modelling was applied to capture the patterns of multiple song types. In every year, song arrangements displayed 'small-world' network structure characterised by clusters of highly connected sounds (units). The transitions between these connected units were further characterised by a combination of patterns indicative of structural stability and patterns indicative of structural variability. The presence of these structural song features may facilitate vocal learning. Similar small-world structures and transition patterns are also found in the song displays of several oscine species, indicating that syntactic patterns may be common among cultural learning across multiple taxa. Understanding the syntactic rules governing the arrangement and structure of vocalisations in multiple, independently evolving lineages will indicate what rules may be important to the evolution of vocal culture.

Mechanisms of tolerance to hypoxia and oxidative stress in primary endothelial cells isolated from seals.

Allen, Kaitlin[1]; Hindle, Allyson[2]; Vazquez-Medina, Jose Pablo[3]

Marine mammals experience hypoxemia and peripheral ischemia secondary to the cardiovascular adjustments supporting diving. In terrestrial mammals, endothelial activation during ischemia stimulates inflammatory pathways, promotes oxidant generation, and impairs vasoregulation, ultimately leading to cell death and tissue injury. Protection against such injury is paramount in diving mammals, but the molecular mechanisms underlying this protection remain unknown. We developed a live, proliferative cell culture system using primary endothelial cells isolated from seal placental arteries to study the endothelial response to simulated diving *ex vivo*. Seal endothelial cell monolayers demonstrate the cobblestone-like morphology characteristic of endothelial cells. Similarly, seal endothelial cells stain positive for the endothelial markers platelet endothelial adhesion molecular (CD31) and vascular endothelial cadherin (CD144) by immunofluorescence and flow cytometry. Seal endothelial cells in primary culture are capable of incorporating dil-acetylated low-density lipoprotein, and generate oxidants after stimulation with angiotensin II and phorbol ester, suggesting that this system is biologically functional. In seal endothelial cells exposed to 1% oxygen, hypoxia-inducible factor 1α (HIF-1α) protein expression increases 20-fold from normoxic levels within 15 minutes, while equivalent human cells demonstrate a 7.5-fold increase. Seal cells maintain a 150-fold increase in HIF-1α protein expression across 2, 4, and 6 hours of hypoxia while expression in human cells peaks (80-fold increase) between 2 and 4 hours and declines to 30-fold higher than baseline by 6 hours. Acute hypoxia/reoxygenation exposure fails to alter oxidant generation in seal endothelial cells, while oxidant generation is increased 35% in human cells ($\alpha = 0.05$; $p=0.25$ and 0.04, respectively). Our data show that seal endothelial cells in primary culture are a viable, novel model to study differential regulation of hypoxia tolerance. Furthermore, our results suggest that seal endothelial cells mount a more rapid, sustained, and controlled response to hypoxia than human cells.

The biology of a mesoparasitic copepod on whales: Pennella balaenopterae (Copepoda; Pennellidae).

Alps, Diane[1]; Passarelli, Julianne Kalman[2]; Falcone, Erin[3]

Corresponding Author: diane.alps@gmail.com

Pennella balaenopterae is a mesoparasitic copepod found on marine mammals. This crustacean is among the largest of the parasitic copepods. Information on *P. balaenopterae* is sparse; little is known of the life cycle of this species and there is no information of a presumed intermediate host(s). A literature review compares the marine mammal hosts and their localities; however presence appears to be highly underreported as well as misreported (due to multiple misspellings of the scientific name). Access to complete and intact specimens is challenging due to the pelagic nature of the marine mammal hosts. Coordination with marine mammal stranding networks has provided new host records, as well as specimens for examination. Additionally, Eastern North Pacific Mark-Recapture (photo identification) studies of fin whales from 2003 to 2013 have documented presence of *P. balaenopterae* on 64% of individual whales recorded. Comparing early (December through May) versus late (June through November) annual parasite scores suggest the same whale is much more likely to have greater numbers of visible parasites later in the year, potentially indicating seasonality. This use of photo identification studies

on whales provides novel insights on growth and development rates of *P. balaenopterae*

Machine learning techniques to automate Steller sea lion ID data extraction from high-resolution images.

The collection of digital imagery via remote cameras has become a common tool in wildlife research, especially for populations in remote, inhospitable sites, such as volcanic islands inhabited by Steller sea lions (SSL) in the North Pacific. SSL declined dramatically throughout much of Alaska and the Russian Far East, likely by over 75%, from the mid-1970's through the late 1990's. The populations in the Western Aleutian Islands and nearby Commander Islands (Russia) continue to decline for unknown reasons. It is important to collect demographic data at these sites to determine spatial patterns in age-specific survival and reproduction across the range. However, access is limited and expensive. In 2012, we began deploying customized autonomous cameras to collect data on SSL sites. However, the extraction of identifiable information from the large quantity of images is a logistical and time-consuming burden. To date, we have collected over 10 million images from most of the SSL rookeries in Russia but have only been able to review approximately 20%. To remedy this problem, we developed machine learning algorithms using R, KERAS, and TensorFlow to automate and accelerate marked SSL ID extraction. A U-Net convolutional neural network was used to detect branded SSLs among unmarked SSL on the image, while the VGG16 neural network was used to classify branded animals. In our pilot study the data extraction from 30,269 images took about 96 hours of machine time, while an observer needed 960 hours to manually review the same number of images. The Deep learning algorithms rarely missed animals (missing 5% of animal encounters seen by an observer) but they discovered more IDs than observers (40% more ID identifications). Using this automated approach, we significantly reduced the time needed to extract ID information, improved performance and unified analysis across all sites.

Drivers of the spatial distribution of great whales in the Southern Pacific Ocean

Alvarez, Ricardo[1]; Rogers, Tracey[2]
(1) Evolution and Ecology Research Centre - UNSW
(2) University of New South Wales, Sydney, Australia
Corresponding Author: ralvarezpa@gmail.com

Within the southern Pacific Ocean, the great whales form a diverse and significant group of marine mammals. They are also highly relevant for conservation due to their high level of threat from human activities and global climate change. In the South Pacific Ocean, the spatial distribution patterns of these species are not well understood. In order to design appropriate cetacean conservation measures, we need to compile information that allows the understanding of their distribution patterns, as well as the interactions with negative impacts.

This study aims to assess the distribution patterns of four great whale species; the blue whale; humpback whale; southern right whale and sperm whale. A large database which contained sighting data that spanned several decades was used, and additionally, three environmental variables were included in the models: bathymetry, distance to the coast and sea surface temperature (SST). Species distribution models' (SDM) tools were applied to identify the most important distribution drivers. Furthermore, these variables were also included in models to estimate the overlap of niche levels between species.

Our results show that the most important drivers of spatial distribution for all four species include SST and bathymetry. Sperm whales show very low levels of niche overlap with the other species. the other three whale species have low to medium levels of niche overlap, which is reflected in the projected distribution.

These results indicate, that the great whales' spatial distribution show significant differences between species. The baleen whales analyzed here consume similar prey items within the southern Pacific Ocean, their differences in distribution patterns are important for avoiding resource competition. In addition, the high importance of SST as a spatial distribution pattern for the blue whale highlights the risk of this species under climate warming scenarios.

Aggregation vs segregation: Temporal dynamics and interspecific co-occurrence in an insular ecosystem with high cetacean diversity.

Understanding ecosystem function is essential for proper ecosystem-based management, yet, such knowledge is still unbalanced for the oceanic environment. Here, we aim to analyze how cetacean species co-occur throughout time in a small (800km^2) pelagic habitat (Madeira Island, NE Atlantic). A large dataset of effort-related sighting data collected on a daily basis from whale-watching boats between 2005-2018 (mean of 322 surveyed days per year, SD=15) was used to model the species' inter- and intra-annual (monthly) distribution patterns. An exploratory data analysis from 9905 daily sightings comprising 24 species showed i) no significant variations in group size for any species, ii) no inter-annual trend for any species, and iii) heterogenous intra-annual occurrence patterns for 15 species. These included year-round occurrence (with no significant intra-annual variation) for four species (Ttr, Pma, Mde, Ggr), and marked seasonal fluctuation (with significant intra-annual variation) for a wide spectrum of taxonomic groups covering small delphinids (Sfr, Sco, Dde, Sbr), large delphinids (Gma), Kogiidae and (five species of) baleen whales. Additionally, while some of the species with marked seasonal fluctuation showed temporal synchrony (e.g. Bbr-Sfr-Sbr with a seasonal peak in summer, or the migratory baleen whales in spring), others showed temporal segregation (e.g. Dde with peak in May and Gma in October). An overall picture shows that the temporal distribution of each species works like a piece of a 'year-round puzzle'. This study highlights the importance of long term data series to properly infer on the interspecific temporal co-occurrence within an area, and serves as an example of science (by using platforms of opportunity) towards conservation. Finally, a discussion on the best modelling approach (e.g. ARIMA, GAMMs, wavelet coherence) to address common biases in time series data, such as autocorrelation, is also presented.

Comparison of dolphin presence at two locations in the Istanbul Strait, Turkey, by the passive acoustic monitoring system

The Istanbul Strait (Bosphorus) is a part of the only connection between the Black Sea and Mediterranean, thus recognized as a critical habitat for cetaceans. Previous studies confirmed the occurrence of cetaceans especially in spring-summer months and indicated the areas of higher sighting frequency, mainly based on visual observation. To understand their occurrence and habitat use at a finer scale, this study compares the passive acoustic monitoring data collected by an acoustic event recorder, A-tag, at two locations in the Strait, namely Poyrazköy (near the Black Sea) and Baltalimani (middle of the strait) in April-July 2013-2016. Based on the intensity ratios of two-band frequencies (130 and 70 kHz), only data classified as delphinids (bottlenose dolphins and common dolphins) were analyzed. In total, 260,379 click trains (CTs) were detected in Poyrazköy, 13,733 CTs in Baltalimani, showing that Poyrazköy showed twenty-fold more detections throughout the study period (264 days). Diel pattern was different between two locations. Continuous presense with slight decrease in early morning and late evening was observed in Poyrazköy, while a typical shift to night time was detected in Baltalimani. Short Inter Click Intervals (ICIs) implying feeding were observed in both areas in early spring, followed by gradual shift to travelling implied by longer ICIs. Dolphins use both areas for feeding during the high fish migration season, but more intensely in Poyrazköy. Besides, in Poyrazköy, higher ICIs (>140ms) implying resting were also observed during late spring-summer. Although these two areas are close (about 15 km apart), dolphins seem to use them differently due to factors such as marine traffic, fish availability, human disturbance. When elaborating the conservation measures for these vulnerable animals, such local difference on a fine scale should also be taken into consideration.

Genomic evidence for hybrid speciation in Stenella dolphins

Hybrid speciation is a process by which a species originates as a mixture between two parental species. Although such cases of hybrid speciation have been described in plants, fish and insects, they are considered exceptionally rare in mammals. Evidence has been presented before for a marine mammal, *Stenella clymene*, arising through natural hybridization between two other species, the spinner dolphin, *S. longirostris* and the striped dolphin, *S. coeruleoalba.* Evidence for this hypothesis came from incongruent mitochondrial and nuclear DNA phylogenies and intermediate morphological characters found in *S. clymene*. In this study we build on previous analysis by generating significant new data in the form of genome-wide single nucleotide polymorphisms obtained from the three species to further elucidate the putative hybrid origin of *S. clymene*. A total of 31,562 single nucleotide polymorphisms (SNPs) were obtained using a genotyping-by-sequencing (GBS) protocol for a total of 54 samples (21 *S. longirostris* from the Pacific and Indian Oceans, 14 *S. clymene* from the Atlantic Ocean and 19 *S. coeruleoalba* from the Pacific, Atlantic and Indian Oceans). Phylogenetic, principal component and admixture analyses showed that *S. clymene* is genetically distinct form its putative parental species, with approximately 70% of its ancestry derived from *S. longisrostris* and 30% from *S. coeruleoalba.* Demographic modelling based on the site-frequency spectrum supports that the best-fitting model of origin for *S. clymene* is the model where it is considered a hybrid lineage between *S. longirostris* and *S. coerueloalba*. Evidence of introgression is further supported by the D-statistic, used to detect gene flow between closely related species. Our study emphasizes the power of population genomic analysis for understanding complex evolutionary histories and highlights the importance of elucidating speciation processes in the face of gene flow in non-model mammal species.

A study of beluga (Delphinapterus leucas) vocal ontogeny.

There is a shortage of literature regarding beluga (*Delphinapterus leucas*) vocal

ontogeny, as presently, there has only been one published study on the vocal

development of beluga calves, despite the value of ontogenetic studies for our

understanding of sound-centered species. Here, we offer the second longitudinal study of

beluga vocal development. Using a calibrated digital hydrophone with a sampling rate of

256 kHz, we investigated the vocal progression of a male beluga calf over his first two years of life. From his first day, the calf produced broadband pulse trains with upper frequency limits extending past the study's Nyquist frequency (128 kHz); higher than what was initially reported in prior studies limited by lower sampling rates. Pulse signals were the most common sound type in the calf's vocal repertoire during his first year. Mixed calls were produced in month

one but were rare overall and not regularly produced until the calf's fifth month of life.

Tonal production was also infrequent and not apparent until month four. Over the calf's

first month of life, pulse repetition rate, source level, and third quartile frequencies of the

calf's pulse trains increased significantly. First and third quartile, center, and peak

frequencies increased significantly over the first year, as did pulse repetition rate and call

duration. In his second year of life, the calf developed a contact call that was most similar

to his mother's, analogous to the contact call acquisition of other beluga calves. Parallel

findings from this and previous studies imply species-specific trends in vocal

development.

Using drone images as a new tool for fin whale (Balaenoptera physalus) photo-identification

Unmanned Aerial Vehicles (UAVs, drones) are a novel, economical and non-invasive tool for cetacean observation and monitoring. During the Fin whale Project, conducted along the Garraf coast (NE Iberian Peninsula), drones have been used since 2015 in order to obtain behavioural data, monitor body condition as well as to identify fin whale (*Balaenoptera physalus*) individuals. Since 2014, 266 fin whale sightings have been recorded off the Garraf coast and 145 individuals have been identified through traditional photo-identification. For each fin whale sighting, when weather conditions were favourable, a DJI drone was launched from the research vessel. The drone was usually flown between 5m to 30m altitude and whales showed no behavioural response towards the UAV. High-resolution vertical images of the whale's chevron have been analysed and a total of 84 different patterns (individuals) have been catalogued. 60 of these patterns were associated to their dorsal fin photo (taken from the boat). While from a research vessel it is just possible to get the photography of the right or left chevron pigmentation pattern, from the drone point of view it is possible to observe the whole chevron pattern, especially the chevron's central pattern (CCP) where left and right chevron's lines join. Every fin whale recorded with the UAV had a unique CCP that together with the blaze shape turned out to be a unique pattern not possible to observe from a vessel. Animals with weak chevron pigmentation or not distinctive dorsal fin that were not consistently available to match by photos taken from the boat, were successfully identified after analysing their CCP. This new fin whale photo-id methodology has a high potential as a tool for individual and population monitoring, behavioural studies from UAVs videos (tracking each individual while studying its diving pattern, movements and interactions within groups) and morphometric analysis.

Feral cat fiasco: Prioritizing and mitigating the threat of toxoplasmosis to endangered Hawaiian monk seals.
Amlin, Angela
NOAA-NMFS, Honolulu, HI
Corresponding Author: angela.amlin@noaa.gov

Prioritizing threats and management strategies for addressing them is a critical component of endangered species management and recovery. It is particularly important given the limited resources most agencies and conservation organizations are working with. When considering threats and strategies, managers must take into account cost, benefit, and feasibility of actions; the relative impact of the threat on the population; roadblocks to implementing solutions; legislative and political tools and obstacles; and public sentiment toward the species and/or management action in question. In this talk, we examine this process through the lens of toxoplasmosis and its impacts on the most endangered pinniped in the United States, the Hawaiian monk seal. Since 2001, there have been a minimum of 11 Hawaiian monk seal deaths from toxoplasmosis. Hawaii lacks native felids, so domestic cats are the only definitive hosts of the parasite *Toxoplasma gondii*, and spread millions of long-lived oocysts into the environment where they infect monk seals and other wildlife. The threat to monk seals is magnified by the disproportionate impact of the disease on female seals and a dearth of preventative or curative measures. NOAA's evaluation and response to the threat of toxoplasmosis is challenged by the highly controversial nature of actions taken to manage cats and the fact that as an agency NOAA has no jurisdiction over cats or the terrestrial spaces they inhabit. Effective management approaches require strategic communications, collaboration across government agencies, and strong social science to support public engagement.

The first successful satellite tag deployment on wild-captured harbor seals in Virginia, USA

In the last few decades, harbor seals (*Phoca vitulina vitulina*) have expanded their range southward along the U.S. East Coast, but their at-sea movements, dive behavior, and habitat use in this newly expanded range are unknown. To help characterize the degree of potential overlap between seals and sources of anthropogenic disturbance, in particular U.S. Navy military readiness activities, we tagged seven harbor seals (5 females, 2 males) in February 2018 in Virginia (U.S. mid-Atlantic coast), marking the first time wild harbor seals were successfully captured and tagged in the area. We deployed six SPOT, one SPLASH, and five VEMCO acoustic pinger tags, and collected biological samples for future analyses of health, diet, and genetic structure. Tag data included: time spent hauled out vs. in-water, ambient water temperatures, short- (n=7) and long-distance movement patterns (n=6); and dive profiles (one). Tracking data revealed a high degree of site fidelity to the capture location, although while in Virginia waters, individual seals showed strong preference for either inshore (i.e. within the Chesapeake Bay) or offshore areas in the Atlantic. A cumulative habitat-use analysis indicated that 33% (6,062 km^2) of areas of highest habitat utilization for all seven tagged seals overlapped with the Navy's VACAPES operation area. Most seals began leaving Virginia waters in late March, and all, with the exception of one seal whose tag stopped transmitting in late April, had moved north by mid-April 2018. Individual seals exhibited varied haul-out behavior patterns throughout the respective satellite tag deployment periods and across their range from Virginia to Maine (U.S. Northeast coast). Understanding the distribution and abundance, habitat use, and health status of these seal populations will eventually provide the foundation for a range-wide ecosystem-based analysis.

Abiotic stressors expose Peruvian fur seal parental care

Amy, Hirons[1]; Edwards, Mick[2]; Adkesson, Michael[3]; Cárdenas-Alayza, Susana[4]

Corresponding Author: hirons@nova.edu

Vulnerable Peruvian fur seals (PFS) *Arctocephalus australis* are genetically isolated subspecies of South American fur seals and have a major breeding colony in Punta San Juan, Peru. PFS display strong site fidelity on densely populated rookeries, likely due to their highly productive foraging environment associated with upwelling. PFS are susceptible to strong environmental fluctuations known as El Niño-Southern Oscillation (ENSO) events, evidenced by sea surface temperature anomaly (SSTA) fluctuations in the Niño 1+2 index. Fur from 2009 (15 adults, 28 pups), 2010 (28 adults, 27 pups) and whiskers from 2015 (6 dam-pup pairs) are comprised of keratin and are isotopically comparable. Stable carbon and nitrogen isotope ratios ($\delta^{13}C$ and $\delta^{15}N$) were employed to detect patterns in foraging habits and how they are reflected in pup tissues. The difference in $\delta^{15}N$ between adult females and pups was no more than 0.8‰ in all three years, and both age classes had an average overall decline of 1.6‰ from 2009 to 2015. This is in contrast with $\delta^{13}C$; females in 2009 and 2015, as well as pups, had nearly identical values. The 2010 adult $\delta^{13}C$ were significantly more enriched by 0.8‰ compared to the other two years, likely indicative of a more productive food web. The adult fur represents growth during the peak of the 2010 moderate La Niña phase (a cooler, productive period), while the pup lanugo, depleted by ~0.5‰ compared to the two other years, was grown during both the ENSO normal and moderate La Niña phase. The lipid-rich diets consumed by the dams of these pups may have provided additional lipid during critical fetal growth that would be represented in depleted $\delta^{13}C$ exhibited in the pup fur. The combined isotopic data from foraging adults and their developing fetuses provide finer-scale resolution of the effects of ecosystem change than population estimates.

Svalbard ringed seal (Pusa hispida) demography in a time of habitat change

Andersen, Magnus[1]; Kovacs, Kit M.[2]; Lydersen, Christian[2]

Magnus.Andersen@npolar.no

Ringed seals have evolved in close association with Arctic sea ice and depend on it for most aspects of their life history. Sea ice has declined markedly in the Svalbard Archipelago over the last three decades, but little data is available on the effects of

these changes on ringed seal demography. This study compares harvest data on body size, age structure and reproductive rates from three periods spread over the last four decades (A: 1981-1984 (n=277), B: 2002-2004 (n=272) and C: 2012-2018 (n=213)) to study potential changes in these parameters. Body length showed no clear pattern over the three study periods; males were longer in period C while females were longer in period A compared to the other periods. Animals in time periods A and B were collected March-May, while period C also had animals collected June-October, precluding direct comparisons of body mass and condition (which vary markedly seasonally) for the whole sample in each period. A subset including only May data suggests that body condition did not vary between the three periods. Age distributions for A, B and C were similar, with the exception that period C had a higher proportion of animals in the 0-3 yr age group. Age at sexual maturity for males and females was similar for periods B and C, both being lower than in A. Ovulation rates did not vary among the three periods, being 0.87 0,86 and 0,91 for C, B and A, respectively. Pregnancy rate was only available for period C (0.79). Although ringed seals in Svalbard have experienced significant change to their habitat over the last 30 years, demographic parameters appear to be largely unaffected to date. More research on the reproduction, survival, density and population size are needed before firm conclusions can be drawn regarding the status of this population.

Cetacean bycatch in Indian ocean tuna gillnet fisheries

Within the Indian Ocean, pelagic gillnet (driftnet) fisheries account for some 34% of tuna catches. We combine published bycatch sampling results from Australia, Sri Lanka, India and Pakistan to estimate bycatch rates and trends for cetaceans across all Indian Ocean tuna gillnet fisheries. Estimated cetacean bycatch peaked at about 90,000 individuals y^{-1} around 2000, but declined by about 20% since then, despite an increase in tuna gillnet fishing effort. These fisheries caught an estimated cumulative total of about 4 million small cetaceans between 1950 and 2018. These bycatch estimates take no account of cetaceans caught by gillnet but not landed, of delayed mortality or sub-lethal impacts on cetaceans (especially whales) that escape from gillnets, of mortality associated with ghost nets, of harpoon catches made from gillnetters, nor of mortality from other tuna fisheries. Total cetacean mortality from Indian Ocean tuna fisheries may therefore be substantially higher than estimated here. Declining cetacean bycatch rates suggests that such levels of mortality are not sustainable. Indeed, mean small cetacean abundance may currently be 13% of pre-fishery levels. None of these estimates are precise, but they do demonstrate the likely order of magnitude of the issue. Countries with the largest current gillnet catches of tuna, and thus the ones likely to have the largest cetacean bycatch are (in order): Iran, India, Indonesia, Sri Lanka, Pakistan, Oman, Yemen, UAE and Tanzania. These nine countries together may account for roughly 96% of all cetacean bycatch from tuna gillnet fisheries across the Indian Ocean.

High frequency hearing in grey seals (Halichoerus grypus): Do they hear 'seal-safe' pingers?

The use of pingers have been successfully proven to reduce the entanglement of harbour porpoises in gillnets. In some areas, grey seals have learned to associate the sounds of pingers with potential food sources (fish entangled in gill nets), also known as the “dinner-bell effect” which is causing increasing conflicts in fisheries.

To overcome the problem of seals homing in on pingers, several so-called 'seal-safe' pinger brands have recently been developed. These pingers emit sounds of frequencies that are sufficiently high to presumably not be audible by grey seals. Here we test this using psychophysical methods in a pool with low ambient noise. Two seals were tested with the signals emitted by pingers at different sound levels in a staircase go-no go psychophysical paradigm. The results show that grey seals indeed can hear at least some of the sounds from pingers, with preliminary data for the Aquamark 100 pinger giving a hearing threshold of 47dB re 1µPa rms. This means that grey seals can hear these pingers at distances of several kilometers. Though the Aquamark is not designed as a 'seal-safe' pinger but a representative for traditional pingers, it is important to now investigate the seals' thresholds of 'seal-safe' pingers.

Such data are critical, especially in the Baltic, where it is important to find a solution to decrease the bycatch of the endangered Baltic harbor porpoise without increasing the seal - fisheries conflict. By understanding the auditory abilities of seals at higher frequencies, the pingers can be modified to an auditory level that is not detectable by seals but still can be heard by harbour porpoises.

Common bottlenose dolphin (Tursiops truncatus) interaction with fish farms in the Gulf of Ambracia, Western Greece.

Fish farming is an expanding segment of marine aquaculture. This study examined the interaction between fish farming and common bottlenose dolphins (*Tursiops truncatus*) in the Gulf of Ambracia, Greece. We used data collected between 2007 and 2018 with the aim of studying if the high concentration of fish cages in western part of the Gulf had any effect on dolphin distribution and behavior. We defined two study areas: a "Control Area" in the north-western side of the Gulf and a "Fish Farm Area" in the south-west, in order to assess differences on dolphin occurrence, abundance, behavior and seasonal fluctuations between both study areas. Analysis on seasonality was limited to 2007-08, since this was the period with year-round effort. Habitat fidelity by single individual was also studied. A total of 136 sightings were included in the analysis: 104 sightings from the Control Area and 32 sightings from the Fish Farm Area, recorded in 169 and 74 days of research effort respectively. Both the probability of detecting dolphins ($U=5{,}115.000$, $P<0.05$) and group size ($U=452.000$, $P<0.05$) were significantly smaller around fish farms. Moreover, dolphin spent 22% of their time engaged in surface feeding in the control area and only 5% when around fish farms, indicating differences in foraging behavior between areas. When looking at seasonality effects, dolphins resulted more prone to interact with fish farms during winter (Kruskal-Wallis, $P<0.05$). From 28 dolphins photo-identified and resighted at least 10 times during the study period, half of them were never observed in the fish farm area. Our results suggest that marine aquaculture influences coastal dolphins distribution as well as their behavior. This information should be taken into consideration when defining ecosystem-based management initiatives measures within the Management Plan (e.g., not granting new fish farming licenses), which is currently in preparation for this Nat2000 site.

Urban Bottlenose dolphins (Tursiops truncatus): Field survey program in Italian North East Adriatic Sea.

Andreini, Rebecca[1]; onoranti, filippo[2]; Zaccaroni, Annalisa[3]; piscopo, giuseppe[2]

Corresponding Author: rebeccaandreini@libero.it

In 2015 Delfini Bizantini research association started a bottlenose dolphins' survey project in Italian coasts of North East Adriatic Sea. As far as we know, this area is one of the less studied of the Mediterranean basis. Despite this, preliminary data collected in few years demonstrate the constant presence of specimen of bottlenose dolphins regularly sighted during our cruises. The study area is small, extended from Goro to Marina di Ravenna. This area is theatre of strong industrial activities as hydrocarbons extraction rigs, professional fisheries and intense naval traffic. Moreover, it represents a site in which many chemical pollutants are poured from Po plan fresh water flows. The study area is divided in square transects run along the midline at a 5-7 nK speed. After the sighting, animals are approached following the ACCOBAMS cetaceans engaging rules, data reported in specific forms and photo Id identification conducted through a side picture of the dorsal fin and then elaborated with specific computer programs. The aim of this research is to collect scientific data on the abundance, population structures and behaviour of bottlenose dolphins in the study area, through the years, to define if there

are environmental or anthropic factors that could interfere with the wellness and the regular presence of dolphins in the Adriatic basis. First data analysed show a different distribution of the subject sights during the months of our field campaigns. This could be linked to numerous factors including fishing lay-off periods, research efforts, presence of calves and weather and sea conditions. Further studies and researches on field need to be conducted to confirm these hypothesis, but these preliminary results are essential to raise public awareness on the necessity to respect the marine ecosystem, to build predictive studies on the future conservation of bottlenose dolphins and to onset concrete actions to protect the species in this geographic area.

Protection and valuation of whales and dolphins by the local community in the municipalities of Anakao, Soalara Sud and Saint Augustin, ToliaraII, south-west of Madagascar.

Andrianarivelo, Norbert
Wildlife Conservation Society, Toliara
Corresponding Author: andnorb@yahoo.fr

For decades, the communities of fishers of the three municipalities of Anakao, SoalaraSud and Saint Augustin in the south-western region of Madagascar were hunters of cetaceans. Socio-ecological interviews indicated that thousands of cetaceans were caught there for local consumption and sale between 1970 and 2000. In 2008, the Fikambanana Miaro nyTrozona sy Fesotra (F.M.T.F), or Association for the Protection of Whales and Dolphins, was created after a series of workshops on the conservation of marine mammals that we carried out jointly with the Madagascar National Parks. The goal of this association is to protect and to increase the value of marine mammals through community-based whale watching and the application of the local laws. Since 2010, the hunters of the cetaceans have been trained to become tourist guides and take whale and dolphin watchers on the water using traditional and motorized dugout canoes. As a result, the number of guides rose from 6 in 2010 to 34 in 2018, and the number of whale watching tourists from 143 in 2010 to 1568 in 2018. The price varies from 40000 Ariary (11,76Euros) to 60000 Ariary (17,65 Euros) per tourist according to the location and the duration of the excursion. All local laws related to hunting and codes of good conduct for whale watching are written in the local convention or Dina which is strongly respected by the local communities. Recognizing the advantages of these activities, the local communities which previously were cetacean hunters, are now becoming strictly protectors of cetaceans.

Higher levels of organohalogen contaminant and mercury levels in seal-eating killer whales (Orcinus orca) than fish-eating killer whales in northern Norway

Andvik, Clare[1]; Jourdain, Eve[2]; Ruus, Anders; Lyche, Jan Ludwig[3]; Karoliussen, Richard[2]; Borgå, Katrine

High levels of organohalogenated contaminants (OHCs) in killer whales *(Orcinus orca)* have raised concerns about individual health and population viability. Mercury (Hg) also has harmful effects on marine mammals, but levels are underreported in killer whales. OHCs and Hg biomagnify in food chains, and OHC levels are highest in killer whale populations specialising on high-trophic prey, such as in the transient populations in the north east Pacific. Killer whales in Norway have long been assumed to specialise on Atlantic herring (*Clupea harengus),* and toxicological risk assessments for this population in Norway have relied on the OHC levels recorded for only nine herring-eating killer whales sampled in 2002. However, there is recent evidence that a subset of killer whales in Norway specialise on seal prey. Our study quantified and compared the OHC levels in blubber, and the total Hg levels in skin, of seal-eating and fish-eating killer whales from northern Norway. Biopsy samples of 31 killer whales, known from photo-identification studies, were collected from July 2017 to August 2018. The sum of polychlorinated biphenyls (ΣPCBs) in the blubber exceeded risk assessment thresholds in 100% of the seal-eating whales (n=7) and 58% of the fish-eating whales (n=26). Total Hg levels in liver, extrapolated from levels in skin, exceeded the risk assessment threshold in 40% of seal-eating and none of the fish-eating whales. Levels of all OHCs and total mercury were higher in seal-eating killer whales than fish-eating whales. Our study is the first to quantify the levels of OHCs and Hg in seal-eating killer whales from Norway, and illustrates the importance of acknowledging intra-population dietary preferences of a species when assessing its risk to contaminants.

Preliminary study on the potential re-organisation of new social groups of long-finned pilot whales (Globicephala melas) in the Strait of Gibraltar.

Corresponding Author: iris.anf@gmail.com

The Strait of Gibraltar constitutes the unique communication channel between the Mediterranean Sea and the Atlantic Ocean. The complex geomorphology and oceanographic conditions of the area sustain high levels of food sources for resident populations of several cetacean species, among those the long-finned pilot whale (*Globicephala melas*). This species present a sophisticated social structure, living in cohesive social groups known as pods. These pods are normally characterised by their long-term duration and can be formed by many individuals, which can remain in the group during their entire lifetime. The aim of this study is to describe any changes in the organisation of the observed pods along time at intra- and inter-annual scales. Individual pilot whale dorsal fins were photographed and analysed between Spring 2012 and Autumn 2018. These pictures were collected by biologists-guides onboard the whale watching boats of Turmares Tarifa following the same photo-ID protocols throughout the entire study period. The connectivity among different individuals was assessed in order to reveal any occurring restructuring and consequent formation of potentially new social groups. The preliminary results showed evident and persistent disaggregations and interchanging of individuals in a time where they are supposed to belong to concrete, particular pods. Our findings demonstrate that an approach based on long-term photo-ID by opportunistic whale watching platforms can assist traditional scientific research for the monitoring of cetacean population dynamics and social structure in the Strait of Gibraltar.

Autonomous detection of humpback whales - migration and distribution in relation to Norwegian spring spawning herring.

Humpback whales (*Megaptera novaeangliae*) até known to travel through the Norwegian Sea between their arctic summer feeding areas and low latitude breeding grounds. Traditionally, it is believed that they do not feed during migration. We use passive acoustic detections from a Seaglider™ (Kongsberg) autonomous vehicle equipped with a JASCO AMAR G4 hydrophone and a fixed hydrophone (Ocean Sonics iListen HF™ at the Lofoten-Vesterålen (LoVe) Cabled Ocean Observatory ti investigate detection and timing differences between the two platforms in January to April 2018, and in relation to ARGOS tracking data from that year. Detections were also assessed in relation to the distribution of the herring fishery and migration routes southwards towards their spawning grounds. The two platforms recorded over 2856 hours of acoustic data at two different regions: LoVe on shelf and the Seaglider at the shelf break, distanced about 300 km. Calls collected by the Seaglider were usually within the 150-500 Hz range and generally lasted less than 2 seconds. In LoVe, on the other hand, a much wider vocal repertoire of sounds was registered, which included the humpback whale song. In addition to signal-type differences, we observed significant changes in detection rates between the two platforms throughout the study period. Detections from LoVe decreased significantly in late February, while the Seaglider continued to receive calls from mid-March to mid-April. Furthermore, satellite tracking showed that the whales follow the shelf break for a period of time before continuing towards their breeding grounds. Both areas were occupied by large densities of herring, particularly in February, though some schools may remain until early spring. This work shows that the Norwegian Sea represents more than a passage route to the whales, which remain in the area until early spring following a migratory pathway driven by prey distribution, beyond traditional assumptions of whale migratory behavior.

Habitat use and behavioural ecology of the Mediterranean monk seal (Monachus monachus) in Samos Island, Greece.

The estimated global number of Mediterranean Monk seal (*Monachus monachus*) individuals left is around 650, with the largest population located in the Eastern Mediterranean Sea.

Samos is a Greek island located in the north-eastern Aegean Sea where the presence of Monk seals was investigated in this study. Daily land surveys were conducted in Mykali bay to record their presence and behaviour. Data collection started in April 2018 and is still ongoing. Habitat mapping and fish identification snorkelling surveys were also carried out in order to have a complete environmental assessment. In addition, stranding and sightings data occurred on Samos were collected from January 2017.

During the land surveys, a total of 5 sightings was recorded (Encounter Rate = 2.66%). The two main behaviours observed were Surface Swimming (24.75%) and Feeding (22.73%) (p-value < 0.01). The predominant substrates of the study area were Cobbles (60.35%) and Sand (24.20%) (p-value < 0.01). Sparse patches of the seagrass species *Cymodocea nodosa* (4.05%) and *Posidonia oceanica* (3.05%) were also noted. The most encountered fish were *Diplodus sargus* (14.67%) and *Diplodus annularis* (14.39%) (p-value < 0.01). The local community reported 18 sightings, 7 of which were in Mykali, and 5 stranding around Samos.

The presence of Monk seals occurred around the island in different habitats without noticeable preference for caves. The recorded behaviours and the fish species suggest that the study area may be a feeding ground for *M. monachus*. This study highlights the urgency to focus on different key habitats for the conservation of this endangered species rather than only on breeding caves. Samos Island stands out as an important area for the Mediterranean Monk seal but further research is necessary to establish the appropriate conservation measures.

Photogrammetry supports tag-derived tissue density as a proxy for body condition: Seasonal and locational changes in body condition of humpback whales on their feeding grounds.

It is essential for animals to accumulate sufficient reserves for survival and reproduction. For diving animals, there may be a trade-off between energy accumulation and locomotion cost because large amounts of low-density lipids could lead animals to deviate from neutral buoyancy, which is assumed to minimize cost-of-transport. We examined body condition of humpback whales using 1) animal-attached data-loggers and 2) aerial photogrammetry in two feeding grounds: June-September in Canada and May-January in Norway. Tissue Body Density (TBD) and diving air volume were estimated for 58 individuals from accelerations during decent and ascent glides. The Length-Standardized Surface Area Index (LSSAI) of 55 animals was calculated from overhead photogrammetry images. LSSAI and TBD correlated negatively (p=0.035) for 20 whales where both indices were available, indicating animals with greater surface area had lower TBD (greater lipid-stores). Seasonal changes in body condition and their relationship to life-history traits (sex, maturity and breeding status) were assessed in a hierarchical model that utilized both LSSAI and TBD as observations of underlying TBD (uTBD). The uTBD decreased over the feeding season (-1.8 kg m^{-3} per 100 days), indicating lipid-stores increased as expected. It was lower for pregnant females (-4.2 kg m^{-3}), indicating greater lipid-stores compared to adult males. uTBD was greater in Norway than Canada (+4.8 kg m^{-3}) in the early feeding season, possibly due to lower lipid-stores following a longer migration. uTBD in the late feeding season remained greater than that of sea water (Canada, 1034.3±4.6 kg m^{-3} ±SD,

n=15 whales; Norway, 1035.8±4.0 kg m^{-3}, n=13), indicating negative buoyancy. Whales could achieve neutral buoyancy while migrating at shallow depths, enhancing locomotion efficiency, using their diving air volume (37±1.7 ml kg^{-1}, ±95% credible interval). This study highlights the benefit of using two different methods to quantify the body condition of free-ranging whales.

Mediterranean monk seal populations characterization through a permanent monitoring system

Among all the Mediterranean monk seal populations still surviving in the world, only the demographic parameters of the Cabo Blanco (Mauritania/Morocco) colony have been obtained accurately. Based on the methodology used, a monitoring system was developed to obtain the demographic parameters of any other monk seal population. The system is based in the permanent implementation, during several years, of autonomous monitoring systems, based in phototrap cameras, in the main monk seal caves used by the population. The systems register the presence/absence of the seals in the caves on a every hour basis, and the pictures obtained allow to individually identified the animals through their natural marks. The method has been tested at Madeira archipelago where 25 systems were installed at 19 caves of Madeira and Desertas from 2012 to 2017. A total of 481.070 pictures were obtained, 9.835 of them with monk seal individuals presence, and 2.748 suitable for their individual identification. The analysis allowed to capture and recapture all the animals of the population and build up a catalog. Most of the animals are recaptured every year, resulting in an annual recapture rate of 0.99, and a mean of 9.8 annual recaptures for each individual from 2014 to 2017.

This intensive and permanent control has allowed to monitor animals from birth to adulthood, building up the life history of every animal and determine yearly, the population size, age and sex structure, reproductive parameters, mortality rates of the different age categories and cave use patterns. The positive results of the methodology, demonstrate that it could be used to describe the main demographic parameters of any Mediterranean monk seal population, providing high quality and accurate information for protected areas and wildlife managers, to better design or adapt focused conservation measures targeting specific age or sex categories and their threats.

Beyond the vegetation consumed by manatees in the Caribbean: Invertebrates and debris found in digestive contents and faeces.

Manatees have been described as generalist-opportunistic herbivores, with a diet composed by a great variety of plant species. However, the incidental consumption of hydrozoa, invertebrates and inorganic elements such as plastics has also been reported. Our goal was to assess the incidental consumption of animals and other elements by Antillean manatees (*Trichechus manatus manatus*) in the Caribbean of Mexico and Belize. A total of 93 feaces were collected (30 from free-ranged, and 63 from captive manatees among 2012 and 2018); also, 15 digestive contents of seven stranded-dead were analyzed. Each sample was washed, sieved, and stored, followed by separation/identification observation in an stereoscopy microscope at 4-20x magnification. The results are presented as the proportion of samples with presence of objects. Free-range manatees presented invertebrates (mollusks) (6.7%), foraminifera (13.3%), sponges (11.1%), undetermined invertebrate species (2.2%), feathers (2.2%), plastic (6.7%), glass (2.2%) and cloth (2.2%). Additionally, we report 4.8% of plastics in faeces from captive manatees. These elements, both organic and inorganic, are presumed to be incidentally consumed by wild manatees. The presence of inorganic elements (such as plastic) in the feaces of wild manatees is an important signal to be evaluated and deserves further monitoring, since it is well known that some plastics could have an important impact on health and survival of the aquatic fauna. Nevertheless, more research is

necessary to precise the possible effects that these inorganic particles have on manatee health.

Sleeping behaviors of captive Commerson's dolphins (Cephalorhynchus commersonii)

Cetacean sleep is studied with the eyes open and closed as the main index. However, the faces of commerson's dolphins are black, so it is difficult to check the status of the eyes. Therefore, to our knowledge, the detailed behavior of sleeping there has not been elucidated. When the amount of activity declines was observed as sleep time, only 14% of the day could confirm sleep. Since this is less than one-third of that of other cetaceans, it has been suggested that Commerson's dolphins may be asleep even in the active state. Sendai Umino-Mori Aquarium is the only environment in the world where the condition of the eyes of Commerson's dolphins can be checked. Therefore, the aim of the present study was to investigate the above hypothesis and attempt to clarify the detailed sleep behavior of Commerson's dolphins. A total of 290 hours of observation was conducted from 06:00 to 18:00 every month about three dayson three Commerson's dolphin family members. Sleep was defined as the eyes being closed for more than 10 s . Swimming speed, breathing frequency, swimming route, and sounds were recorded simultaneously. In total, 1720 sleep episodes were recorded. The results showed that the average swimming speeds during the waking and sleep states were 1.17 and 1.19 m/s, respectively, showing no significant difference. Furthermore, no significant difference in breathing frequency was observed. On the other hand, clear sleeping characteristics were confirmed in the swimming route and sounds. The swimming route was limited to repetitive loops around a large circular course along the tank wall, and the average number of sounds decreased to one-quarter of those during the waking state. These results support the above hypothesis and suggest that Commerson's dolphins remain in the same physical condition during both waking and sleeping states.

Just pissing in the wind? Aerial urination in river dolphins in Brazil.

For many mammals, scent marking via urine spraying facilitates mate selection, marking territories and communication with conspecifics. The chemicals in urine may transmit information about the state of the urinator (e.g., physiological). However, for cetaceans, olfaction is not a sense known to be used while gustation is poorly studied. An unusual behavior of urinating in the air by botos (*Inia geoffrensis*) in the Tocantins River (central Brazil) appears to be unique to cetaceans. Aerial urination begins with an animal slowly positioning itself upside down and extruding and exposing his penis above the water. The stream of urine may reach almost one meter into the air and arcs anteriorly. When another individual is present (categorized as 'receiver'), it remains nearby the urinator and lifts its rostrum in the direction of the stream or actively pursues the urine stream. In some occasions the receiver will remain underwater but just below the stream. Behavioural data were obtained during land-based surveys where the duration of each aerial urination event was recorded as well as the presence of receivers. From September 2014 to March 2016, 22 aerial urination events were recorded during 152 hours of sampling (0.14 events/hour of sampling). About 68% occurred in the presence of at least one receiver. The mean duration was 27 seconds with the longest event lasting 58 seconds. No apparent seasonality in this behavior was observed. All aerial urination events involved males (thus far, no females have been observed partaking in this behavior). Because botos also performed this behaviour in the presence of others, which actively pursued the urine stream, it is likely that aerial urination has a socialization or communication function. Botos possess bristles on their rostrums, which are thought to serve a sensory purpose (haptosense) and so may play an important role during aerial urination.

Increase of cetaceans' ship strikes in the Canary Islands

The Canary Islands is an archipelago composed of seven main volcanic islands, located in the northwest of Africa. It is one of the richest areas for cetacean biodiversity in the Northeast Atlantic, with 30 species identified. Strikes between vessels and cetaceans have become an issue of concern in the last decades due to an increase of the number and speed of ships. Areas with high cetacean diversity and high maritime traffic overlap have been identified as hot spots as ship strikes may compromise the population status of some cetacean species in those areas. In Europe, these areas include the Ligurian Sea, the Helenic Trench and the Balearic Islands in the Mediterranean Sea, the Strait of Gibraltar, and the Canary Islands. International but mainly inter-island ferry traffic in the Canarian waters has increased considerably in the last years including normal ferries, fast ferries, and high-speed ferries. According to the Canary Islands Cetacean Stranding Network data, ship collisions have affected a total of 81 cetaceans belonging to 12 species in the last 20 years (7 misticetes and 74 odontocetes: 5 short finned pilot whales, 10 pigmy sperm whales, 11 beaked whales, 46 sperm whales and 2 small delphinids), 33 of these cases were confirmed by forensic studies. The average per year of ship strikes in this period (1999-2018) is 4.5, 0.37 per month. During the months of January to April of 2019, 4 confirmed cases affecting to sperm whales (3) and Bryde´s whale (1), and another possible case, affecting a short-finned pilot whale, have been reported. This increase in ship strikes (from 0.37 to at least 1 per month) in the Canary Islands is coincidental in time with the introduction of new high-speed ferry routes, raising the concern of the impact of ship strikes in the conservation of sperm whales.

Modelling habitat suitability of low density cetaceans species in the Mediterranean Sea

The conservation of low density cetacean species is extremely challenging. In the Mediterranean sea, Risso's dolphin (*Grampus griseus*), Cuvier' Beaked Whale (*Ziphius cavirostris*), and long-finned pilot whale (*Globicephala melas*) are listed as 'Data Deficient' in the IUCN Red list of threatened species, highlighting the lack of information about their abundance, preferred habitat, distribution and trends. For these species, information about preferred habitat and the detection of eventual changes in distribution is essential for their conservation. The Fixed Line Transect Mediterranean monitoring Network (FLT MedNet) is operating in the Mediterranean basin since 2007, regularly collecting cetaceans' data along fixed trans-border transects during all the seasons. The high frequency of surveys allowed recording quite a large number of sightings also of the more elusive species such as *Z. cavirostris* (111), *G. melas* (33), *G. griseus* (65). We used this homogeneous dataset to model suitable habitat of the three more rare species by means of Maximum

Entropy model, using as background file the area of western Mediterranean and the Adrion region were the surveys were performed. The long term FLT MedNet data were used for building the model while data from the more recently activated FLT MedNet routes and the Mediterranean dataset recorded by ORCA were used for the model validation (58 records). Distribution of sightings was also investigated during the two time periods of the Habitat reporting (2007-2012, 2013-2018) using the Kernel density estimator to highlight potential shifts in the core areas of occurrence. Based on AUCs, validation data, and well known sites of species presence, the model results showed high performance over the large basin wide scale. Important changes in distribution were highlighted for some species such as Risso's dolphin and long-finned pilot whale.

Who are we? A demographic survey of marine mammalogists.

Archer, Frederick (Eric)[1]; Cox, Tara[2]; Freeman, Dante

In response to the growing recognition of the importance of enhancing diversity and feelings of inclusion within scientific communities, in late 2018, the ad-hoc Diversity and Inclusion Committee of the Society of Marine Mammalogy (SMM) conducted a demographic survey of the field of marine mammalogy. This anonymous survey was designed to document the composition of who is currently working in the field, to identify their concerns, and to solicit suggestions for how SMM could help the community. Invitations to participate were sent to all current and past SMM members as well as posted through several social media outlets, resulting in 879 responses. Although the female:male ratio of responses was approximately 2:1, across most age groups, a higher percentage of males reported having doctorates. Across several demographic measures, younger respondents were more diverse. Approximately 50% of respondents considered the United States as their country of birth, primary citizenship, or current residence, with the next highest number of respondents listing Canada (6%). Overall, 78 countries were represented in at least one of these three categories. Respondents from Latin America, the Caribbean, the Middle East, and Africa had the highest rates of citizenship or residency in a country other than their country of birth. English was the primary language for 68% of respondents, and Spanish the second most common (10%). Some major themes from comments included requests for accessibility of all types, events such as mixers or special publications that highlight marginalized groups, outreach and support for people in underprivileged communities, more financial accommodations, and support for parents at conferences. We thank all who participated in this survey and will use their comments as a baseline for monitoring demographic change in the field and to guide recommendations for SMM as it moves forward in creating a more inclusive and diverse community.

Community marine reserves benefit both fishermen and pinnipeds.

Improving commercial stocks is the main goal of community marine reserves, which are implemented and managed by fishermen. Fishing areas surrounded by pinniped rookeries often show conflicts between these predators and fishermen, and it has raised the question if these reserves are effective. To answer it, we conducted a survey of fish biodiversity and biomass in four islands in the Pacific side of Baja California, Mexico. These islands are subject to exclusive concessions to small artisanal fishermen cooperatives, two of which have implemented marine reserves, Natividad eight years ago and San Jeronimo a year before surveys. There are important rookeries of California sea lion (*Zalophus californianus*) in three of them and Pacific harbor seal (*Phoca vitulina richardii*) in all four. We did a general linear mixed model considering all fish species and another filtering by potential prey for each species of pinniped using known prey species reported in the literature. Both the general fish model and the model of potential prey of California sea lions showed that Natividad (oldest reserve) has the highest fish biomass and the pattern is shown but inside and outside of the reserve polygons. The model for potential prey of harbor seals did not showed significant effects on biomass. Species richness and fish biodiversity was also higher in

Natividad. These results indicate that reserves increase overall fish diversity and biomass, despite the presence of top predators, and even increase their potential prey in the case of sea lions. An ecosystem with higher biodiversity and biomass tends to be more resilient, therefore, community marine reserves may also help improve the resilience of marine mammals to climate driven phenomena, as well as maintaining a healthy marine ecosystem for the benefit of both pinnipeds and fishermen.

Seals as sentinels of antimicrobial resistance genes in UK waters: A preliminary screen to test for temporal changes in gene detectability.

Antimicrobial Resistance Genes (AMRG) are a pressing concern to human and animal health. These genes are ubiquitous in the environment, and can spread rapidly because of human and industrial waste, agriculture, and aquaculture. Many of the waste products from these processes eventually make their way to ocean waters, providing AMRG ample opportunity to disseminate. Pinnipeds are apex predators in UK waters, sampling the entirety of the water column when they forage. These animals regularly return to hall out on shore, allowing us to examine what they have eaten in an accessible manner, and providing a way to look for potential upstream resistance. Previous studies have examined a limited and biased number of known pathogens for AMRG, resulting in a poor understanding of which specific AMRGs are prevalent in non-pathogenic strains. AMRG have the capacity to be transferred between bacteria, suggesting that even genes that are not currently found in pathogenic bacteria can be used as an early warning of the potential for transfer to pathogens. This study uses a novel medium throughput screen developed as part of a larger project to test for the presence of AMRG independent of the bacteria they are found in. This screen was used to analyse faecal matter from seals for common antimicrobial resistance genes using PCR and gel electrophoresis.
We analysed samples at time of collection, two months after collection, and six months after collection respectively to assess the effect of storage duration on the probability of detection of environmentally important AMRG, allowing us to determine if previously collected samples can effectively be used as a part of a larger study. Analysis of grey seal gut resistome provides much needed information about possible time related degradation of these genes in previously collected samples for future work creating a baseline of AMRG in UK waters.

Environmental influences on breeding biology and pup production in Australian fur

Arnould, John
Deakin University, Burwood, VIC
Corresponding Author:
john.arnould@deakin.edu.au

Knowledge of the factors which affect the breeding biology of a species is crucial to understanding how environmental variability impacts population trajectories and enables predictions on how species may respond to global change. While its population is still recovering from the over-exploitation of the commercial sealing era (currently estimated at 50-60% of pre-sealing levels), the Australian fur seal (*Arctocephalus pusillus doriferus*, AUFS) represents the greatest marine predator biomass in south-eastern Australia. The region is currently one of the fastest warming oceanic regions in the world and is expected to experience substantial changes to current regimes that will impact the abundance, distribution and diversity of prey species. Therefore, understanding the environmental factors that influence the breeding of the species is urgently needed to predict how it, and the prey populations it depends upon, may respond to anticipated ecosystem changes. The present study investigated annually the timing of breeding and pup production in AUFS on Kanowna Island, northern Bass Strait, between 1997 and 2018. During this period, pup production varied greatly (1386-2574) but sustained an overall increase of 1.3% per annum. Median and spread of pupping dates varied by up to 9 d and 10 d, respectively. Median birth date was earlier in years when adult female body condition (measured during pregnancy) was greater ($r^2 = 0.33$, $P < 0.05$), which was negatively correlated to sea-surface temperature ($r^2 = 0.30$, $P < 0.05$) within Bass Strait. Pup production was positively correlated to summer (before implantation) and winter (active gestation) SOI ($r^2 = 0.38$, $P < 0.02$ in both cases). Higher SOI periods are associated with stronger zonal winds, which have been shown to influence prey availability. With SOI and regional winds forecast to increase in the coming decades, these results suggest the AUFS population may experience advantageous conditions and continue to grow.

Estimating beaked whale density from passive acoustic recordings

Beaked whales emit frequency-modulated clicks that facilitate their detection using passive-acoustic monitoring (PAM). Here we provide an independent validation of the precision of PAM estimates from acoustic point sampling. El Hierro (Canary islands), holds year-round coastal populations of Cuvier's (*Ziphius cavirostris*) and Blainville´s (*Mesoplodon densirostris*) beaked whales. Here, acoustic monitoring can be combined with land observations to optimize visual detection probability. We evaluate acoustic parameters, including click rate and detection probability, required for density estimation and use these to calibrate the accuracy of density estimators by using it in combination with reliable ground-truth density from visual surveys. We recorded simultaneous observations from double-platform land-based surveys and acoustic detections from drifting SoundTrap recorders (200 m depth, 144 kHz fs). Density was estimated using a PAM cue-counting method. Click production was estimated from DTAGs and modeled to assess its variation due to social parameters. Click detection probability was obtained from DTAG and PAM deployments and modeled to assess the effect of click detector characteristics. Mark-recapture and distance sampling methods were used to estimate density from visual data. 32,870 beaked whale clicks were identified in 206 recording hours, 68% [95% CI 61, 75] of which were classified as certain beaked whale clicks. Click rate averaged 0.39 clicks$\cdot s^{-1}$ [CI 0.32, 0.50]. Acoustic detection probability was 0.15 (CV 0.25). The resulting animal density was 4-10 beaked whales [CI 2.7-5.5]-[CI 8.2-12.4] *CV* 14-18%, depending on whether the uncertain clicks were considered or not. Estimated density from visual surveys was 4 beaked whales [CI 1.2-6.7] CV 24%, which falls within the acoustic estimate's CI. These results have implications not only on the long-term monitoring of potential impacts of naval activities in these taxa, but also on the evaluation of the number of beaked whales at risk in order to minimize possible accidental exposures during real-time mitigation situations.

Fat embolism and sperm whale ship strikes.

The Canary archipelago is a geographical area with an important overlap between cetaceans and maritime traffic. Among different species, sperm whales (*Physeter macrocephalus*), currently listed as a vulnerable species, are the most affected by ship strikes in the Canaries. Subcutaneous, muscular and visceral extensive hemorrhages, and hematomas, indicate unequivocal antemortem trauma. However, when carcasses are highly autolyzed, distinguishing if the trauma have occurred ante- or postmortem can be very challenging. In other species, the presence of fat emboli within the lung microvasculature has been extensively used to determine a severe "in vivo" trauma. We hypothesized fat emboli detection could be a reliable and accurate forensic tool to assess ante-mortem ship strikes in stranded sperm whales, even when carcasses present an advanced autolysis. In the current study, the presence of fat emboli was evaluated, using an osmium tetroxide (OsO4) based histochemical technique, in the lung tissue of 24 sperm whales, 16 of them with evidence of ship strike, stranded and necropsied in the Canaries between 2000 and 2017. About 70% of them presented an advanced autolysis. Results revealed the presence of OsO4-positive fat emboli, with varying degrees of abundance and distribution, in 13 out of the 16 sperm whales with

signs of ship strike. The main conclusions were: 1) the usefulness of fat detection as a diagnostic tool for "in vivo" trauma, even when carcasses presented and advanced autolysis, and/or tissues were kept in formaldehyde for long periods of time; and 2) that, in the 18-year period studied, at least, 81% of the sperm whales that presented signs of ship strike were alive at the moment of the strike and died subsequently. This information is highly valuable in order to implement proper mitigation measures in this area.

Occurrence of allo-suckling and non-filial mother-pup interactions in a declining harbour seal population.

Arso Civil, Mònica; Hague, Emily; Langley, Izzy
Sea Mammal Research Unit - University of St Andrews, St Andrews, United Kingdom
Corresponding Author: monica.arso@gmail.com

Fostering and allo-suckling have been reported in numerous mammal species, including phocids. Although the reasons behind these non-filial behaviours are poorly understood, it is suggested that fostering can represent costs and benefits to mothers and pups. Here we document non-filial interactions observed at harbour seal (*Phoca vitulina*) haulout sites in Orkney (Scotland), a region where harbour seal numbers have declined by 85% since the year 2000. Photo-identification data were collected between 2016 and 2018, on a daily basis during the pupping season, at four haulout sites. Mum-pup pairs were identified from the unique pelage patterns, and field observations of filial and non-filial interactions documented. Non-filial interactions (NFI) were classified as aggressive (female reacts aggressively to an alien pup), wanted (female interacts positively with an alien pup), and allo-suckling (female suckles an alien pup). NFI were observed throughout all pupping seasons, in 22, 29 and 57 separate occasions involving 29-49% (n=13-20) of females that had a pup that year. Allo-suckling was the most commonly observed behaviour, occurring in 46-76% of the documented NFI, involving 20-39% (n=9-12) of all identified mothers and 20-50% (n=9-18) of all identified pups each year. Females suckled 1 to 4 alien pups in a season. Eight females suckled alien pups in different years. Allo-suckling of assumed abandoned (i.e. starving) pups was observed 1-2 times each year; all other allo-suckling events involved 'healthy' pups also suckling from their mothers. In contrast, allo-suckling was not observed in other regions of Scotland (Isle of Skye and Kintyre) where photo-identification data were also collected as part of the same study. Observations at one of the study sites in Orkney from 1982 document "beggar pups", suggesting allo-suckling might be independent from the current declining population trajectory. However, allo-suckling could have added costs for females if adult survival and/or recruitment are already compromised.

Bottlenose dolphins in the Western Ligurian Sea (Mediterranean Sea): Preliminary study on social structure and residency patterns.

In recent years, a relative increase of common bottlenose dolphin *(Tursiops truncatus*) presence has been observed in the Western Ligurian Sea (Mediterranean Sea) by fishermen, whale watching companies and observations from land. Purpose of this work is to provide the first analysis of the social structure and residency patterns of this population. Data were collected during 67 dedicated daily boat-surveys, conducted from April 2018 to March 2019, in all 4 seasons. A total of 31 sightings was reported and 66 dolphins were photographically identified and re-sighted up to 14 times (average = 6.4 times). In the analysis, only dolphins with 3 or more recaptures were considered, corresponding to 39 individuals. Social structure was investigated quantifying the associations among individuals, through the half-weight index (HWI) and estimating the temporal pattern of association. Residency index was calculated for each dolphin as number of recaptures per total surveys and their residency patterns as dolphins' presence or absence in the 4 seasons. Analysis showed that this community is organised in 4 subgroups with rapid association patterns (median time interval: 2 days) and 2 levels of acquaintances. Association values was low (0.2-0.4) for most dolphin pairs, except for few strongly associated couples (HWI>0.8). The residency indices ranged from 0.04 to 0.21, 38% of dolphins showed an index greater than 0.10. Dolphins could be seen year-round; however, 48% of the individuals were encountered in 3 seasons and could be classified as year-round residents. Only 5 individuals were encountered in 4 seasons; they belonged to the same social unit and their HWI values were greater than 0.5. High values of both residency and association indexes characterised only one of the 4 social subgroups. A future long-term monitoring will contribute to increase the knowledge about this dolphin community and will

help develop management and conservation strategies.

Re-sight occurrence and frequency of satellite tagged humpback, fin, and sperm whales off Virginia, USA

Satellite tagging studies provide opportunities to track animal movements following an initial observation during which a tag is deployed. Often times, those animals are not re-sighted post-tag deployment, leaving tag site healing, and even survival, as mostly unknown variables. Medium-term Wildlife Computers satellite tags (SPOT6, SPLASH10, and SPLASH10-F) in the LIMPET configuration were deployed on humpback (*Megaptera novaeangliae*), fin (*Balaenoptera physalus*), and sperm (*Physeter macrocephalus*) whales off the coast of Virginia between December 2015 and March 2019. Forty-nine tags were deployed on humpback whales, 15 tags on fin whales, and 20 tags on sperm whales. Five humpback whales and one sperm whale were tagged twice each during different years. Thirty-two of 45 (71.1%) individual tagged humpback whales, 3 of 15 (20.0%) fin whales, and 3 of 19 (15.8%) individual sperm whales were re-sighted after tagging. For animals that were re-sighted, individual humpback whales were re-sighted up to 10 times after tagging (mean=2.7), fin whales were re-sighted up to 2 times after tagging (mean=1.7), and sperm whales were re-sighted once after tagging (mean=1). Re-sights occurred 1-774 days apart (mean=167; median=33) for humpback whales, 100-356 days apart (mean=269; median=353) for fin whales, and 9-401 days apart (mean=250; median=343) for sperm whales. Re-sights occurred both when the tag was still attached and after the tag had been shed. Follow-up photos of the tag site were taken whenever possible to assess tag site healing. Due to the more accessible nature of nearshore waters, re-sightings of humpback whales occurred more frequently than those of fin and sperm whales, which were observed further offshore, typically in the mid-shelf area for fin whales and in deep water past the continental shelf break for sperm whales. These observations can provide valuable opportunities to assess tag site healing and can also provide insight on survival for these large whales.

Acoustic identification of cetaceans using deep learning techniques

Modelling cetacean population dynamics is paramount for effective conservation and management. Cetaceans are also prime candidates for modelling ecosystem change under the ecosystem sentinel concept. Moreover, robust population data can aid in assessing the risk presented by anthropogenic activities. One methodology for cetacean research utilises passive acoustic monitoring (PAM) to investigate cetacean occurrence and behaviour ecology. Advantages of PAM include: it is less expensive and labour intensive compared to visual methods; and can record data over long temporal scales. Due to the large volumes of data collected and stored in PAM systems, there is a need for effective, automated solutions that can detect and classify cetacean vocalisations. Current technologies provide identification of some cetacean species using echolocation clicks and whistles, such as C-POD and ROCCA. However, they do not harness deep learning techniques and/or use signature whistles to identify individuals within a species, which could allow for estimating abundance and monitoring of individual dolphins' occurrence and residence patterns. In this study, through collaboration between computer scientists, engineers, and marine biologists, methods have been developed which utilise digital signal processing and deep learning techniques to detect and classify individuals within dolphin species. The system in development detects the possible presence of a cetacean whistle using Goertzel's algorithm by considering a ratio between the produced whistle and background noise frequencies. Once detected, the audio is segmented to contain only the whistle and represented as a spectrogram. This is passed to a Convolutional Neural Network (CNN) that has been pretrained to identify signature whistles of individual *L. albirostris*. The CNN uses the spectrogram to predict matches between new and previously recorded and classified signature whistles allowing for the use of capture-recapture analyses. Initial work has provided promising results, providing evidence of *L. albirostris* producing signature

whistles similar to those described in *Tursiops truncatus*.

When the whales win, everyone wins: Employing participatory research to create a culture of environmental stewardship in Guerrero, Southwest Pacific Mexico.

Guerrero, one of the most biologically diverse and understudied states in México, hosts 16+ marine mammal species and a once thriving fishery. Poverty, corruption, pollution and a lack of education and opportunities are leading to environmental destruction. As of 2013, awareness of and protection measures concerning marine mammals were non-existent, despite the predominance of marine-based tourism and commercial fishing methods known to be deleterious to marine mammals.

Between 2014-2019, we collaborated with Guerrero communities to identify the potential for marine mammal-based ecotourism activities through a first-ever, 1600-hour participatory humpback whale survey. It was our goal to cultivate a shift toward marine conservation through this survey in tandem with capacity building; education; outreach; ecotourism market development; and fishermen's learning exchange programs.

Advances included: an 85% increase in awareness and investment in marine mammals; a community-supported safe whale watch program (75 guides trained); development of ecotourism market and activities to alleviate pressure on the fishery and motivate environmental stewardship; a voluntary 30-member stranding network; a 100+ fishermen marine mammal spotting network; and groundbreaking humpback whale survey results.

The fishery continues to decline and we now know that marine mammals are threatened in Guerrero; many species present with pollution-borne diseases, emaciation and anthropogenic scarring and some species sighting rates have declined by more than 75% since 2014.

However, because of our transparent and inclusive approach, the community has developed an interest in restoring their marine environment and the potential for conflicts between stakeholders has been reduced.

Community-requested next steps underway include: Year-round immersive nature programs; strengthening ecotourism market supply and demand; student-run dolphin studies; and a community-developed marine management plan, including marine mammal monitoring.

Nesting Instinct: Distribution and habitat use of humpback whale mother-calf pairs in the southern Pacific coast of México.

North Pacific humpback whales (*Megaptera novaeangliae*) feed in mid- and high-latitude waters and overwinter in the tropics. While winter habitat use in Hawaii and Northern Mexico has been well-documented, data regarding potential breeding, nursing and calving ground sites in Southern Mexico is scarce.

Whales of Guerrero (WoG) is a non-profit organization focused on humpback whales and other marine mammals on the southern Pacific coast of Guerrero, México. With a peak presence of whales from January to March, Guerrero has been confirmed as a nursing and calving ground, as well as a breeding site and migration corridor for *M. novaeangliae*.

1688 effort hours of boat-based surveys were conducted between 2014–2018. Humpback whale mother-calf pair sightings (n=151) were divided into four group types: mother-calf (n=116), mother-calf and escort (n=28), mother-calf and two non-competing whales (n=6) and mother-calf with 3+ competing whales (n=1). Models were fit to estimate and predict the distribution of the four groups of humpback whales in Guerrero, along with environmental parameters that could influence it. Distribution of mother-calf pairs were mostly related to depth and proximity to the coastline. Prediction maps met most of the sightings and showed various areas of distribution in the area.

Mother/calf pairs were resighted up to five times seasonally, observed nursing and resting in shallow bay waters. Calf size and visible fetal folds also support the thesis that this region is a calving ground.

Since Guerrero's humpback whales are more similar to the Distinct Population Segment (DPS) of Central America (listed as endangered; n=411 individuals) than the Mexican DPS (listed as threatened; n=3624), these results provide meaningful information regarding North Pacific humpback whale status and identify an important site for an endangered group of whales. These findings will contribute to effective local and international management, protection and conservation recommendations regarding humpback whales.

Numerical modelling approach for estimating listening space reduction in narwhal (Monodon monoceros) from vessels transiting through ice in Eclipse Sound, Nunavut, Canada

This study investigates the potential for underwater noise from vessels, transiting through ice, to impact the listening space for narwhal in the Eastern Canadian Arctic, specifically in Eclipse Sound, Nunavut. A numerical modelling approach was used to examine the underwater sound footprint from commercial vessels transiting through ice along a newly established shipping route that overlaps with a summer calving ground for narwhal. Vessel noise partially overlaps in frequency with the lower range of narwhal hearing sensitivity and therefore has the potential to interfere with their ability to utilize sound to communicate, navigate, and forage. To investigate the extent to which vessel sounds could impact narwhal listening space, underwater sounds from vessels were modelled in 1/3-ocatve bands as a function of range and depth from the vessels. The modelled received sound levels were compared against median measured ambient sound levels and the assumed hearing threshold of narwhal (beluga audiogram used as a proxy for narwhal). The signal excess was examined to estimate the potential listening space reduction as a function of range from the vessels. The analysis was performed for individual 1/3-octave bands that correspond with the dominant frequencies for three narwhal vocalization bands: 1 kHz, 5 kHz and 31.5 kHz.

Bridging population genomics and conservation for harbour porpoises (Phocoena phocoena) in the North Atlantic and adjacent waters.

The harbour porpoise (*Phocoena phocoena*) is a highly mobile cetacean found in waters across the Northern hemisphere. It inhabits basins that vary broadly in salinity, temperature, and food availability, which drives differentiation among populations. First ddRAD analysis showed a distinct genetic differentiation between the North Atlantic and the Baltic Sea population, with a further subdivision between the inner Baltic Proper and the Belt Sea. Additionally it could be shown that the population in the North Sea are genetically closer to Icelandic individuals than to the geographically adjacent Baltic Sea populations. We have extended the ddRAD sequencing data, adding samples from a broad distribution range (spanning form the Western Black Sea, the entire North Atlantic, and the Baltic Sea), and utilizing a newly assembled high quality reference genome, to further unravel subtle population structure. Using this new assembly as a reference, we have identified 51.055 genome-wide SNPs from 226 individuals. Initial results support the classification of a distinct Inner Baltic proper subpopulation, genetically differentiated from the population in the Belt Sea, and because of low numbers, critically endangered. These results support conservation measurements for the Inner Baltic Proper subpopulation, and provide the basis to develop a SNP panel to further management and monitoring of European populations, in particular the Baltic proper subpopulation. For such a panel, specific

SNPs are currently selected and tested for suitability for population diagnosis across the North Atlantic and adjacent waters. Together with the draft genome annotation (22,154 predicted genes), these genetic variants can also be linked to the proteins they encode, allowing for further investigation into local adaption and functional evolution in the different harbour porpoise populations. Our study underscores the value of whole genome resources in conservation genomics, and provides a crucial addition for the study of porpoise evolution and phylogeny.

The identification of critical habitats for cetaceans in the southern Adriatic Sea

Critical habitat identification forms an essential stage in the implementation of Marine Protected Areas (MPAs). Whilst MPAs have been shown to be an effective conservation strategy, they cover just 6% of the Adriatic, with a single MPA, Karaburun Sazani, in the southern Adriatic. Apex predators can be used both as indicators of the health of critical habitats and flagship species of MPAs. The Adriatic Sea has been identified as a cetacean hotspot and yet is under a wide range of anthropogenic threats which have caused population declines up to 50% in bottlenose dolphins (*Tursiops truncatus*) and regional absences of common dolphins (*Delphinus delphus*). The current study runs the first dedicated cetacean research into critical habitat identification in the southern Adriatic. In Montenegro, 438 surveys have been conducted since September 2016 alongside 15 surveys in Albania since Novemeber 2018. A regular bottlenose dolphin presence and more sporadic striped dolphins (*Stenella coeruleoalba)* sightings have been confirmed in both countries, with a mixed group association in Albania as well as an unusual sighting of a group of common dolphins. Whilst the Albanian project remains in its preliminary stage, frequent delphinidae sightings have been observed at the Cape of Rodon. Montenegro revealed an encounter rate of 4 groups/100km, with similar seasonal sighting variations, and 90 identified dolphins to date. Montenegro is likely to hold migration corridor(s), important foraging habitats, nursing ground(s) with critical habitats delineated at the entrance of Boka Kotorska and the coastal waters of Katic, Bar, Utjeha and Ulcinj. The offshore waters of Platamuni may hold critical habitat(s) for striped dolphins, specifically between the 300 and 700m contours. The critical habitats delineated here show a striking overlap with current proposed MPAs in Montenegro and thus highlight the importance of cetacean research on MPA selection.

Fin whale and striped dolphin distribution patterns as response to environmental variability

Highly mobile species interact with dynamic oceanographic processes that vary at time-scales from days to decades. Aim of this study is to outline the lessons learnt from a long-term monitoring study concerning occurrence, spatial and temporal distribution of cetacean species in an area of about 30,000 km^2 included within the Pelagos Sanctuary in the NW Mediterranean Sea. The data series derives from 29 years of dedicated shipboard summer surveys, conducted between May and October from 1990 to 2018. Indices of spatial patterns have been applied to the sighting data of the most frequent species (i.e. *Stenella coeruleoalba,* N: 3,953; *Balaenoptera physalus,* N: 958 sightings) and their variability was analyzed in

time. The analysis of the species distribution patterns revealed temporal and spatial significant variability (Kruskal-Wallis: $P<0.01$). Concurrently, a satellite area-averaged time series of 4 km chlorophyll-a was analysed. A Hierarchical Cluster Analysis allowed to identify five clusters of chlorophyll-a monthly patterns. The spatial distribution of the two species was found more clumped in years where the chlorophyll-a concentration was lower, and its spatial pattern more homogeneous, while it was dispersed in years where the chlorophyll-a concentration was higher, and its spatial pattern more heterogeneous (Kruskal-Wallis: $P<0.01$). These results suggest that the temporal variability of the species distribution may be affected by chlorophyll-a spatial patterns varying in time. A following simulation study based on 1,000 randomized sightings over an area of about 90,750 km^2 allowed to demonstrate how such patterns have also the potential to affect the estimates deriving from synoptic surveys aimed to assess abundance of species at the large scale. Spatial distribution patterns should be better investigated as function of environmental covariates, to improve the understanding of the species' ecology, and to inform models fed on data deriving from time-limited surveys, that are essential for conservation.

When is a peak in strandings relevant? 30 years of carcass collection provides basis for detecting exceptional events.

Since the 1970s, the German Oceanographic Museum conducts a monitoring to collect marine mammal carcasses in Mecklenburg-Western Pomerania. From 1990 until today, a continuous development of the stranding network helps to investigate the three native marine mammal species in the German Baltic Sea. All harbour porpoises, harbour seals and grey seals are dissected to gain insight into different life history parameters and population health. A close cooperation between national parks, municipalities, authorities and a citizen science approach ensures that carcasses are collected and transported to freezers distributed along the coast. The analysis of stranding locations revealed annual patterns characterised by spatial and temporal species-separation. Harbour porpoises mostly wash up on western beaches, whereas grey seal carcasses were rather recorded at eastern beaches. Due to the long-term monitoring unusual events are easily detectable. For example, a grey seal mass stranding event in 2017 was detected due to fresh carcasses found in an unusual time of the year. The year 2018 was especially noticeable within the 30-year monitoring period, since maximum numbers for all species (69 porpoises, 16 harbour seals, 47 grey seals, 12 unidentified seals) were recorded. In grey seals, the recolonization on the German Baltic coast, with a steady increase of seal abundance, is a reasonable explanation for this strandings peak in this species. For harbour porpoises, on the contrary, passive acoustic monitoring does not reflect this development. Therefore, further investigations on the increase of harbour porpoise strandings at the German Baltic coast are necessary to find possible explanations to further conservation and management of this vulnerable small cetacean.

Using lagged re-identification rates to define associations from photographic data

In studies of cetacean social structure, the challenge of finding suitable criteria to define associations when working with photo-identification data has been largely overlooked. Most studies define associations based on proximity in space and/or time, using criteria from previous studies on the same species. However, we now know that social dynamics of different populations can differ within the same species, which invalidates the use of generalized preconceptions of their social organization when collecting and analysing association data. Furthermore, association criteria based upon field observations are often subjective, which becomes problematic when data are collected over long timespans by different people or when protocols evolve over time (e.g., film and digital photography, which impose different constraints on the way data are collected).

We suggest a data-driven approach to define associations based upon photographic records by estimating the probability of re-identification of an individual over different lags (time or number of frames), and by determining when this probability becomes the same as that of a randomly chosen individual. We evaluated the effectiveness of this technique using both simulations and real

association data from populations with well described social structures, such as Northeast Pacific resident killer whales.

We found that this method removes the biases of subjectively defining associations in the field, allows for the combination of film and digital photograph data and for the homogenisation of data collected across sampling periods by different people. This is a promising approach to study populations with prominent fission-fusion dynamics and it is applicable to any dataset of sequential identifications when associated individuals can be assumed to be in close proximity to one another.

Where are we at: What is the state of play of harbour porpoise conservation in the North Sea region?

Harbour porpoises (*Phocoena phocoena*) are an abundant and wide-ranging species in the North Sea but they face many threats from anthropogenic activities across international borders. Across the region their distribution and abundance has changed over the past few decades.

Different parts of international and national legislation are relevant to species conservation. A variety of different entities are working together through conventions, agreements, treaties and programs with the aim to contribute to harbour porpoise conservation and to manage threatening activities. These entities can have similar goals but their mandates have different coverages, approaches, cycles, structures and management actions. Multiple international directives, regulations and policies with different implementations at national level serve as legal tools to help this process. There is a need to optimize the coordination of these different entities and their activities to create more synergy with the ambition to improve conservation of this species in an adaptive way towards the future.

We conducted a three way conservation effort evaluation based on an extensive literature search and interviews with experts working in this field. First, we focused on the legislation basis for conservation (legal power and content), secondly, on mandate of the entities involved (spatial, temporal, jurisdiction and responsibilities), and lastly, on tools used to establish conservation (monitoring, assessment, juridical tools and impact).

Besides an overall North Sea region evaluation, the Netherlands species conservation approach was used as an example to evaluate efficiency of conservation in more depth and provide an example on the complexity and differences in implementation between countries of applied species conservation and management.

Our work shows that synergy is necessary in order to more efficiently and comprehensively implement all conservation efforts, solve gaps and increase effectiveness of harbour porpoise conservation. Suggestion for improved synergy and an action plan for the upcoming years are provided.

First assessment of the ecotoxicological status of Cuvier's beaked whale (Ziphius cavirostris) in the NW Mediterranean Sea

Cuvier's beaked whale (Cbw) is one of the least known species in the world. The Mediterranean subpopulation is ranked as Vulnerable (VU) in the "IUCN Red List of Threatened Species", considering both the declining population trend both the low number of mature individuals estimated in the basin. While effects of underwater noise, known to be one of the main threats to the species, are being widely investigated, the ecotoxicological risk of the species is still unknown. The objective of this study is to investigate for the first time the ecotoxicological status of Cbw in the NW Mediterranean Sea (Pelagos Sanctuary). The levels of organochlorine compounds (PCBs), polybrominated diphenyl ethers (PBDEs), and related biomarkers responses (induction of cytochrome's P450 CYP1A1 and CYP2B isoforms) were investigated in 22 skin

biopsies from free-ranging organisms. This sample set represent about the 20% of estimated size of the resident population in the area which has been monitored during the last fifteen years. All the animals were sexed and categorized into three different age classes (juveniles, subadults, adults) by both the estimated size and coloration patterns. CYP1A1 and CYP2B protein activity show different trends among different age groups and between sex. The contaminants analysis highlight that the average abundance pattern for the target contaminants was PCBs>PBDEs and the concentration values are linked to age and sex, with males showing higher levels (∑PCBs 23.77 mg/kg l.w., ∑PBDEs 0.516 mg/kg l.w.) than females (∑PCBs 8.08 mg/kg l.w.,l ∑PBDEs 0.172 mg/kg l.w.). 80% of sampled cbw had PCB concentrations above the toxicity threshold for physiological effects in marine mammals, suggesting a potential effect on this mediterranean population fitness. This study represents an important step forward in our understanding of the effects of toxic compounds in combination with other known or suspected threats to this population of Cuvier's beaked whale.

The perils of relying on handling techniques to reduce bycatch in a partially observed fishery: A fatal flaw in the U.S. false killer whale take reduction plan.

Baird, Robin
Cascadia Research Collective, Olympia, WA
Corresponding Author:
rwbaird@cascadiaresearch.org

False killer whales (*Pseudorca crassidens*) are the most frequently-recorded bycaught cetacean in the Hawai'i-based deep-set longline fishery. High levels of false killer whale bycatch in this fishery led to the formation of a Take Reduction Team (TRT) in 2010 and subsequent implementation of a Take Reduction Plan (TRP) in 2013. The TRP mandates a combination of technical approaches (i.e., "weak" circle hooks and "strong" terminal gear, making the hook the weakest part of the gear) and handling techniques (putting tension on the gear). Combined, these approaches should reduce the proportion of hooked individuals that are seriously injured or suffer mortality (SI&M), a determination which is based, in part, on whether whales are able to free themselves from gear (e.g., hooks straighten or pull out). Observers on ~22% of trips provide information on observed SI&M rates that are extrapolated to the unobserved portion of the fleet to derive overall bycatch estimates. More than six years into the plan, rates of SI&M remain high. Even with observers on board, fishermen often (~29%) cut the line, rather than applying tension to straighten the hook. It is impossible to know whether an observer effect (e.g., fishermen cutting lines at higher rates when no observers are on board) occurs, but any such effect could result in bycatch estimates that are negatively-biased. At the time of abstract submission the TRT is deliberating the benefits of weaker hooks and stronger terminal gear to reduce SI&M rates. However, the reliance on handling techniques is a fatal flaw in a fishery that is only partially observed. Electronic monitoring (EM), specifically video monitoring, in the entire fishery could overcome this shortfall. The presence of EM would increase compliance with handling techniques and allow for a full assessment of compliance, to help determine whether additional changes to the TRP are needed.

Species identification of cetaceans by environmental (e)DNA metabarcoding – a new tool for surveys of the high seas.

We are developing methods for detection and identification of cetacean species using environmental (e)DNA collected from seawater at the surface and at depths, in open-ocean conditions. Referred to as 'eDNA metabarcoding', the potential to confirm species identity and population identity, from environmental sampling can complement the interpretation of acoustic and visual surveys now used to monitor cetaceans on

the high seas. Here we have used droplet digital (dd)PCR to detect and quantify eDNA, and next-generation sequencing (MiSeq) for species identification. Opportunistic, focal sampling in the vicinity of whales and dolphins has now been completed in open-ocean conditions in the western North Atlantic, the South California Bight, Hawaii, the Bering Sea, New Zealand, and the Mediterranean Sea, from both small and large vessels. To date, eDNA metabarcoding of focal samples has confirmed identification of 7 species of odontocetes including two beaked whales: Baird's beaked whales (*Berardius bairdii*) and True's beaked whales (*Mesoplodon mirus*). For Baird's beaked whales, we found differing presence/absence and frequencies of two haplotypes, indicating the potential for population level differences. For the True's beaked whales, we found two new haplotypes not previously reported in the literature. 'At depth' sampling of eDNA by CTD casts (60-1,000m) at the Cross Seamount, west of Hawaii, identified false killer whales (*Pseudorca crassidens*) in the absence of any coincident visual or acoustic detection. The haplotype detected at the Cross Seamount did not match those reported for the island-associated populations of Hawaii but was, instead, most similar to those of pelagic populations in the central and eastern North Pacific. Our results confirm the power of eDNA metabarcoding to improve success with identification of elusive species and the potential for use in systematic surveys of species occupancy in high-seas habitat, such as Important Marine Mammal Areas (*IMMA*s) in remote locations of the world's oceans.

Development of a SNP panel for genotyping polar bears from non-invasive samples.

Obtaining genetic samples from polar bears (*Ursus maritimus*) typically involves live-capturing individuals, a difficult and expensive process. Hair and scat are potential non-invasive source of DNA; however opportunistically collected samples may be exposed to UV and freeze-thaw cycles over an unknown extent of time, resulting in DNA degradation. In this study we investigate the quality and quantity of DNA recovered from non-invasive sampling methods and develop an inexpensive protocol for genotyping potentially low-quality and low-quantity non-invasive samples of polar bear hair with a panel of single nucleotide polymorphisms (SNPs). SNPs are preferable over microsatellites (traditionally used for individual genetic identification) for degraded samples as they are more robust against DNA fragmentation, providing higher genotyping success and confidence. We compared opportunistically collected and three sources of hair : pulled directly from live-captured individuals (positive control), collected from hair snares; and collected opportunistically from "daybeds" to determine whether these methods are useful for genetic identification. Hairs were processed individually with a forensic approach to prevent the possibility of cross-contaminating with hairs from different individuals. Hair samples were first DAPI stained and inspected under a microscope to visually estimate the concentration and distribution of DNA throughout the hair. We then optimized extraction and sequencing library preparation protocols to maximize DNA recovery from degraded samples. We used high coverage whole genomes of six Alaskan polar bears to develop a panel of SNPs that is sufficiently informative to genotype individuals from low-quality samples and genotyped the hair extracts at these loci. The results of this study will inform future sampling efforts and provide a methodology for genotyping individuals from non-invasive for applications such as genetic mark recapture, abundance estimates, and population assignment.

Population-level impacts of natural and anthropogenic causes of death in Main Hawaiian Islands monk seals

Prioritizing measures to conserve endangered species should be informed in part by the degree to which individual threats are impeding population recovery. We therefore quantified the impact of various causes-of-death (CODs) on the intrinsic growth rate, λ, of Hawaiian monk seals in the main

Hawaiian Islands (MHI). Seals are exposed to natural CODs, including reproductive complications, natural trauma, and malnutrition. Anthropogenic CODs include fisheries interactions and intentional killing by people. Disease is another source of mortality, and may ultimately be attributable to either natural or anthropogenic factors. We reviewed all known deaths in the MHI and used gross necropsy results, histopathology, and other evidence to assign probabilities of 11 distinct CODs to each case. Next, survival estimation linked to lifetable analysis was repeated 1000 times using Monte Carlo sampling of the COD probabilities to assign causes to each death occurring from 2004 to 2018 (including 81 known deaths and 102 others inferred from sighting histories). Inferred deaths were randomly attributed to causes according to the age- and sex-specific COD probabilities derived from known cases. We estimated influence on λ (and its associated uncertainty) by using right censoring to selectively remove each COD's effect on survival rates. The baseline scenario, with all CODs influencing survival, yielded mean λ=1.044. When the effect of an individual COD was selectively removed, the magnitude of the resulting λ relative to this baseline provided a measure of that COD's drag on population growth. The CODs with the greatest population impact were intentional killing, drowning in nets, and protozoal disease; removing any one of these was estimated to raise mean λ to at least 1.061. In aggregate, removing anthropogenic CODs had a larger mean effect (λ=1.093) than either natural (λ =1.059) or disease CODs (λ=1.068). This analysis provides a common currency for assessing the relative potential benefits of mitigating individual threats, thereby informing prioritization of conservation measures.

Prolonged, sub-surface, visual observations of free-living killer whale (Orcinus orca) feeding behaviour in northern Norway.

Cetacean behaviour is typically inferred from visual observations or from analysis of data from instruments attached to the animals. Proxies for behaviour are employed when using instrumental data (e.g location, depth, speed, acceleration and sounds produced). Direct visual observation is typically limited to above or just below surface displays while indirect visual observation even at depth through photos or videos is usually limited in view field. We gathered direct sub-surface observations up to a depth of 15m of orca feeding and social behaviour that can be integrated with other data for a more profound understanding of the ecology of this species. A single person snorkelling in the proximity of the animals gathered the data over six years using a minimal-impact protocol that aimed at maximising the chance of observing naturally acting animals. Particular behaviours have been recorded on video. Our observations revealed that in our area, although feeding mostly on herring, occasionally orcas take seals. Herring capture happens frequently for up to two hours in a carousel situation often with reduced acoustic behaviour, at different depths often herding the bait ball. Tail slapping with actual fish contact follows, occasionally simultaneous by up to 3 individuals. Sharing of the stunned fish is the norm. The bait-ball is incompletely consumed and usually no stunned fish are left. Large whales irrupt in the carousel and depredate the ball after which the carousel is resumed, but aggressive reactions by the orcas have occasionally been witnessed. Shallow water feeding by adult males alone or in small groups involves isolating individual fish for direct capture. Predation on harbor seals after feeding on fish has also been observed testifying that these orcas are not specialists. We believe that our observations can provide essential information for the interpretation of tag data with particular regard to accelerometry.

A review of recent cetacean stranding records in the United Arab Emirates (UAE) suggests the need of cooperative systematic data collection to better address main threats in the region

Balaji, Pooja[1]; Antonopoulou, Marina[2]; Clara Zarate Rodriguez, Jimena; Natoli, Ada[3]

Strandings provide an insight on the presence of species in a region and access to morphological, life history traits and ecological data otherwise difficult to obtain. Stranding analysis can also identify the main cause of death and in turns the main threats that affect a population in a region, such as by-catch, boat strikes, overfishing or pollution. Ultimately this information can play an important role in supporting the formulation of effective conservation measures.

In the UAE waters (Arabian/Persian Gulf and northernmost Arabian Sea) recent information about cetaceans are scarce. Most published stranding records are from the 20th century, but not many are available from the last two decades. The Gulf accounts for the presence of 13 cetacean

species but little is known about their population status. For some them, stranding data is the only documentation of their occurrence.

In this study we collated all stranding records available in the UAE online newspaper and those received by the public and local authorities through the UAE Dolphin Project initiative. Each record was reviewed for the location, date of stranding, the authenticity of the associated photographic material verified and utilised to assess the species. All strandings from the region published in scientific papers were tabulated and compared it with the unpublished records found.

A total of 46 strandings (12 Mysticetes, 29 Odontocetes) were found occurring between 2006 and 2018 in UAE waters and neighboring countries (Saudi Arabia and Kuwait). Among the Mysticetes seven Bryde's whales, one blue whale and one humpback whale were confirmed. Among the Odontocetes four toothed whales (three sperm whale and one dwarf sperm whale), 22 dolphins (16 Indo Pacific bottlenose dolphins, three Indian Ocean humpback dolphins, one spinner dolphin) and three finless porpoises. This highlights the importance of **systematic data collection and the implementation of organised stranding networks.**

Space vs Sea: A novel method for estimating marine mammal density.

Implementing informative, regular and representative surveys to assess whale spatial usage remains a logistical and economic challenge. Consequently, they are broadly omitted from Southern Ocean marine protected area designations and ecosystem-based fisheries quota assessments. Here we compare at-sea measurements of whale density in the Western Antarctic Peninsula with density estimates from satellite images. We demonstrate that Very-High-Resolution WorldView-3 imagery can provide useful data on whale occurrence and density. Densities, when unadjusted for surface availability are shown to be underestimated by a factor of 9 (CV = 0.24) in relation to concurrent ship based survey methods, but once adjusted (0.049 to 0.089 whales per km^2), are within an order of magnitude of those derived by traditional line-transect estimates (0.369 whales per km^2). Satellite mediated surveys, whilst in their infancy, represent an exciting development for high resolution image-based cetacean observation at sea, particularly in remote and inaccessible regions, presenting opportunities for future research.

Diving in the deep? Sei whale's dive behavior in the western South Atlantic.

Sei whales (Balaenoptera borealis) are widely distributed in all major oceans, but their diving behavior is relatively poorly understood, especially in their wintering grounds. In this study, six whales were instrumented with archival satellite tags (n=6) and a digital acoustic transmitter (DTAG) off the southeast coast of Brazil as part of the Cetacean Monitoring Project (PMC-BS/PETROBRAS). The transmission of the satellite tags lasted from three to 59 days and recorded 4773 dives. Dive depths recorded by these tags ranged between 5 and 577m (mean = 19.11, SD=34.51m). Dives between 5 and 15m (83%) and lasting from 5 to 10min (30%) were the most frequent. Surface interval ranged from 5s to 16min and 15s (mean = 13min, 27s, SD=3min, 12s). The individual tagged with DTAG was monitored for 5hs resulting in a total of 584 dives, of which 85% (n=498) were performed less than 1m from the surface and 15% (n=86) were below 2m of depth. The dives performed below 2m had an average duration of 2.8min, SD= 2.9min and reached an average depth of 5.5m, SD=3.5m. The maximum dive depth and duration recorded by the DTAG were 29m and 11.2min, respectively. Data from the DTAG motion sensors revealed a characteristic feeding behavior with lunge feeding near the surface. All the whales remained over the continental slope throughout the transmission period. Results suggest that while sei

whales typically dive shallow, dives can exceed 500m. The feeding behavior recorded by the DTAG may indicate that the occurrence of the sei whale in the Santos Basin is also related to feeding, even during the breeding season. Most dives recorded were within a depth range known to make cetaceans susceptible to collisions with vessels (<20m), emphasizing the importance of adopting measures to minimize ship strikes in this region.

An ounce of prevention is worth a pound of cure: Vaccination and other conservation interventions in Hawaiian monk seals

Barbieri, Michelle
NOAA National Marine Fisheries Service, waialua , hi
Corresponding Author: shellbarbieri@gmail.com

Morbilliviruses have caused thousands to tens of thousands of deaths in several phocid species around the world. Exposure to morbilliviruses has not been documented in endangered Hawaiian monk seals, despite several decades of health monitoring. This naïveté in a small population (1,400 individuals) with poor genetic diversity indicates that the species is not likely capable of sustaining an outbreak. To protect Hawaiian monk seals, a vaccine targeting canine distemper virus in ferrets was evaluated and has been in use to proactively vaccinate wild seals since 2016 at a level sufficient to prevent an outbreak of morbillivirus from devastating the species.

The conservation crisis of cat scat: We need greater consistency in the evaluation of Toxoplasma gondii infections in marine mammals.

The impacts of *Toxoplasma gondii* infections in marine mammals are reaching a critical conservation threshold, especially in endangered populations like Hawaiian monk seals (*Neomonachus schauinslandii*) where toxoplasmosis is the leading disease-related cause of death. Although infections from this parasite are geographically and taxonomically widespread, their impacts on species decline can be insidious. This stalls our collective ability to relate infections to measurable conservation impacts and take subsequent action. Best studied are sentinels such as the Southern sea otter (*Enhydra lutris*), which demonstrate a clear threat from land-to-sea flow of *T. gondii* oocysts from felids, the only known definitive hosts, to marine ecosystems. For many marine mammals, sample sizes are small, disease severity and detectability vary considerably, and findings are difficult to reconcile with dynamics in individual susceptibility. Our ability to detect and characterize transmission in diverse marine food webs is limited, sample availability and quality from marine mammals and the environment is variable, and validated diagnostic tests are scarce. These aspects of *T. gondii* research make it challenging to characterize and communicate a terrestrial-sourced marine mammal conservation threat in a unified way that allows managers and stakeholders to embrace much needed, yet often polarizing solutions. Despite information gaps, current knowledge is sufficient to inform plans of action in many cases. In the future, the paired use of histopathology and sensitive/specific molecular diagnostics will improve how we define the impacts of infection across taxa and resolve the influence of other stressors on immunity. More broadly, *T. gondii* in marine mammals serves as a red flag for the global health problem of environmental pathogen pollution, especially in coastal ecosystems. Our interdisciplinary scientific community must work across regional and taxonomic boundaries to improve consistency in research and messaging on this important health threat.

Stenella longirostris and Stenella attenuata (Odontoceti: Delphinidae): Whistle comparisons in the Western South Atlantic Ocean.

Dolphins produce a variety of whistles, which together make up the repertoire of such tonal sounds of a particular species. Despite being phylogenetically related, *Stenella longirostris* (*Sl*) and *Stenella attenuata* (*Sa*) are expected to have different acoustic repertoires, since whistles are related to behavioral, individual, social and species-specific factors. In the present study, we describe and compare the acoustic parameters of whistles for both species recorded in Northeast Brazil. The whistles were divided into contour categories and its parameters were extracted for each type of contour using Raven Pro 1.5 (Hann window of 1024 samples, DFT of 2048 samples and 80% of overlap). The Mann-Whitney test ($\alpha<0.05$) was applied through R to compare the parameters of each type of contour between the two species. The whistles of *Sl* (n=82) and *Sa* (n=77) presented the following contour types respectively: ascending [n=53 (66%); n=56 (74%)], descending [n=10 (12%); n=4 (5%)], ascending descending [n=5 (6%); n=10 (13%)], descending ascending [n=7 (9%); n=3 (4%)], constant [just for *Sl* n=6 (7%)] and multiple [just for *Sa* n=3 (4%)]. For all whistles analyzed, regardless of the contour, only the center frequency parameter did not present a significant difference. When considering contours, ascending, descending and descending ascending whistles presented significant differences between the two species for at least seven of the eight parameters analyzed. The ascending differed in all eight parameters (beginning frequency, ending frequency, high frequency, peak frequency, center frequency, delta frequency and duration), whereas for descending and descending ascending only the low frequency did not differ significantly. The results indicate that ascending, descending and descending ascending whistles have the potential to carry species-specific information, while the ascending descending whistles, apparently, contributes less to the discrimination of these two species.

Gross and microscopic anatomy of the olfactory system of a grey seal, Halichoerus grypus

Barboza, Meghan; Restrepo, Gabriella
Southern Connecticut State University
Corresponding Author: barbozam3@southernct.edu

There is very little research on olfactory sensory processing by marine mammals and much of this has focused on species that do not appear to have the ability to smell, such as the toothed whales. However, behavioral research and anecdotal evidence indicates that seals have a well-developed sense of smell, similar to canines, their terrestrial counterparts. These animals spend a significant amount of time living in the ocean but haul out onto land for major events such as mating and would likely use their sense of smell predominantly during these terrestrial periods. To date, little to no research has been completed on the anatomy of the seal's olfactory system, however, the presence of the vomeronasal organ (VNO) has long been assumed. This organ is known to play an important role in pheromone detection and would explain the reproductive behavior of seals. We have examined the head of a female grey seal, *Halichoerus grypus,* which died naturally. The tissue was fixed in formalin and dissected using an autopsy saw to expose the nasal cavity and hard palate. Grossly, the seal does have a VNO, well developed ethmoturbinates, and a large olfactory nerve (CN1). Histologically we have identified respiratory and olfactory epithelium. The histology of the VNO is still being examined. Overall the grey seal has very intricate ethmoturbinates and a potential VNO which is comparable to that of the olfactory system of canines. This anatomy would explain seals' behavior during reproductive periods and represents the first examination of the olfactory system of a pinniped.

Population genomic structure of common dolphins (Delphinus delphis) in Australia and New Zealand

Clarifying population structure and connectivity in widely distributed marine taxa can be challenging due to vast spatial scales and poor knowledge about environmental barriers to dispersal. Genomic datasets provide great power for detecting population structure and environmental adaptation. Common dolphins (*Delphinus delphis*) are highly mobile and gregarious, exhibiting potential for large-scale connectivity. Their populations, however, may associate with meso-scale oceanographic features, and their movements perhaps dictated by the distribution of their prey. Association with schooling fish targeted by major fisheries consequently increase their vulnerability to fisheries by-catch. We analysed 480 samples from biopsied, bycaught and stranded common dolphins collected from across 20 locations that cover majority of the species range in Australia and New Zealand. Our aims were to elucidate their population genomic structure, fine and large-scale connectivity and patterns of adaptive divergence across environmentally heterogeneous coastal and oceanic regions. Using ddRAD-seq and over 15,000 high quality neutral SNPs, we identified three metapopulations across the region linked by low contemporary connectivity: a) eastern Australia, b) southern Australia, and c) Tasmania/New Zealand. We also detected further subdivision and asymmetric migration rates within these metapopulations. We identified a major oceanographic barrier to common dolphin movements and gene flow between the Indian and Pacific Oceans. However, contrastingly high connectivity was also inferred across the Tasman Sea. Genotype-environment association analyses detected adaptive divergence among metapopulations, with preliminary analyses suggesting at least 50 putatively adaptive markers. These findings improve current understanding about the nature and extent of dispersal barriers, as well as migratory corridors, for pelagic marine predators. They also clarify the number of common dolphin populations in Australia and New Zealand for the management of fisheries interactions.

Temporal acoustic occurrence of deep-diving cetaceans off western Ireland in areas under seismic license.

Sperm whales (*Physeter macrocephalus*) and long-finned pilot whales (*Globicephala melas*) are the two most abundant deep-diving cetaceans off western Ireland. The aim of the present study is to investigate their temporal variability in occurrence off western Ireland to address a knowledge gap in these waters which hold significant potential for the exploration hydrocarbon resources. Fixed bottom-mounted autonomous acoustic recorders were deployed across 13 stations along the shelf-edge and canyon habitats as part of a Woodside Petroleum LTD study and ObSERVE-Acoustic. Three SM2M were deployed from May to September 2014 (123 days of recordings) on northern, south-western and southern slopes and canyons of the Porcupine Bank, four AMARs from May to December 2015 on Ireland's northern slope (214 days) and six AMARs from March to November 2016 on the western and southern slopes and to the east and north of the Porcupine Bank (230 days). Seasonal, lunar and diel effects will be explored using Generalised Estimating Equations (GEE-GAMs) for each mooring. Preliminary analyses of the data collected by Woodside revealed that sperm whales and pilot whales were detected across 47% and 41% of the recording days in 2014 respectively, and 78% and 28% in 2016. In 2014, 69% of the sperm whale clicks (9,295) and 55% of the pilot whale whistles detected (1,347) occurred to the southwest of the Porcupine Bank. In 2016, 80% of the pilot whale whistles were recorded by the northern mooring (984), while sperm whale clicks were more evenly spread out among the two locations. Based on these joint datasets, analysis will be performed on the largest offshore acoustic dataset from such devices collected across Europe to date, providing robust results contributing towards mitigation strategies by minimising the spatial and temporal overlap between these species and human activities.

Cloudy with a chance of whales: Forecasting blue whale occurrence based on tiered, bottom-up models to mitigate industrial impacts.

A blue whale foraging ground was recently discovered in the South Taranaki Bight region of New Zealand, where anthropogenic pressure exists

from oil and gas extraction, vessel traffic, and proposed seabed mining. A knowledge gap on blue whale habitat use patterns impedes effective management of potential threats. While species distribution models (SDMs) of cetaceans often use remotely-sensed data due to the accessibility of satellite imagery, this approach makes assumptions about underlying relationships between oceanography, prey, and predators. We investigated these assumptions and built a series of models linking: a) blue whales and prey, b) prey and *in situ* oceanography, c) blue whales and *in situ* oceanography, d) *in situ* oceanography and satellite imagery, and e) blue whales and satellite imagery. We implemented the SDMs using three years of vessel-based survey data, including 151 blue whale observations over 4,752km of effort, prey metrics extracted from 156 hours of hydroacoustic backscatter data, and oceanographic features such as temperature, thermocline strength, and fluorescence calculated from 196 CTD casts. Significant predictors of blue whale presence from the blue whales and prey model included number of krill aggregations, aggregation density, depth, and thickness (deviance explained = 45%). Blue whale presence was higher where the thermocline was weaker, and thermocline strength was negatively related to number of krill aggregations and aggregation density. The blue whales and satellite imagery model revealed that 36% of the pattern in blue whale presence could be described using sea surface temperature alone, and identified an apparent preferred range of 17-18°C. Finally, predictive models of blue whale presence using satellite imagery were positively validated with independent sightings data, demonstrating their utility for forecasting blue whale distribution using remotely-sensed environmental features. By linking functional ecological relationships with readily accessible data sources, we aim to provide managers with a practical tool for real-time conservation.

Abundance estimation for Mesoplodon beaked whale species using drifting acoustic recorders.

Barlow, Jay[1]; Moore, Jeff[2]; Keating McCullough, Jennifer[3]; Griffiths, Emily T.[4]

Using typical visual survey methods, abundance estimation for beaked whales in the genus *Mesoplodon* is especially challenging. Because surface times are brief and species-specific sighting characteristics are largely limited to males, only 23% of 461 *Mesoplodon* sightings on SWFSC surveys are identified to species. In contrast, beaked whale echolocation pulses are easier to identify, and although not all pulse types have been mapped to species yet, steady progress is being made. We use duty-cycled passive acoustic recordings from drifting recorders to estimate density and abundance for three *Mesoplodon* pulse types along the U.S. West Coast (thought to be *M. stejnegeri*, *M. carlhubbsi*, and *M. perrini*). Point-transect distance-sampling methods are used with a "snapshot" approach. Detection probabilities as a function of range are estimated from observed distributions of vertical detection angles and from distributions of foraging depths. Tagging and acoustic localization data for *M. densirostris*, *M. europaeus*, and *M. mirus* show mean echolocation or foraging depths of ~800-900 m. With these as informed priors on the echolocation depths of West Coast species, we use a Bayesian simulated likelihood approach to estimate detection probabilities as a function of slant range, translate that to probabilities of detection as a function of horizontal range and apply point-transect sampling theory to estimate the density of echolocating whales. These estimates are extrapolated to account for non-echolocating whales using diving and foraging behavior from other *Mesoplodon* tagging studies (largely *M. densirostris*). Pooled abundance estimates for all species are roughly comparable with estimates from visual sighting surveys, but, for the first time, this method allows the potential of species-specific abundance estimates and precise trend monitoring.

Eavesdropping on foraging and social sounds of conspecifics influence the horizontal movement of Risso's dolphins

Risso's dolphin (*Grampus griseus*) is a social odontocete species living in long-term stable groups composed of males or females and their offspring. Its vocal repertoire includes various

social and foraging sounds. We hypothesized that Risso's dolphins can gather information by eavesdropping on sounds produced by their congeners, enabling them to adjust their behaviour according to the perceived context. To investigate this hypothesis, we conducted sound playback experiments on free-ranging Risso's dolphins in the North Atlantic Ocean (Azores archipelago). We exposed animals to conspecific foraging sounds potentially indicating the presence of food patch (Fo, N=6 groups), male social sounds simulating a potential risk of agonistic interaction with territorial males (SM, N=4 groups), and female-calf social sounds likely representing no risk of threatening interaction (SF, N=7 groups). Individual and group track was recorded using visual or airborne (camera drone) focal follow observations. Horizontal movement responses during sound playbacks were quantified using the horizontal track of the animal. Overall, Risso's dolphins were horizontally attracted towards both Fo and SF stimuli whereas they avoided SM stimulus. When attracted, animals probably aimed at investigating the sound source and gathering additional information. The detection of conspecific foraging sounds by individual eavesdroppers may indicate the presence of a food patch being predated upon by conspecifics thus providing a "diner bell" signal. To confirm this hypothesis, further investigation on the behavioral response of dolphins during their approach is needed. In a social setting, male sounds could be perceived as a potentially risky interaction that individuals may avoid. Our results demonstrate that Risso's dolphins can discriminate between conspecific sound stimuli emitted in different contexts, and show evidence that eavesdropping on conspecifics sounds clearly influence their behavior.

Mitochondrial phylogeography of southern elephant seals (Mirounga leonina) around Antarctic waters with emphasis on the population structure of the colony at Isla 25 de Mayo (King George Island) South Shetland Islands, Antarctic Peninsula

The southern elephant seal (SES) (*Mirounga leonina*) has a circumpolar distribution, breeding mainly on sub-Antarctic islands, and making long trips up to thousands of kilometers between breeding colonies, molting locations and foraging areas. Although individuals show fidelity to a set of established breeding colonies, their migratory habits to forage at sea at large distances from their colonies, may allow long-range gene flow. To assess mitochondrial phylogeography of SES around Antarctic waters, with emphasis on population structure of the colony at Isla 25 de Mayo (62º15'S, 58º39'W), skin samples from free-ranging sub-adult male and adult females SES (n=60) were collected with a remote biopsy dart during 2015-2016 austral summer. The mitochondrial DNA Control Region (mtDNA-CR, 325bp) and 10 microsatellite loci were analyzed. The mtDNA-CR results indicate that SES from Isla 25 de Mayo are closely related with individuals from Elephant Island, Livingston Island, and Islas Malvinas (Falkland Islands), but maintain restricted genetic flow with individuals from Victoria Land Coast in the Ross Sea and Macquarie Island. Haplotype diversity was high and similar to the values found at other locations around Antarctica. Microsatellite analyses confirmed data indicated high genetic diversity (allele number ranging between 2 and 12; observed heterozygocity ranging between 0.422 and 0.883). Parentage analyses ran on ML-relate software identified 2% of individuals in the sample as mother-offspring, 16% as full/half siblings and 82% as unrelated individuals. These results agree with previous findings of long-distance genetic dispersal mediated mainly by SES males. Migration, accompanied by high genetic diversity may facilitate dispersal and discovery of emergent habitats, particularly in the potential loss of habitat due to climate change.

Radiographic assessment of pectoral fin bone maturation in bottlenose dolphins (Tursiops truncatus), as a novel technique to accurately estimate chronological age.

Accurate age estimation in wildlife conservation is an important diagnostic tool in the interpretation of biological data, necropsy examination, reproductive status and population demographics. The most frequently utilized methods to age bottlenose dolphins (*Tursiops truncatus*) include tooth extraction (counting dental growth layer groups) and dental radiography. These methods are inaccurate in dolphins > 13 years old, due to overlapping of the growth layer groups in dolphins, or worn teeth. Establishing a non-invasive method of accurately ageing bottlenose dolphins across the entire age range is important to long term conservation efforts to understand health status, lifespan, reproduction and survivability.

A database of 120 radiographs from 93 dolphins, in managed care, of known chronological age, was utilized to establish the stages of skeletal maturation over time. A numerical score from -1 to 8 was assigned to 16 anatomic locations on the pectoral radiograph, to create a formula to estimate age. The most informative areas to evaluate morphologically were the metaphyseal regions of the radius and ulna, and the proximal and distal epiphysis of metacarpals II and III. Third order polynomial regression calculated separate age predictor formulas for male and female dolphins, with females reaching bone maturity earlier than males. Completion of epiphyseal closure of the long bones correlated with average sexual maturity. Ages could be estimated to within 3 months in animals < 5 years old, within 2 years between 5 and 30 years, and within 5 years in animals > 30 years old. This diagnostic tool could also be applied to diagnose atypical ossification patterns consistent with nutritional disorders or growth abnormalities, identifying subclinical health issues. Knowledge of the lifespan of the cetacean and the onset of sexual maturity may allow this model to be applied to other cetacean species, to facilitate age estimation via pectoral radiography in future research.

Diversity and abundance of marine mammal strandings along the SE/S Brazilian coast (2016-2018).

Since August 2015, marine mammals stranded between 25°05'S and 25°55'S have been recorded by the Santos Basin Beach Monitoring Project (Projeto de Monitoramento de Praias da Bacia de Santos - PMP-BS). The PMP-BS is one of the monitoring programs required by Brazil's federal environmental agency, IBAMA, for the environmental licensing process of the oil production and transport by Petrobras at the Santos Basin pre-salt province(25°05'S 42°35'W a 25°55'S 43°34'W), between 2100m and 2300m isobaths. As part of its goals, the diversity and abundance of marine mammals have been evaluated. A total of 1032.7Km of beaches on coastal areas and islands is monitored, 79.7% of it being regularly monitored, and the remaining 20.3% only by responding calls from the local population. A total of 3532 marine mammals (495 pinnipeds and 3037 cetaceans) were recorded, of which 92.4% were dead. Thirty species were recorded, six of them from the order Carnivora and 24 from the infraorder Cetacea. Among the carnivores, the species with the greatest abundance was *Arctocephalus tropicalis* with 39.5% of the records. For cetaceans, *Pontoporia blainvillei* comprised 61.7% of the records, followed by *Sotalia guianensis* with 24.30%. While some species were relatively abundant, the following had only single records during the three years: *A. gazella, Balaenoptera physalus, Feresa attenuata, Kogia sima, Lagenodelphis hosei, Orcinus orca, Peponocephala electra, Physeter macrocephalus, Stenella attenuata* and *S. coeruleoalba*. Considering each year separately, 2016 presented the greatest species richness, with 23 species, while 2018 had the highest number of animals, with a total of 1338 records (2016 = 1223, 2017 = 971). The rarefaction curves were also calculated, indicating that the species richness has not yet been reached in this area. The monitoring program is ongoing and future data will probably allow identifying finer biogeographic patterns.

Investigating the energetic cost of human disturbance on the southern sea otter (Enhydra

lutris nereis).

With increased human populations and tourism in coastal areas, there is increased potential for disturbance of marine wildlife. Impacts of disturbance are not well understood for many coastal species, such as the southern sea otter (*Enhydra lutris nereis*). Due to high metabolic rates, sea otters are at particular risk of increased energetic costs due to human disturbance. To investigate effects of disturbance, behavioral scans were conducted over three years to record sea otter activity in response to potential disturbance stimuli at three locations in California: Monterey, Moss Landing, Morro Bay. We developed a hidden Markov model to examine how activity varies as a function of location, time of day, group size, pup to adult ratio, habitat (kelp vs. open water), and occurrence of and proximity to potential disturbance stimuli. We combined our results with published estimates of activity-specific metabolic rates, translating changes in activity state into corresponding energetic costs. Our results indicate that the effects of disturbance stimuli on sea otter behavior are location specific, and vary non-linearly with distance from disturbance stimuli. Our model quantifies the distance-disturbance relationship, and calculates the distance at which the likelihood of disturbance is low: averaged across locations, there is <10% potential disturbance when stimuli are >54 meters away. We also estimate energetic costs(kJ) associated with various disturbance scenarios: for example, daily energy expenditure is expected to increase by 212.53kJ± 15.75, 154.64kJ ± 13.84and 62.54kJ ± 5, for Monterey, Moss Landing and Morro Bay, respectively, with six small-craft approaches of <20m for a 27.7kg male otter in kelp with 10 otters and a pup ratio of 0.25. Our analyses represent a novel approach for estimating behavioral responses and energetic costs of disturbance, thereby furthering our understanding of how human activities impact sea otters and providing a sound scientific basis for management.

The answer for resident killer whales: Mating is by female choice. What was the question?

Species that mate in three-dimensional environments frequently exhibit reverse sexual size dimorphism, where male agility is advantageous. In killer whales, however, males are larger than females, suggesting sexual selection mediated through female mate choice. Here, we present relevant observations from 126 combined field seasons of boat- and drone-based killer whale research in the Northeast Pacific. First, we found male-male sexual interactions to be common. These putative practice mating sessions did not appear to include any practice of sexual coercion. Second,we found heterosexual interactions to be less common and less protracted, as expected in social species where females have opportunities to evaluate males prior to making mating choices. Third, we found that heterosexual interactions usually involved a single male and we found no evidence of male coalitions that could constrain females during mating. Evolutionary theory predicts that females should be more selective than males in choosing mates. In light of this and the above observations, we hypothesize that a robust female mate choice system is responsible for two strikingly-unusual characteristics of resident killer whales. First, we propose that their unique social system – characterized by stable matrilines in which male and female siblings remain in association throughout their lives – exists because mating control allows females to realize inclusive fitness benefits of living with kin while avoiding fitness costs of incestuous matings. Second, we propose that the extreme subdivision of killer whales into small, closed populations is a consequence of females choosing mates from other matrilines, ultimately creating discrete kinship networks that diverge socially and genetically from other kinship networks. Finally, we make the case that the effectiveness of female mate choice in preventing inbreeding may be compromised by skewed sex ratios and/or limited numbers of adult males, as evidenced by previous studies showing substantial differences in consanguineous mating rates between two resident killer whale populations.

Intra-skeletal variability of stable isotope ratios of C and N in pinnipeds and cetaceans.

Stable isotope ratios of different bones (atlas vertebra, humerus and basioccipital) from different skeleton regions of two phylogenetically unrelated groups of marine mammals, Otariidae and Delphinidae, were analysed before (bluk) and after delipidation and demineralization (dml). Results revealed that combined delipidation and demineralization resulted in a significant increase in the $\delta^{13}C$ and $\delta^{15}N$ mean values of the basioccipital in both species, no effect on the $\delta^{13}C$ and $\delta^{15}N$ mean values of the atlas of any species and species dependent effects on the $\delta^{13}C$ and $\delta^{15}N$ mean values of the humerus. Furthermore, results confirm that the $\delta^{15}N_{bulk}$ values of different skeletal elements from the skull, the axial skeleton and the proximal part of the appendicular skeleton of cetaceans and pinnipeds are interchangeable. However, caution is needed when dealing with bones made up only by cortical bone, such as basioccipital, because the $\delta^{13}C_{dml}$ value and the collagen contents could differ significantly from those of other bones. Bones from the distal part of the appendicular skeleton may also differ in stable isotope ratios, as suggested by previous research. Finally, combined treatments have a strong influence in both $\delta^{13}C$ and $\delta^{15}N$ and hence values from bulk and pretreated samples should not be compared directly.

Dolphins of Montenegro - walk the walk, talk the talk

The South Adriatic is an underrepresented territory regarding scientific research and conservation. Montenegro Dolphin Research was initiated in order to actively increase public awareness and conservation efforts regarding the cetacean population of Montenegro. Along with 400 days of scientific research, we've created several awareness campaigns to educate and inform the citizens of Montenegro. Since September 2016, we built up a website and initiated a social media account with 12.7k followers, gave five school and pre-school presentations, organized 11 beach cleanings, opened an 'Awareness Stand', generated an 'Adopt a dolphin' campaign and gave an interview for the national newspaper 'Vjesti', collaborated with the local and international NGO's, invited residents to our 'Community day', constructed a lifesize dolphin from recycled materials and displayed it on the beach, organized four arts and crafts workshops with everyday single-use plastic, shared daily posts and arranged meetings with the municipality. Following the pre-seismic surveys that took place in Montenegro in December 2018, we published a seismic report and created a stranding network in order to track possible stranding cases.

Our intention is to support citizen science and motivate the public to contribute to conservation efforts and let them be conscious of the effects of threats, such as plastic pollution, ghost nets, seismic surveys, and dynamite fishing. This year, we will create an art exhibition that displays the hardships of cetaceans' everyday lives and the obstacles that they encounter. The exhibition will feature as an interactive performance where the observers will ''walk the walk'' whilst facing and experiencing the hazardous and inevitable consequences of the anthropogenic effects of our time through a hall of pictures.

Montenegro Dolphin Research is creating new conservation ideas continuously to raise public awareness by broadcasting environmental issues regarding our ecosystem and nature.

We only care when we are aware.

Analysis of humpback whale (Megaptera novaeangliae) behavioural response to two acoustic deterrent devices (ADDs) in their Icelandic feeding ground

Cetacean entanglement in fishing gear is of global concern and recently focus has been put on mitigation of such events particularly for large whales such as the humpback whale (*Megaptera novaeangliae*). Entanglements can have detrimental impacts on individuals and populations, as well as on fishers. In Icelandic waters there are approximately 12,000 humpback whales during the summer feeding season, as well as a large commercial fishing fleet utilizing many types of gear. It is estimated at least one-quarter of these whales have been previously entangled. This study conducted behavioural response tests on humpback whales in Skjálfandi Bay and Eyjafjörður, Northeast Iceland, to two acoustic deterrent devices (ADDs): Future Oceans Whale Pinger (WP) (3kHz, 145dB, 5s interval, 400ms duration) and Lofitech Seal Scarer (SS) (14.5kHz, 189dB, 0.6-90s interval, 550ms duration). The individual focal whale for each test was tracked from a boat approximately 100m away using GPS, angle, and range-finder distance for 30 minutes prior to deployment of one device (PrT), for 15 minutes of exposure to an active device (T), and for 30 minutes after exposure (PoT). A total of 9 WP and 7 SS tests could be utilized. Available behaviour data in the forms of average dive time, breathing rate, speed and directivity were analyzed, as well as feeding behaviour for the WP tests, using mixed effect models in R. Results for the WP tests showed that the probability that an observed surfacing event is accompanied by feeding behaviour is significantly lower during the T phase than during the PrT and PoT phases. For dive time, breathing rate, speed and directivity we did not find a significant response that was consistent across individuals for either device. Continued testing of humpback whale response to sound and use of ADDs on commercial fishing gear would be useful in further determining the potential of such devices for entanglement mitigation.

Cetacean distribution in relation to environmental parameters between Drake Passage and northern Antarctic Peninsula.

Corresponding Author: manu.bassoi@gmail.com

The Drake Passage is a dynamic oceanographic region influenced by the main frontal systems of the Southern Ocean, with little information about cetacean distribution and their relationship with environmental parameters. This study explored the use of Generalized Additive Models (GAM) to model the relationships of some cetacean species according to oceanographic (chlorophyll *a* and sea surface temperature) and a suit of physiographic (depth, bottom topography, distances from lands and fronts) variables adjacent to the Antarctic Peninsula and Drake Passage during the austral summer. The results suggest that the physiographic features, mainly the distances from land, were the most significant parameters related to the presence/absence of cetaceans. Distances from Antarctic Peninsula and the Polar Front influenced the occurrence of many species. Sea surface temperature showed an effect only on humpback whale presence around lower temperatures, and chlorophyll *a* was not found to have a significant relationship with either cetacean species. Most of the species occurred mainly South of the Polar Front, with killer, minke and humpback whales mostly occurring in coastal areas, whereas conversely fin and sei whales occurred more frequently in offshore waters. The southern bottlenose whale seems to occupy a wide range of latitude. Hourglass dolphin and long-finned pilot whale are species frequently occurring in the Drake Passage, suggesting their northernmost and southernmost ranges, respectively. We encourage further dedicated cetacean surveys in this peculiar dynamic region, based on *in situ* oceanographic data and krill acoustic sampling, and either taking into consideration cetacean species density or abundance.

Changes in bottlenose dolphin distribution patterns in response to harmful algal blooms and hypoxic events in a southwest Florida estuary

Bottlenose dolphins (*Tursiops truncatus*) in the Charlotte Harbor/Pine Island Sound (CHPIS) estuarine complex along the southwest coast of Florida are typically year-round, long-term residents. This estuary occasionally experiences extreme environmental perturbations such as red tide (*Karenia brevis*) harmful algal blooms (HABs), as well as seasonal hypoxic events. During 2001-2006, boat-based photo identification surveys (338 boat-days, 1957 sightings) along repeated transects were conducted to estimate abundance, trends and patterns of distribution during Jan/Feb and Sep/Oct of most years. Hypoxic conditions were documented yearly during the rainy season (Jul-Oct) in northeast CHPIS near two river mouths. Fewer dolphins were observed during surveys in northeast CHPIS during these hypoxic events compared to winter surveys. During 2005-2006 a severe red tide HAB occurred along the central and southwest coast of Florida including the CHPIS inlet passes, and large fish kills were observed. Fewer dolphins were observed near these passes during Sep/Oct 2006 compared to non-HAB survey years. Dolphins were more concentrated in central CHPIS during these two concurrent environmental perturbations in Sep/Oct 2006, unlike other survey periods, possibly as a result of changes in prey availability and distribution. Following this red tide HAB event, we received increased reports about begging or patrolling dolphins. This suggests that such environmental disruptions not only change dolphin distribution but may also increase the frequency of human-dolphin interactions. Public outreach about safe boating and angling around dolphins to area stakeholders would be beneficial, especially following red tide events.

A whole genome study of bottlenose dolphins reveals signatures of selection associated with resistance and susceptibility to cetacean morbillivirus.

Cetaceans are increasingly faced with a number of natural and anthropogenic stressors that can drive their population demography and evolutionary processes. Of these stressors, cetacean morbillivirus (CeMV) has emerged as one of the most significant viral threats to cetaceans worldwide contributing to the death of tens of thousands of individuals within multiple species. Variability within genes are known to influence host susceptibility and resistance to disease, and it is therefore important to identify genetic variants which impact on the ability of individuals to survive CeMV outbreaks and for populations to persist. Initially we sequenced a reduced representation of the genome in survivor and non-survivor bottlenose dolphins of a 2013 CeMV outbreak in southern Australia. Out of 35,493 single nucleotide polymorphisms (SNPs), association analyses identified five candidate genes associated with resistance and susceptibility to CeMV. These genes have functions related to stress, immune and pain responses. We now build on this study by sequencing the whole-genome of a larger number of survivors and non-survivors of the outbreak, to test for differences in genetic variants between the two groups for genes known to be associated with morbilliviruses and immune responses in other species. The whole genome dataset consists of 16,658,049 high quality SNPs. Association analyses found significant allele and genotype frequency differences between survivors and non-survivors at 471 SNPs located on 70 different scaffolds. Annotation of the candidate SNPs revealed several additional genes associated with host immunity and biological processes. This study provides vital information about genes involved in host resistance and susceptibility to CeMV and will contribute to a better understanding of disease evolution. In addition, biomarkers can be developed to assess potential genetic risk factors in other cetacean populations and species.

The Argos satellite system is used since 1978 by the biologists for tracking high-migratory animals and collecting biodata.

The Argos biotelemetry is used specifically by marine mammals' biologists among other scientific methodologies (photo-ID, genetics, habitat models, oceanographic environment). Many species of baleen whales, toothed whales, dolphins, porpoises, belugas, pilot whales, dolphins, pinnipeds, orcas,

narwhals, etc. have been tagged and provided huge amount of data allowing to:

- Observe large-scale movements of cetaceans, map hot spots and delineate vulnerable areas
- Understand behavior processes through Argos-transmitted data such as depth dive, accelerometry, and parameters of surrounding waters such as temperature, salinity, fluor, oxygen.

Beyond marine mammalogy and research goals, these data are used to provide stakeholders with evidence showing the necessity to establish conservation measures, establish and monitor marine protected areas.

The talk will present the present and future Argos satellites constellation (20 nanosatellites operational in 2022, allowing an improving revisit time and a downlink capacity), the Argos-tracked animals main figures, statistics and maps on around 15,000 marine mammals tracked among the 77,000 Argos wildlife platforms, 3,000 Argos programs deployed since more than 10 years, and some interesting case studies from some Argos marine mammals' important scientists.

Manatee/green sea turtle behavioral interactions: Interspecies play?

The eminent neuroethologist, Theodore Bullock, proposed that play and complexity of social interaction are candidates for establishing a more complete view of animal intelligence than provided by traditional learning theory. Here, we investigated play in an adult, male Florida manatee (*Trichechus manatus latirostris*) and adult, male green sea turtle (*Chelonia mydas*) housed together at Mote Marine Laboratory where they were observed to interact frequently. Video analysis indicated that both animals initiated interactions including flipper and torso touching, face-to-face touching, tandem swimming, and body riding (turtle on manatee and manatee on turtle). Although these activities might be attributed to a variety of motivations (e.g., affiliation), the complexity and eccentricity of the behaviors suggests another alternative: play. The behaviors are consistent with Gordon M. Burghardt's five criteria for play: 1) Limited in immediate function; 2) Spontaneous, apparently intentional, or autotelic ("done for their own sake"); 3) Structurally or temporally different than ethotypic behavior; 4) Repeated but not rigidly stereotyped; 5) Initiated in an apparently relaxed field (e.g., free from hunger, adverse health, or stressful conditions) or competing systems (e.g., feeding, mating, predator avoidance). This report provides unusual examples of play by both manatee and turtle. Furthermore, it provides rare documentation of manatee and turtle interspecies play. Taken within Bullock's framework, these observations provide an unexpected example of cognitive sophistication not traditionally attributed to manatees and sea turtles.

Simultaneously detecting and classifying tonal and pulsed marine mammal sounds over a very wide range of frequencies in a single acoustic analysis system

Baumgartner, Mark
Biology department, Woods Hole Oceanographic Institute, Woods Hole, MA
Corresponding Author: mbaumgartner@whoi.edu

Detection and classification of marine mammals using passive acoustic monitoring is traditionally conducted on a species-by-species basis using separate algorithms for each species' characteristic calls. When an application requires the detection of many species simultaneously, this approach becomes inefficient at best, and impractical at worst. The low-frequency detection and classification system (LFDCS) uses (1) pitch tracking to detect and characterize tonal sounds in a recording or real-time audio stream, and (2) a separate discriminant function analysis (DFA) to classify sounds by call type and species, allowing the detection and classification of many species simultaneously in a single processing run. The LFDCS, like most tonal marine mammal detectors, relies on spectrograms produced on a linear frequency scale, despite the fact that sound is both produced and perceived on a logarithmic frequency scale. This limits the band of frequencies that can be effectively monitored to roughly 4 octaves, yet marine mammals make tonal and pulse sounds over a range of 12+ octaves. To overcome this limitation, I have implemented an efficient algorithm to create spectrograms based on the constant-Q transform (CQT), a technique to estimate spectral content on a logarithmic frequency scale. The same pitch tracking and DFA approach used in the LFDCS is used on CQT-based spectrograms to detect, characterize, and classify tonal sounds from 15 Hz to 50 kHz (e.g., baleen whale moans to dolphin whistles). The system also incorporates a detection (Teager-Kaiser energy operator) and classification (DFA) system for pulse

sounds (e.g., echolocation clicks, minke whale pulse trains, walrus knocks) that takes advantage of the wide-band processing required for the creation of CQT-based spectrograms. The new system is implemented on a desktop computer for processing archived recordings and will be implemented on the digital acoustic monitoring (DMON) instrument for in-situ real-time detection and classification from autonomous platforms.

Stereotypy of whistles: Can whistles be used to estimate dolphin abundance?

Bazúa Durán, Carmen[1]; Montejano-Zea, Elena[2]

Corresponding Author: bazua@unam.mx

Whistles have been studied extensively for both wild and captive dolphins. They are used in the communication between individuals, to maintain contact within individuals of a herd, and to coordinate herd movements, having some whistle types that are an individual distinction or signature. However, little is known on how whistles can be used to ascribe individuals. Therefore, the present study is focused on determining the stereotypy of the most frequently emitted whistles by four captive bottlenose dolphins, *Tursiops truncatus*, housed in two different marine parks. Stereotypy was computed by changing the similarity index while classifying whistles into whistle types using Matlab BELUGA and ArtWARP. The whistling dolphin identity was determined using the method described in López & Bazúa (2010). Results indicate that signature whistles have a similarity index greater than 94-95%, therefore, allowing to assess the minimum number of whistling dolphins in a pod that emit signature whistles. This is especially important in the wild, where in some occassions, it is very difficult to assess how many individuals are present. This very simple method promises to be useful to quantify the number of signature whistles from underwater recordings, and to relate it with the possible number of dolphins present. Further work will include testing this method with wild bottlenose dolphin recordings. It is necessary to implement such methods to better understand how dolphins are using whistles, since acoustic communication is the most important sense in dolphin species. [Work supported by PAPIIT & PASPA-UNAM]

Fine-scale distribution of harbour porpoise Phocoena phocoena within a coastal Marine Protected Area

The designation of protected sites for cetaceans has been largely shaped by patterns in site fidelity, often favouring species with clear residency patterns or highly localised breeding and foraging areas. Conservation of the harbour porpoise Phocoena phocoena, a species that does not typically exhibit strong patterns in site fidelity, has been challenging. However, studies have reported predictable foraging hotspots that may be suitable for long-term monitoring through an MPA framework. The objective of this study was to conduct static acoustic monitoring within the Skerries and Causeway Special Area of Conservation (SAC), suitable for the assessment harbour porpoise occurrence at a fine spatio-temporal scale. The study aimed to determine the degree of heterogeneity at this site, identifying any localised hotspots, and from this discuss the capability of land-based visual techniques for ongoing monitoring. Generalised Addictive Mixed Model (GAMM) revealed site specific differences in harbour porpoise occurrence with strong cyclical patterns attributed to tidal preferences. Foraging click trains were evident at all sites and so while harbour porpoise are likely foraging throughout the SAC, the significant difference in overall detection rates is suggestive of localised hotspots. The fine-scale (< 5 km) patterns in harbour porpoise occurrence found in this study can be used to inform MPA management through the timing of human activities, for example by avoiding peak porpoise times or facilitating local eco-tourism ventures. Further investigation on the seasonal persistence of the identified hotspots is recommended as part of long-term monitoring within this protected area.

Predicting cetacean abundance and distribution in a changing climate.

Substantial changes in abundance and shifts in distribution as a result of a warming climate have been documented for many marine species, but opportunities to test our ability to forecast such changes have been limited. In 2014, waters in the California Current Ecosystem (CCE) became anomalously warm as an unprecedented marine heatwave spread over the area. The profoundly altered ocean conditions provided a unique opportunity to evaluate whether species distribution models (SDMs) could accurately predict changes in marine mammal abundance and distribution during a period with unusually warm ocean temperatures. We constructed SDMs based on 1991-2009 CCE sighting data and environmental output from a regional ocean model for eight cetacean species with a diverse range of habitat associations. Model selection was based on established metrics including AIC and root-mean-squared error. Models were then used to forecast species abundance and distribution patterns during 2014, and predictions compared to actual 2014 cetacean survey sighting data to assess model performance. Ratios of model-predicted abundance to design-based estimates were close to 1:1 for all but one species and accurately captured changes in the number of animals in the study area during the anomalous year. Predicted distribution patterns also showed good concordance with the actual 2014 survey observations and captured substantial shifts in the distribution of some species. Our results indicate that models of cetacean-habitat relationships built on two decades of survey data were sufficiently robust to capture changes in abundance and shifts in distribution under anomalous conditions, for both cool and warm temperate species. This is likely because the models were based on long-term survey data collected during periods that encompassed a large range of environmental variation. They also revealed species-specific responses to warming ocean waters, enhancing our understanding of the effects of climate change on cetaceans and other marine predators in the CCE.

Late evoked potentials in porpoises speak against a per-click view of echolocation and suggest potential for electrophysiological audiograms at low frequencies

Actively sensing animals like odontocetes offer an opportunity to study the control of sensory streaming and the type of control loop they employ for perceptually organizing and negotiating obstacles in the environment and for finding prey. Within the field of odontocete biosonar, an open question is whether returning echoes are evaluated on a click-by-click basis or if a running central evaluation that incorporates several clicks in shaping the animal's perceptual organization of their complex echo scene. During the buzz phase of small odontocetes inter-click intervals (ICI) may be as low as 2 ms, which fact seemingly precludes the possibility of individual click processing. However, the time separation between events that would be necessary for discrete click processing is unknown. Here we address that problem by studying the low-frequency auditory evoked potentials (AEP) in a stationary porpoise presented with clicks at ICIs of 0.5-1 s. By using low presentation rates and averaging over tens of sessions, we found a consistent late component in the AEPs occurring at latencies out to at least 150 ms. We argue that these late responses represents cortical evoked potentials, whereby 150 ms should form a lower limit to the ICIs at which click-by-click processing of echoes could take place. The ICI of echolocating porpoises is usually much lower than 150 ms (2-50 ms), so it appears that they do not process echo information cognitively before emission of the next click. The slow, presumably cortical, components of the AEPs hold an exciting potential for assessing the audiogram of odontocetes electrophysiologically down to frequencies well below what is usually thought possible with traditional amplitude modulated tonal stimuli, usually assumed to be limited to frequencies above several kilohertz.

To be seen or to be heard? Combining passive acoustic monitoring and visual boat-based observations for studying killer whale depredation.

Within the French economic exclusive zones (EEZ) of Crozet and Kerguelen Islands (Southern Ocean), longline fisheries are highly impacted by the depredation of the Patagonian toothfish mainly by killer whales. Within the purpose to mitigate depredation, it is crucial to understand how they

depredate on longlines underwater. However, those interactions have mostly been assessed from visual observations from the fishing vessels during the hauling of longlines. Fortunately, killer whales rely on acoustic signals for both communication and foraging. In this context, passive acoustic monitoring is a good approach to assess the temporal and spatial behaviour of cetaceans around fishing gears. Here, near Crozet islands we deployed one hydrophone on a longline to record all fishing operations in the vicinity. The aim of this study is to improve the estimation of interactions using acoustic encounters of killer whales (echolocation and vocalization). Thus, 400 hours of recordings collected among 11 deployments of the hydrophone have been manually processed to assess killer whales acoustic encounters. In our study, killer whales were acoustically detected only on 6 deployments. Acoustic encounters of killer whales around the hydrophone were compared with visual observations from the fishing vessel during the hauling. Almost 80% of the longlines were hauled in presence of killer whales at the surface, and for the half, acoustic encounters have been also detected in the vicinity of the hydrophone with a maximum detection range estimated between 5 and 10 km. Moreover, almost 20% of killer whale acoustic encounters have been detected during hauling sessions with no visual observation from boats. This revealed that killer whales may remain near some of the longlines instead of following the boat. Since echolocation signals (clicks and buzzes) were recorded during these events, we strongly suggest that killer whales were foraging or even depredating.

Application of Artificial Intelligence to the photo-identification of common bottlenose and Risso's dolphins.

Photo-identification of cetaceans is labor-intensive and time-consuming particularly in the case of large studies when manually performed. To that regard, Artificial Intelligence (AI) can support photo-identification studies with an extensive variety of statistical methods. The unique element of this work is the development of an AI-based system which makes decisions in terms of photo-identification not differently than a human mind would, thus providing users with an automated dorsal fin cropping and an individual-recognition pipeline for cetaceans. Both machine and human intelligences process symbols to interpret and learn from data. The developed system automatically identifies two categories of symbols: a) internal descriptors on the dorsal fin surface and b) outline descriptors, which are key-points over the fin contour. Internal and outline descriptors are both used for individual recognition in the classification process. The species of interest are the common bottlenose dolphin *Tursiops truncatus* and the Risso's dolphin *Grampus griseus*. Sighting data have been acquired in the Gulf of Taranto in the Northern Ionian Sea (North-eastern Central Mediterranean Sea) and in the coastal waters around Pico Island in the Azores Archipelago (Eastern Atlantic Ocean). The accuracy of the dolphin photo-identification, computed by the proposed system, varies between 85% and 95%. Experimental results highlight that the developed automated system supports the work in terms of photo-identification of dolphin species, as essential prerequisite for insight studies on their spatial distributions, habitat uses, residency and migration patterns. Moreover, to make the proposed system accessible to a wider users' community, we have also invested on the development of a well-documented graphical interface, together with a digital platform to smartly collect data.

Isometric relationships in humpback whales studied using drone-based imaging

Assessing body size in free-ranging cetaceans is important for a number of scientific purposes. One approach is to take photogrammetric measures of visible body parts at the surface, such as the fluke, in order to extrapolate the individual's estimated body length from previously an established allometric relation. In humpback whales (*Megaptera novaeangliae*), a linear relationship has been reported between fluke width and body

length, but this was largely based on a heterogenous sample of stranded individuals (n=45) containing many new-born calves. Here, we used an unmanned aerial vehicle (drone) to obtain aerial photographs of free-ranging Northern humpback whales. We managed to photograph and extract trait measures of N=55 individuals, which allowed us to reassess the allometric relationships between body size and different trait variables. For fluke size, our data largely confirmed the historic data and showed a strong linear regression between body size and fluke width ($R^2 = 0.94$, $P < 2e\text{-}16$) which also revealed a strong isometric relation between body size and fluke width ($p < 2.2e\text{-}16$). We then expanded our trait analysis to include head surface, pectoral and dorsal fin length, and blowhole to dorsal fin distance and discuss our findings in light of eventual physiological constraints i.e. which would predict non-isometric (i.e. allometric) relationships. Our study highlights the promise of using unmanned aerial vehicles in morphometric studies and applied problems that require estimating body size of free-ranging cetaceans.

Variation, selection, and heritability of foraging strategies and their influence on lifetime reproductive success in northern elephant seals.

A fundamental question in biology is which behavioral traits confer fitness advantages and whether those traits are passed onto offspring. Our aim was to explain the great variation in lifetime reproductive success (LRS) of female northern elephant seals, *Mirounga angustirostris,* by examining their at-sea behavior. We sought to determine whether diving behavior, foraging routes and location, and life history phenology contributed to LRS. We examined the diving records of 271 instrumented females whose LRS was determined independently and varied from 0 to 20 pups produced. No ready explanation for the drastic individual differences in LRS emerged from the diving behavior or life history phenology data. However, we found a strong interactive effect of birth year and Pacific Decadal Oscillation (PDO) phase on how tracking route related to lifetime reproductive success. For cohorts that experienced enhanced offshore productivity (PDO+) during their first trip to sea (2003, 2005), the offshore strategy was associated with high lifetime reproductive success. Conversely, for cohorts that experienced enhanced coastal productivity (PDO-) during their first trip to sea (2000, 2002), the coastal strategy was associated with high lifetime reproductive success. We found no evidence for heritability of foraging route in mother-pup pairs ($N = 10$); pup migration routes were no more similar to the routes of their mothers than to random seals. We conclude that the climate phase at birth is an important determinant of successful initial foraging and that causes for the great variation in LRS warrant further study.

Determinants of dispersal and phylogeographic history of a highly mobile cetacean species: The North Atlantic harbour porpoise.

Understanding the determinants of individual dispersal, population structure, and evolutionary history can provide insights about how species will evolve with climate change. However, such a task is complex for highly mobile marine species such as cetaceans for which it is intuitively difficult to infer what could limit their dispersal. The harbor porpoise (*Phocoena phococena*) is widely distributed in the North Atlantic. Its biogeographic history has been shaped by environmental variation during the last Glaciations with the divergence of three ecotypes (or sub-species) in the Eastern North Atlantic (ENA). However, we still do not know the degree to which populations in the ENA are connected to those in the Western North Atlantic (WNA), what environmental determinants drive the dispersal of porpoises, and whether distinct ecotypes exist in the WNA. Here we analyze the genetic diversity of 10 microsatellite loci and one-quarter of the mitogenome for an unprecedented sampling of 1,533 individuals. Using spatially explicit population genetics approaches, we investigated fine-scale population structure over the entire North Atlantic. Our study suggests that porpoises from the WNA and ENA are part of the same "*continental shelf ecotype*" that stretches from the northern Bay of Biscay to the WNA. We identified a clear signal of restricted dispersal in the

mitogenome data supporting previous evidence of female philopatry. We also discovered a cryptic divergent mitochondrial lineage in one individual from Western Greenland suggesting a fourth distinct ecotype may exist. Finally, we reconstructed the phylogeographic history of these porpoises using coalescent simulations of population evolution, shedding light on the likely scenarios that shaped the current pattern of genetic diversity. These results provide key insights into the factors and processes shaping population structure in this species and will help model its evolution in the forecasted climate changes.

The humpback whale sentinel program reveals 2017 as an anomalous year in the eastern Antarctic Sea-ice ecosystem

s.bengtsonnash@griffith.edu.au

In 2017, the world observed some of the most dramatic changes recorded in Antarctica in modern history. July 2017 saw 10% of the Larsen C ice-shelf cleave off as a massive iceberg. The year continued with the appearance of a 300,000 m^2 polynya in the winter sea-ice off east Antarctica, and summer sea-ice coverage was the lowest on record, 27% below the mean annual minimum. Southern hemisphere humpback whales (*Megaptera novaeangliae*) were recently implemented as sentinels of the Antarctic sea-ice system owing to their dependence upon sympagic Antarctic krill (*Euphausia superba*) and extreme energetic adaptations. To date, populations migrating to Colombian (G), Brazilian (A), western (D) and eastern (E1) Australian breeding grounds have been included into this Southern Ocean Observing System (SOOS)-endorsed effort for circum-polar surveillance. The longest continuous record of annual sentinel parameter measurements (11-years) is available for the E1 stock. Temporal analysis of blubber biochemical signals, histology, and the demography of the migratory cohort of the E1 population, revealed 2017 to be an outlier. Biopsied blubber samples had high proportions of the fatty acid 21:5ω3, which was not present in whales sampled in other years. The inverse Adiposity Index (AI^{-1}) of southward migrating whales was the second lowest on record, 15% below the mean for this sampling time-point. Finally, the sex ratio of the migratory cohort showed a greater than average skew towards males within precisely comparable time windows; potentially indicating missed or delayed migration among reproductive females as an energy conserving strategy. The role of Antarctic sea-ice extent, and the timing of sea-ice break-up, in influencing krill abundance and availability to predators remains an active area of research, and one which carries clear consequences for Southern Ocean baleen whale populations. Results presented here lend strength to the use of migratory baleen whales for capturing present-day changes in the remote Antarctic ecosystem.

Balancing the risk: Harbour porpoises respond to piling and vessel activities during offshore windfarm construction.

aude.benhemma@gmail.com

Offshore windfarm (OWF) developments are expanding, requiring assessment and mitigation of construction activities. Typically, this focusses on pile-driving, as intense impulsive noise elicits adverse behavioural responses in marine mammals. However, construction activities such as jacket, turbine and cabling installation also change acoustic habitats through increased vessel activity.

We quantified variation in harbour porpoise occurrence and foraging activity over the two-year construction of Beatrice OWF in Scotland, and related this to changes in vessel activity and the acoustic environment. Following a BACI design, arrays of echolocation click detectors (CPODs) were deployed in 25km by 25km impact and reference blocks throughout construction. Echolocation clicks and buzz inter-click intervals were used to investigate porpoise occurrence and foraging activity respectively. In parallel, deployments of acoustic recorders enabled us to measure broadband noise levels in different construction phases, identify acoustic signatures of key activities and relate these to variations in porpoise occurrence and activity. To characterise vessel activities at the site, AIS vessel-tracking data were integrated with engineering records. Generalised linear mixed effect models were used to describe relationships between porpoise occurrence and foraging activity and different construction works.

A decline in porpoise occurrence was observed in the impact block during the 2017 construction phase, but short-term responses to piling events did not result in broad-scale displacement. Higher probability of buzzing at the site highlighted a change in activity budgets, suggesting porpoises maximised foraging activity during shorter periods spent in exposed areas. These same patterns were observed in 2018 during the jacket and turbine installation.

These findings suggest that assessments should account for all construction activities that may result in variation in local soundscapes, particularly where efforts to mitigate one noise source (e.g. piling) may increase other vessel-based activities.

Exploring influences of lower-frequency Acoustic Deterrent Devices (ADDs) on harbour porpoise in Scottish coastal waters.

Benjamins, Steven[1]; Risch, Denise[2]; Lepper, Paul[3]; Wilson, Ben[1]

Steven.Benjamins@sams.ac.uk

Acoustic Deterrent Devices (ADDs) are widely used to deter pinniped depredation from finfish farms by emitting loud, aversive sounds, which may also impact non-target species such as harbour porpoise (*Phocoena phocoena*). One potential method of reducing ADD noise impacts on species such as porpoises involves lowering output frequencies from typical ranges of 10-20 kHz down to <2 kHz, where porpoises' hearing sensitivity is poorer compared to pinnipeds.

We compared responses of wild harbour porpoises to experimental playbacks of an artificial ADD-like sinusoidal tonal burst signal (RMS source level 154-170 dB re 1 µPa-m) transmitted at two frequency ranges (8-18 kHz [HF] and 1-2 kHz [LF]). Signals were transmitted from a salmon farm in Bloody Bay (Sound of Mull, Scotland, UK). An array of 22 C-POD click train detectors was deployed to 5 km from the source and farm. Signal playbacks varied randomly between HF- and LF-signals and a silent control, and occurred over 33 days (08/09-11/10/2016). During this period, 138 experimental playback bouts occurred, including 53 HF-signals, 38 LF-signals and 47 silent controls. C-POD data were used to infer porpoise presence and analysed using nonparametric Kruskal-Wallis tests and GAM-GEE models to evaluate effects of different signals and environmental covariates on porpoise detection probabilities.

At most C-PODs, porpoise detection rates were significantly lower during both HF- and LF-signal playbacks relative to silent controls. GAM-GEE modelling identified "ADD-like signal presence" as an important factor determining porpoise detection probabilities at distances up to 800 – 1000 m from source. At greater distances, other covariates (e.g. day-night, ebb-flood and spring-neap cycles) dominated.

Based on these results, widespread application of lower-frequency ADDs with signal characteristics similar to those tested would, by themselves, be unlikely to significantly reduce risk of acoustic impacts on harbour porpoises in Scottish waters, when compared to conventional ADD signals.

Energy balance effects of persistent organic pollutants in marine mammals: Linking in vitro experiments on blubber tissue function with mass change trajectories in grey seals.

Lipophilic environmental pollutants can alter adipose function and hormone levels, but impacts on whole animal energy balance are poorly understood. We investigated whether blubber persistent organic pollutants (POPs) influence body mass trajectories during suckling or natural fasting in wild grey seal pups through impacts on adipose tissue metabolic characteristics, thyroid hormone (TH) levels and blubber TH sensitivity measured in vitro. Pups with higher blubber glucose uptake rates gained mass faster during suckling (LM: $F_{(4,52)} = 6.54$; $p = 0.002$; $R2 = 0.33$; $T = 2.19$, $p = 0.032$), in addition to established effects of maternal mass, sex, suckling duration and birth mass. T3 concentrations were negatively related to blubber polychlorinated biphenyl (PCB) levels. Blubber explants increased glucose uptake in response to acute T3 treatment (GAMM: $T = 1.97$;

p = 0.05; R2 = 0.27), but not in response to overnight PCB exposure (T = 0.47; p = 0.63). However, PCBs abolished the acute response to T3 (T = 0.47; p = 0.63). Dioxin-like-PCBs may slow mass gain by reducing blubber glucose uptake directly, and by lowering T3 levels and blubber T3 sensitivity. Dichlorodiphenyltrichloroethane (DDT) and its metabolites (DDX) were associated with lower efficiency of mass transfer from mother to pup (LM: F (5,78) = 23.07; p < 0.001; R2 = 0.57; T = 2.39; p = 0.019). Fasting pups that were heavier at weaning and had higher blubber DDX levels lost mass faster. These findings are consistent with a positive effect of blubber DDX on lipolysis in vitro. Our data show how negative effects of POPs on fat tissue function, measured in vitro, can be linked to whole-animal mass change trajectories during key life history stages. Legacy contaminants, even at doses below toxic thresholds, may have ongoing ecological consequences for marine mammals through impacts on energy balance.Lipophilic environmental pollutants

In summer 2017 I studied the abundance and distribution of marine mammals and associated birds at the Five Finger Lighthouse in Southeast Alaska. My objectives were (1) to identify the areas of highest habitat use by species of conservation concern, (2) to make recommendations for an ecosystem-based management plan for the island, and (3) to initiate a citizen science project supporting continued place-based research and conservation. This study documented seven species of marine mammals and 20 taxonomic groups of birds derived from 110 field surveys. My analysis found higher relative abundance and greater biodiversity of both birds and marine mammals on the south and west facing sectors of the island compared to the north and east facing sectors. I attribute this to the greater habitat complexity on the south and west facing sectors that comprise a near-shore reef, a mixed kelp forest, and a channel between the reef and rocky cliffs, areas used extensively for foraging, nesting, traveling, socializing, and resting by many of the documented species. These findings provided the basis for recommendations to avoid development and to minimize anthropogenic disturbance on the southern and western portions of the island including the adjacent reef and channel. In 2018, novel results from this study were used to prevent disturbance to harbor seals (*Phoca vitulina*) during pup rearing season, a species of high conservation concern in Alaska both due to declining numbers and importance to traditional subsistence harvest practices. As both the Five Finger Lighthouse ecosystem and management continue to evolve in response to changing environmental conditions and human interests, this study also established a baseline for future study that will inform future adaptive management, document changes over time, and engage community stakeholders in science and conservation.

Insights into habitat use and identification of critical areas for two endangered populations of franciscana dolphins (Pontoporia blainvillei) in southeastern Brazil.

The franciscana (Pontoporia blainvillei) is considered the most threatened small cetacean in southwestern Atlantic because of high range-wide bycatch mortality. Franciscanas in Espírito Santo and Rio de Janeiro States, southeastern Brazil, comprise two isolated populations in areas known, respectively, as Franciscana Management Area (FMA) 1a and 1b. Serious concerns regarding the status of these populations have been expressed due to their geographic isolation, genetic distinctiveness, and low density. Here we present data on habitat use and identification of critical areas for franciscana conservation achieved through three summer aerial surveys (2012, 2017 and 2018). Design-based line transect surveys were carried out by four experienced observers using a twin-engine airplane. Fifty-seven franciscana sightings form the database of this study. Habitat preference by depth was investigated by correcting the franciscana encounter rate by the available area within each 10m-depth interval. Franciscanas in FMA1a presented extremely coastal habits in summer, with 80% of the population being distributed less than 3nm from the coast. Habitat

use of the 0-10m interval is 1.25 greater than the 10-20 interval. We identified that 50% of the FMA1a population is concentrated in only 20% of their available distribution area. This small concentration area (500km2; 30km of coastline) is located south of Doce River (19o39´S) and represents great conservation potential. Franciscanas in FMA1b shows a slightly more spread inshore-offshore distributional pattern, with 45% of the population using waters less than 3nm from the coast. Franciscana utilization of the 0-10m interval is 1.33 and 5.6 greater than the 10-20 and 20-30m interval, respectively, even though it represents only 10% of the surveyed area. The area between Cape São Tomé (21º59´S) and Carapebus (22º13´S) is critical since it concentrates 70% of this population. Our findings highlight that the conservation of these franciscana populations depends on robust measures to protect the coastal environment.

Bottlenose dolphin, Tursiops truncatus, predator – prey responses to red tide harmful algal blooms.

Red tide blooms, caused by the toxic dinoflagellate *Karenia brevis*, occur regularly along Florida's west coast and often result in massive fish kills and marine mammal mortalities. Previous research during an intense, protracted, and wide-spread bloom (2005-2006) showed decreases in fish abundance, species richness, diversity, and changes in community structure in Sarasota Bay, Florida. Concurrently, juvenile resident bottlenose dolphins, altered activity budgets, increased sociality, and expanded ranging behavior during bloom periods. The objective of this study was to determine the impact of a recent intense but relatively short-duration bloom (summer 2018 – winter 2019) on the fish community and on dolphin foraging in Sarasota Bay, Florida. Data on fish abundance, species composition, *K. brevis* cell densities, and water quality were analyzed to quantify changes in fish, and specifically dolphin prey, abundances, overall species richness, diversity, and community structure. Standardized dolphin survey data were analyzed to determine dolphin foraging encounters relative to *K. brevis* and fish abundance. During bloom conditions, fish abundances decreased significantly, species diversity increased, and community structure shifted due primarily to changes in temperature and *K. brevis* density. Preliminary analyses indicate that dolphin foraging behaviors were observed more often at locations lower in *K. brevis* density. Hot spot analyses will further explore spatial relationships between dolphin foraging encounters, *K. brevis* density, and fish abundance. These results support previous findings that recurrent *K. brevis* blooms likely play an important role in regulating fish communities, specifically by reducing fish abundances, and altering species diversity and community structure. Additionally, these analyses indicate that the recent 2018-2019 bloom event was a relatively less severe ecological disturbance than the 2005-2006 bloom. A better understanding of the patterns and processes of bloom disturbance, as well as the factors that contribute to ecosystem resilience, are essential for management and conservation.

Quantifying harbour porpoises foraging behaviour in CPOD data

Berges, Benoit[1]; Scheidat, Meike[2]; Geelhoed, Steve[3]; Tougaard, Jakob[4]

Harbour porpoises (Phocoena phocoena) are regularly monitored to assess how they are impacted by the construction and operation of offshore wind farms. A suitable method to do this is passive acoustic monitoring (PAM) by stationary hydrophones, for example CPODs. These devices provide information on echolocation click activity, which can then be analysed.

Prey occurrence is considered one of the main drivers in porpoise distribution and successful feeding is vital to the fitness and survival of individual porpoises. Information on foraging behavior, however, is difficult to obtain in the field, in particular as animals feed under water.

Harbour porpoise use narrow band high frequency signals in a sequence of clicks (called click trains) for echolocation, communication and foraging. The

different behaviors are characterised by the modulation in time lag between clicks (inter-click interval). For foraging behavior, the click train sequence is noticeably characterised by low inter-click intervals and a final increase in inter-click intervals. While such a train sequence can be resolved in recordings made on the animals, the detection of foraging events is more challenging for stationary hydrophones such as CPOD devices.

Using CPOD data collected in Dutch water during and after the construction of the Gemini wind farm (June 2015 to February 2016), the present study first investigated different data processing methods for the quantification of foraging behavior. The results indicate that a click-based classification provides the best results (as opposed to using click trains). This analytical tool was then applied to the entire data set to explore the potential applications of this method. The results show that foraging events could be detected in sufficient numbers to reveal patterns over time, such as correlation with pile driving activities, as well as to compare behaviour between CPOD stations.

NanoPAM: A novel low-cost acoustically networked system for marine mammal monitoring.

Passive Acoustic Monitoring (PAM) has become an important tool to monitor cetacean occurrence and behaviour ecology by recording and analysing whistles, calls and echolocation clicks. Autonomous PAMs require retrieval to download data, are frequently lost and expensive, limiting their application. They are also limited to few species algorithms, sometimes not available to the user. To address this, we have developed NanoPAM, a novel low-cost acoustically networked PAM system which includes new hardware and software for l detection of echolocating cetaceans and acoustic transfer of data. NanoPAM consists of a broadband hydrophone (20 kHz – 160 kHz) and ultra-low energy digital signal processing to detect and classify cetacean click trains. The high level data from animal detections is then transferred back to shore in near real time via an underwater acoustic communication network, with each NanoPAM device acting as network router spaced by up to 2km. With a single WIFI connected surface buoy, networks of up to 256 devices may be deployed to cover an area of hundreds of km^2. The current NanoPAM development includes algorithms for harbour porpoise, common bottlenose and white-beaked dolphin and boat sonar and can distinguish between regular and foraging buzz clicks. Performance of NanoPAMs low energy algorithms compares favourably, in terms of detection and false positive rates, with state of the art click logging devices and offline processing of raw hydrophone recordings. Typical data transmissions consist of a 1s signal burst each hour, at a source level of 168 dB centred on 28 kHz, and the device may be programmed to wait until cetacean detections have stopped before transmitting. NanoPAM devices are designed to be moored on the seabed with no surface buoy required, can be quickly deployed due to their relatively small size and weight, and battery life will support up to 12 months deployment.

Exploring oceanographic influences on northern elephant seal pup and weaner strandings in California.

Berglund, Chris[1]; O'Hern, Julia[2]

Corresponding Author: 13christopherb@gmail.com

The Marine Mammal Center (TMMC) responds to stranded marine mammals along 600 miles of the California coastline annually. These marine mammals are considered stranded when they are unable to return to their normal habitat or in need of medical attention. The present study explores the relationship between strandings of one of the most commonly admitted species to TMMC, the northern elephant seal (*Mirounga angustirostris*), and oceanographic conditions. Large-scale indices reflecting basin-wide conditions such as the Pacific Decadal Oscillation and the El Niñ̃o Southern Oscillation that contribute to long-term trends as well as more temporally and spatially localized features such as wave energy and water level are considered. While large storms increase incidents of maternal separation and elephant seal pup mortality at rookeries, the conditions that produce live elephant seal strandings outside of rookeries are less thoroughly understood. From 2007-2018, 447 elephant seals under one year of age that stranded within 30km of the nearest rookery in January-March are compared to wave energy determined from NOAA Wavewatch III model outputs. Strandings near the Point Reyes and Añ̃o Nuevo rookeries

in January and February when the majority of pups are still nursing show a strong relationship with wave energy while strandings near the San Simeon rookery in the same time period do not. In contrast, no conclusive relationship is found between wave energy and strandings in March when most pups have weaned from their mothers. A better understanding of the oceanographic conditions producing strandings will enable more informed planning with regards to stranding response in a future with a changing global climate.

Emerging pathogens and immunotoxic pollutants in cetaceans stranded along the coasts of Liguria, Pelagos Sanctuary, Italy

Stranding events are generally multi-factorial and anthropogenic chemical pollutants can contribute to increase the susceptibility of marine mammals to infectious pathogens. The examination of cetaceans stranded in recent years along the coast of Liguria, North-Western Italy, Pelagos Sanctuary, has shown that infectious diseases represent an important cause of death. Moreover, several studies revealed toxicological stress by organochlorine (OC) xenobiotics in Mediterranean resident marine mammals.This study was focused on the pathogenic role of infectious agents in connection with toxicological stress, being also aimed at investigating the putative exposure sources.Between 2015 and 2018, 32 cetaceans were found stranded, mostly represented by *Stenella coeruleoalba* (81%) specimens. The National Reference Centre for Diagnostic Activities on Dead Stranded Cetaceans (C.Re.Di.Ma.) carried out necropsies and diagnostic investigations on over 80% of cases, including screening for the most relevant pathogens and specific characterization in case of positivity. OC levels were detected in the blubber from some specimens, being also evaluated for immunotoxicity with the help of theoretical reference models.Overall, 27 necropsies were performed (27/32, 84.3%) and it was possible to hypothesize the cause of death in 25 cases (25/27, 94.5%), mostly attributable to infectious diseases (20/25, 80%). In 10 individuals (10/20, 50%), serious coinfections were detected, involving cetacean viruses and/or pathogens either zoonotic (*Salmonella* 1,4,[5],12:i:- antibiotic-resistant strains, *Listeria monocytogenes*, *Brucella ceti* ST26) or indicative of terrestrial contamination (*Toxoplasma gondii, Aspergillus fumigatus*).High PCB levels were found in all individuals (12/12, 100%) and toxicological stress was evident in 50% of the cases, in particular in 5 out of 8 animals with coinfections (62.5%). Our results indicate a high level of contamination by terrestrial pathogens and OC xenobiotics along the North Western Italian coastline and demonstrate the importance of applying a multidisciplinary approach and of performing an adequate pathogens' characterization.

Conservation implications of loss of both blubber and muscle mass in cetaceans

Marine mammals may lose body mass for many different reasons such as disease and reduced food availability due to overfishing and/or climate change. This loss in body mass may have detrimental effects on the animal's health and ability to survive. We studied the relative distribution of tissues (body composition) in different species of cetaceans to assess what occurs when an animal losses body mass. We performed mass dissections on multiple individuals with different body conditions from three cetacean species (*Stenella coeruloalba*, *Delphinus delphis*, and *Mesoplodon densirostris*). Our results indicated that animals in poor body condition lost both blubber and muscle mass. The animal with the worst body condition lost half of its blubber and muscle mass. A loss in blubber mass implies a loss in thermal isolation, which results in a higher metabolic rate for thermoregulation. Moreover, the loss in total body mass results in increased mass-specific metabolic rate, and the loss of muscle mass reduces the total O_2 store resulting in a reduction in the aerobic dive limit (ADL). This together reduces the foraging time. Consequently, an animal with poor body condition will have to spend more energy to obtain the same amount of prey at a higher energetic cost, resulting in greater body mass loss, leading to a snowball effect that can have fatal consequences. Reduction of the ADL might be more critical to deep diving species that unavoidably need longer dives to reach their prey. Loss of body mass may have a greater implication for individual animal survival and marine mammal conservation than previously thought, especially given the reduction of available food resources due to climate change and/or overfishing, and merits further investigations.

Elevated persistent organic pollutants exposure in St. Lawrence Estuary belugas (Canada): Relationships with lipid profiles and body condition.

Exposure of St. Lawrence Estuary (SLE) belugas (*Delphinapterus leucas*) to elevated levels of persistent organic pollutants (POPs) was identified as an environmental stressor that may contribute to altering beluga health and potentially be associated with certain causes of death. Several POPs (e.g., PCBs and PBDEs) are known to disrupt thyroid functions and affect lipid metabolism and body condition. The objective of this study was to investigate the relationships between blubber POP concentrations (flame retardants and organochlorines), lipid profiles and body condition of SLE belugas. A secondary objective was to investigate the relationships between these variables and the cause of death of these animals determined by necropsy. Blubber concentrations of POPs and lipid compounds (fatty acids, phospholipids, acylcarnitines) were determined for 51 SLE beluga found dead between 1998 and 2016, and for which cause of death was established. Body length, body mass, age, sex and body condition (using a scaled mass index) were determined. Kruskal Wallis post hoc tests were used to determine significant differences between groups (sex, cause of death). SLE female belugas that died as a result of dystocia were younger and were in better body condition than other females, whereas those that died by starvation had a lower body condition index. SLE belugas that died from cancer exhibited greater concentrations of medium-chain fatty acids (C14:0, 16:0, 18:0) compared to beluga dying from other causes. Concentrations of PCBs and pesticides were 7 and 42 times greater in male than female SLE belugas, respectively. Covariance analyses were used to examine the relationships between these variables and POP concentrations, and Akaike Information Criterion to identify the variables related to the different causes of mortality. Preliminary findings suggest negative relationships between blubber POP concentrations and some of the lipid profile markers such as polyunsaturated:saturated fatty acid ratios, omega-6/omega-3.

Reproductive seasonality and breeding grounds of the fin whale, Balaenoptera physalus, in the Gulf of California.

The fin whale, *Balaenoptera physalus*, is distributed in all of the world's oceans. Until now, only three resident populations are recognized: East Sea of China, Mediterranean Sea and the Gulf of California. The latter is a resident population considered genetically isolated, with an estimated population of 325 individuals (95% CI: 248-427), and a low genetic variability. This suggests that the population is vulnerable to genetic drift, anthropogenic events, disease, and changes in its habitat. Even though this population has been studied for 30 years, most of its reproductive strategies remain unknown, which makes studies about reproduction a priority. The objective of this study was to determine reproductive seasonality of the fin whale, as well as identifying possible breeding grounds in the Gulf of California, through the measurement of steroid hormones in fin whale biopsies and the analysis of mother-calf sightings. Skin biopsies were obtained from field work during 2015-2018 along the gulf. Blubber was used to measure 10 steroid hormones through liquid-liquid extraction, followed by high precision liquid chromatography-tandem mass spectrometry. Skin samples will be analyzed to determine sex. Testosterone, progesterone, 17B estradiol, androstenedione, aldosterone, 17 hydroxyprogesterone, cortisol, cortisone and corticosterone were detected and quantified using 50 mg blubber samples (Extraction efficiencies: 63-89%; RSD: 0.71-18%). Progesterone peaks and concentrations coincide with pregnant beluga whales, which could indicate pregnancy in fin whales. Once the sex of the individuals is known, statistical analysis will determine if hormone levels change throughout the year. The analysis of mother and calf sightings suggest a higher number of calves in the winter (January-April; $U=12,271$, $p<0.05$) and breeding grounds in the Southwest part of the gulf, especially in Bahia Loreto-Bahia La Paz corridor ($U=11,208$, $p<0.05$). Additionally, re-sighting of mothers during different years suggest a site fidelity in the breeding ground.

CARIMAM project: Adaptation and development of standardized protocols for the study of marine mammals in a Caribbean context.
Bernus, Jeffrey
AGOA SANCTUARY, Martinique
Corresponding Author:
jeffrey.bernus@afbiodiversite.fr

The Agoa Sanctuary (second largest MPA in France) is leading an INTERREG Caraibes project called CARI'MAM (Caribbean Marine Mammal Preservation Network). This project aims to develop a network of MPAs dedicated to the conservation of marine mammals in the Caribbean, a veritable hot spot of biodiversity suspected to host up to 31 cetacean species.

The technical objective is to standardize scientific protocols and develop common management tools. In an international context with strong inequalities and various levels of knowledge, it is a challenge to standerdize methods that accord the needs and possibilities of all.

Several methods ranging from passive acoustic monitoring to photo-identification are adapted and used by several territories to study the diversity and seasonality of species in order to adapt the associated management measures (eg periods and locations of seismic campaigns). Given the high number of islands, the large influx of data and the need for constant analysis for comparisons, tools for assisting standerdized data entry and artificial intelligence algorythms were favored by valuing as much as possible pre-existing tools.

High re-sighting rate and residency time of humpback whales in inshore Irish waters.
Berrow, Simon[1]; Massett, Nick[2]; Whooley, Pádraig[2]
(1) Galway-Mayo Institute of Technology
(2) Irish Whale and Dolphin Group, Kilrush, Ireland
Corresponding Author: simon.berrow@gmit.ie

Over the 20-year period (1999 and 2019) the Irish Whale and Dolphin Group recorded 92 individual humpback whales in Irish waters using photo-identification of tail flukes and dorsal fins, largely through citizen science. 80% of these individual whales were recorded more than once with 67% recorded over five times and 14% recorded over ten times. One individual has been recorded 48 times. A discovery curve is still increasing suggesting there are many more whales to capture from this population. Over one-half (55.4%) have been recorded in more than one year, with 9% recorded in five years or more and one in 13 of the 20 years of this study. The mean annual re-sighting rate ranged from 0-83% with a mean ± SD of 37.3±29.6%. The overall re-sighting rate of 55% is high showing great site fidelity. The number of re-

sightings of individual whales within a year ranged from 1 to 22 with a mean of 2.8. Residency times for individual whales were available for 143 occasions where two or more sightings were made within a year, and ranged between 2 and 168 days with a mean± SD of 38.8±37.3 days. The first whales were recorded in March and last in January. Residency time increased significantly with year ($P<0.05$). Most (89%) of all records were from Counties Cork and Kerry in the southwest. Mean residency in Kerry (35.5±35.9 days, n=52) was greater than in Cork (16.9±18.1 days, n=44) but was not significantly ($P<0.05$) and this longer residency likely reflects photo-id opportunities rather than any biological significance. Residency times on feeding grounds are often long providing they are obtaining sufficient food resources. Humpback whales in Ireland are thought to feed on sprat, herring and sand-eels and this study demonstrates the importance of Irish waters for a small but increasing humpback whale population.

Feeding in marine mammals: An integration of evolution and ecology through time.

Berta, Annalisa[1]; Lanzetti, Agnese[2]

(2) San Diego State University, El Cajon, CA
Corresponding Author: aberta@mail.sdsu.edu

Key ecologic (e.g. competition, predator-prey changes), productivity (diatom diversity) and climatic (e.g. ^{18}O, ^{13}C) factors have driven patterns of marine mammal diversity through time. Based on a comprehensive diversity data set derived from the Paleobiology Database we considered feeding strategies (e.g., suction, biting, filter feeding and grazing), prey type (e.g. squid, fish, benthic invertebrates, zooplankton, tetrapods, sea grasses), tooth pattern and cusp shape (e.g. homodont, heterodont, pointed, rounded, or edentulous), and habitat (e.g. marine, riverine, estuarine) in fossil and extant marine mammals. These variables were then tested for correlation with each other and their changes through time examined in relation to productivity and climate variables. Among novel findings are that from an ancestry that involved a biting strategy with fish consumed, suction feeding of benthic invertebrates evolved as the principal prey capture strategy in the late Oligocene (cetaceans) and Pliocene (pinnipedimorphs). Bulk filter feeding in mysticetes became dominant beginning in the early Miocene. Sea otters arose during the late Pliocene feeding on hard-shelled benthic invertebrates, thereby filling a niche occupied during the late Miocene by the aquatic bear *Kolponomos*.

Examination of climate variables indicates that pinnipedimorphs are only correlated with diatom diversity (productivity) while cetaceans are correlated with diatom diversity and ^{18}O (temperature). Sirenians and desmostylians are correlated with neither ocean temperature nor productivity. Evidence for ecologic replacement among herbivores is indicated by the disappearance of desmostylians that coincided with appearance of the sirenian *Hydrodamalis* lineage in the North Pacific 11 Ma. Convergent evolution of herbivory in aquatic sloths was limited to the South Pacific during the late Miocene through Pliocene. Combined, these results show that many factors likely influenced marine mammal feeding diversity patterns in the past and a historical framework enables analysis of present day trophic structure and predictions of future changes in marine ecosystems.

Disturbance response of grey seals (Halichoerus grypus) to small Unmanned Aerial Vehicles (UAVs).

Corresponding Author: c.m.bertelli@swansea.ac.uk

The application of Unmanned Aerial Vehicles (UAVs) in the field of ecology is being increasingly recognised with a number of studies using different systems for collecting abundance, identification and measurement data for monitoring populations of marine mammals. However, there are few studies which have looked at the disturbance effects of UAVs on the animals they are surveying. The need for setting limits on UAV height and distance is needed for the management of the use of small UAVs for surveying marine mammals to ensure minimal or no disturbance is caused. Hauled-out seals are an excellent example where the use of UAVs can reduce costs of survey work and enable the survey of poorly accessible sites. This study aimed to test the disturbance effect of two UAV types, a fixed-wing and a quadcoptor, at varying heights above two colonies of grey seals (*Halichoerus grypus*) on the coast of Pembrokeshire, UK. An ethogram was created with six categories of behaviour from rest to flight, to enable observers to determine fine-scale levels of disturbance. Data was collected using focal follows and scan surveys to give a detailed picture of seal behaviour before during and after UAV flights. The fixed wing UAV caused no significant disturbance effect on the seals. The quadcoptor UAV enabled survey flights at much lower heights than the fixed-wing. Generalised Linear models were used to look at significant effects of type of UAV, and UAV height on the disturbance response of the seals. Results show no significant effect of

the fixed-wing UAV, but a significant effect of the quadcoptor on the disturbance response of the hauled-out seals. UAV height of the quadcoptor had a significant effect on the disturbance response of the seals, but seals only flushed when the quadcoptor was flown at 10m high.

Using multi-model ensemble forecasting to identify key feeding habitat for four cetacean species in Icelandic coastal waters

Icelandic whales, dolphins and porpoises are under various anthropogenic pressures such as whaling, whale-watching and fishing activities in the region, and knowledge on their habitat preferences is lacking. The aims of this study were: 1) to investigate the functional ecological relationship between environmental variables (EGV's) and distribution of four cetacean species in Icelandic coastal waters, and 2) to predict areas (of seven bays located from south to northeast) of high suitability of these species and identity hotspots for spring (March-June) and autumn (July-October) months. We used an ensemble forecasting approach (BIOMOD) which has been shown to capture the distribution of species more accurately. Opportunistic sightings (2010-2014) of surface feeding humpback whale (*Megaptera novaeangliae*, *N*=156), white-beaked dolphin (*Lagenorhynchus albirostris*, *N*=123), common minke whale (*Balaenoptera acutorostrata*, *N*=436), and harbour porpoise (*Phocoena phocoena*, *N*=121) occurring on the SW (Faxaflói Bay off Reykjavik) and NE (Skjálfandi Bay off Húsavík) coasts was used. Seven EGV's were included in the models: depth, slope, SST, chlorophyll a concentration, aspect, tidal height, and shore distance. Models show that cetacean feeding distribution was better explained in the spring by aspect-chlorophyll and depth and in the autumn by aspect-chlorophyll and shore distance. Locations of suitable feeding humpback whales were mainly in northern coastal run-off areas in the spring and almost absent in the autumn. Minke whales were concentrated south in spring but show increased abundance at the northern coastal run-off areas in autumn. White-beaked dolphins were consistently found in deeper waters in both seasons while harbour porpoises were limited to deeper waters in southern bays. Predictions for the 7 bays reveal suitable habitat potential for all four species ranging from 22% (humpback whale) to 67% (white-beaked dolphin) of the total bay areas, highlights potential areas of conflict with human activities which should be considered for management and conservation.

Measurement of feeding-related dental microtexture using 3D surface texture analysis in Eastern Atlantic harbour seals (Phoca vitulina).

Marine mammals are increasingly threatened in their habitat by various anthropogenic impacts. This is particularly evident in prey abundance. Understanding the dietary strategies of marine mammal populations can help predict implications for their future health status. The documentation of marine mammal diets therefore is essential for their conservation.

Dietary proxies might help in reconstructing dietary traits of marine mammals. In this study, we used 3D surface texture analysis (3DST, using 30 parameters according to ISO 25178) to quantify dental wear as an indicator of dietary behaviour. This method is an established approach to reconstructing diets in terrestrial mammals, but has not yet been applied to pinnipeds.

We analysed Eastern Atlantic harbour seals (*Phoca vitulina*) from the Baltic Sea (Hesselø, Denmark) and the North Sea (Wadden Sea, Germany), curated at natural history museums of northern Europe. Our aim was to 1) establish a workflow, opening 3DST to pinnipeds, 2) test 3DST for its ability in detecting dietary spectra of populations,

and 3) detect shifts in the dietary spectrum over the last 60 years.

A trend of increasing enamel texture roughness was found along the tooth row which should relate to prey processing biomechanics. The second to fourth postcanine tooth positions were established as a reference. We detect significantly rougher textures in the Baltic Sea population as compared to the North Sea populations. This signal is identified to reflect the deviation in prey species and thus suggests 3DST to be well suited to differentially infer ingesta composition in harbour seals.

Applying indirect dietary proxies, such as 3DST, thus will allow time series analyses of ingesta quality and prey availability using existing collection records. Furthermore, health status tracking over the last decades should be possible using collections. This approach will also help detect shifts in marine environments, both natural and anthropogenic.

Using emerging hot spot analysis of stranding records to inform conservation management

Monitoring highly mobile species in relatively inaccessible habitats presents a considerable challenge to managers and policy makers. Effective conservation strategies require ecological knowledge that is often challenging and expensive to obtain. Despite their caveats, stranding data represent an underused resource to study the long-term dynamics of cetacean populations. We present a novel approach – emerging hot spot analysis (ArcMap 10.6.1) – to explore how stranding records can inform conservation management. While emerging hot spot analysis has been used to investigate malaria outbreaks, fatal landslides, and forest loss, it has not yet been applied to cetacean strandings. Using long-finned pilot whale (LFPW; *Globicephala melas edwardii*) stranding records from New Zealand as a case study, we demonstrate how emerging hot spot analysis can provide crucial insights into both the ecology and management of frequently stranded species. A total of 8,571 LFPWs stranded on the New Zealand coast within a 40-year period between January 1978 and December 2017. Strandings occurred in all months, though significant seasonal variation was evident, with 66% (n=189) of stranding events reported during austral spring and summer months (October – February). Hot spot analysis identified the majority of LFPWs stranded at Golden Bay, Great Barrier Island, Stewart Island and the Chatham Islands, with emerging hot spot analysis used to identify spatiotemporal trends. While no significant trend in the overall number of stranded LFPWs was evident, the number of stranded individuals has declined in areas of the Far North, Coromandel, Canterbury, Otago and the Chatham Islands, but increased in Golden Bay and Stewart Island. Such trends help identify significant clusters of stranding events and provide valuable ecological data that can be used to guide conservation management.

Companionship between female Grey Seals (Halichoerus grypus) on their breeding sites.

There has been a significant rise in the grey seal population in the Netherlands since 2000s . While grey seals are considered solitary animals during most of the year, they are also known as colonial breeders. During the breeding season the species exhibits natal philopatry and site fidelity, which results in aggregations of the same individual females for many successive years. However, past studies have suggested that the association between female grey seals may not only be determined by habitat preferences, but might also be the result of sociality. This study aimed to gain insight in the social behaviour of female grey seals during the breeding season. The study was carried out on the uninhabited island Griend, located in the Dutch Wadden Sea, which has seen large morphological changes, both natural and human-induced. In this period the total amount of breeding females was ~60 . Photographs of females during the breeding season (from 2013-2018) were processed using the photo-id programme ExtractCompare, which recognises each individual animal by reading the

fur pattern of the neck, head or the flank. MapSource was used to estimate the GPS locations of the individuals. The between-year movement of each individual relative to their geographical location and that of neighbouring individuals in preceding years (5 year period) was estimated, to determine the strength of site-fidelity and companionship. Understanding sociality in temporarily aggregating species can contribute significantly to socioecological models of social evolution' .The study showed individual animals change their locations from the original spot between years. Any prominent companionship was not seen between the individuals over years.

Contrasting population-genetic structures in the Saimaa ringed seal (Pusa hispida saimensis) and its specialist helminth parasite Corynosoma magdaleni

The Saimaa ringed seal (*Pusa hispida saimensis*) is one of the few pinniped species living in a freshwater environment and is exclusive to Lake Saimaa, Finland. The endangered population of approximately 400 individuals shows spatial genetic sub-structuring, potentially due to the high fragmentation of its lacustrine habitat. To further investigate the spatial genetic structure of the Saimaa ringed seal, we studied the population-genetic composition of one of its specialist endoparasites, the acanthocephalan helminth worm *Corynosoma magdaleni*.

We sequenced the standard 655-bp DNA "barcode" fragment of the mitochondrial COI gene from 176 worms collected from 25 seals. We identified 49 variable sites, representing 40 different haplotypes. Despite the high haplotype diversity, genetic structuring in the *C. magdaleni* samples was not explained by water basin, seal individual or seal intestinal section, and no pattern of isolation by distance was found.

We propose two explanations for the contrasting levels of spatial genetic differentiation in the Saimaa ringed seal and its helminth parasite *C. magdaleni*. First, in addition to the Saimaa ringed seal, the life cycle of *C. magdaleni* requires two intermediate hosts—a crustacean and a fish species—that could act as additional vectors of dispersal. Second, the sub-structuring of the seal population may be attributed to its small effective population size and its severe demographic fluctuations, while the effective population size in *C. magdaleni* could be much larger, as each seal may present tens or hundreds of worms. Further investigation using nuclear markers would enable to clarify this matter.

Guess who's coming to dinner. Dwarf minke whales along the Antarctic Peninsula: Evidence of climate migration or historic misidentification?

The global distribution of dwarf minke whales (*Balaenoptera acutorostra subspecies*) is poorly understood, but it appears they tend to occupy low latitude waters off the coasts of Brazil, South Africa, and Australia, and have occasionally been observed in the South Indian Ocean. In March 2019, we encountered dwarf minke whales (n = 5) in the coastal waters of the South Shetland Islands (SSI), identified post-encounter through unoccupied aerial system (UAS) photogrammetry and resulting morphological and phenotypical comparison between Antarctic minke whales measured similarly around the Western Antarctic Peninsula (WAP) (n = 50). The only published study documenting dwarf minke whales along the WAP and SSI includes 11 sightings from 2007-2010, suggesting they are rare and only recently encountered in this region. One possible explanation for the paucity of sightings in this region is a southward range expansion concurrent with regional warming and ecosystem forcing that has facilitated southward range expansions of other sub-Antarctic species. This hypothesis is supported by ongoing changes in the distribution and abundance of myctophid fishes, an important prey item of dwarf minke whales. Alternatively, they may have always been present along the WAP and SSI, but have been misidentified as Antarctic minke whales. While distinct from other cetaceans, Antarctic and dwarf minke whales are difficult to distinguish from one another, especially from boat-based surveys. UAS photogrammetry provides opportunity to view these animals in high-resolution to distinguish subtle differences in morphology and phenotype. This study quantifies

phenotypic differences between dwarf and Antarctic minke whales, and compares them to other Southern Hemisphere populations, setting a foundation to effectively test hypotheses related to southward range expansions or historic misidentification. However, to address these competing hypotheses, comprehensive monitoring of minke whale encounters with high-resolution UAS imagery should be combined with biologging foraging studies, biochemical diet analyses, and prey field assessments.

Ideal flight parameters for the integration of Unmanned Aerial Vehicles in traditional cetacean surveys.

The transition towards unmanned aerial vehicles (UAVs) in cetacean surveys and the subsequent shift to the automated collection and analysis of footage have enhanced our wildlife research capacity. Considerable advantages over traditional manned platforms include reduced costs, decreased noise and pollutant emissions, improved sighting accuracy and counting precision, etc. However, the short observation window provided by the UAV as well as the subject animals' behaviour (e.g., diving asynchrony) may result in an underestimated group or population size. Presented in this study is a new approach to determine the ideal coverage-to-resolution ratio for two cetacean species and the accuracy of group size estimates obtained from UAVs. The methodology includes survey passes at altitudes of 60-100 m and a speed of 33 km/hr, with a 70% front overlap between images; focal follows of each observed group for a minimum of 5 min provide for post hoc comparison with counts from survey passes. Fieldwork is carried out in the Mediterranean shelf waters of Israel, recently qualified by the IUCN as an important marine mammal area (IMMA) for the common short-beaked and bottlenose dolphins (*Delphinus delphis* and *Tursiops truncatus*, respectively). The challenging selection of small-bodied, fast-moving species which form large groups in this area was aimed to provide for maximal robustness and protocol standardisation across research groups and monitoring programmes employing UAVs.

Effective population sizes and modeling future genetic variation in the endangered Australian sea lion.

Knowledge of genetic variation in the endemic and endangered Australian sea lion (*Neophoca cinerea*) is needed to evaluate inbreeding risk and resilience towards ongoing and future threats. The rate at which genetic variation is lost *via* drift is a function of the effective population size (N_e). We used 2238 genome-wide neutral single nucleotide polymorphisms (SNPs) from 81 Australian sea lion samples to estimate the N_e for two genetically distinct populations, one off South Australia (SA), and one off the west coast of Australia (WA). We used a linkage disequilibrium method to estimate N_e and applied adjustments for overlapping generations, life history parameters and chromosome number to derive an adjusted N_e of 424 (CI=397-458) for SA and 160 (CI=146-178) for WA. With stable population sizes and current observed heterozygosity (H_o) of 0.21(±0.004) for SA and 0.09(±0.003) for WA, modeling resulted in relatively small losses of genetic variation over 20 generations. Population declines are however ongoing. Including relatively conservative estimates of future population declines of 1.5% reduction/year resulted in a marked loss of genetic variation and increase in homozygosity, thereby increasing the risk of inbreeding depression. After modeling 20 generations H_o declined by 33% in SA, and 47% in WA. Incorporating population declines of proportions observed following disease epidemics in other pinnipeds resulted in higher losses of genetic variation. Models based on a single disease epidemic resulted in approximately half the genetic variation being lost within 20 generations (H_o=46%

for SA; and H_o=44% for WA). Small effective sizes and relatively low genetic variation leave the species vulnerable to future changes, and we show that that these risks are likely to be compounded if population declines are not reversed. Our results underscore the importance of safeguarding the Australian sea lion from future challenges, especially those that will greatly exacerbate losses of genetic variation.

Exploring Taiwanese white dolphin conservation using a social-ecological systems analysis framework: Process, achievements, and challenges.

Bing-Heng, Chen

Corresponding Author: 1001nights@yahoo.com.tw

The social-ecological systems [SES] framework was proposed by Ostrom (2007). It is an integrated analysis structure serving as a unitary, holistic framework for researchers coming from different disciplines and who may be in different geographic regions, resource sectors, and biological, physical, socio-economic-political conditions. This framework facilitates incorporation of empirical research results by natural resource managers and policy makers, as well as their analysis of the process, results, and needed improvements in their work on conservation and sustainable development. In 2007 a group of Taiwanese conservation groups formed the "Matsu's Fish Conservation Alliance" for the purpose of conserving the highly endangered Taiwanese white dolphin (*Sousa chinensis taiwanensis*) and its habitat. The alliance's actions have focused on mitigating five major threats to the TWD, efforts that have included *inter alia*: forging alliances between religious and conservation groups; successful lobbying for the establishment of a new government Ocean Conservation Agency; promoting enactment and amendment of Water Pollution Act, Marine Coast Act and Wetlands Act; and stopping major industrial developments involving large scale land reclamation in TWD habitat. This research incorporates the SES framework in analyzing conservation action and governance process, achievements to date, as well as recommendations for improvements to conservation work based on this analysis.

The effects of seasonal variation, El Niño-Southern Oscillation events, and climate change on the tuna-dolphin association in the eastern tropical Pacific Ocean.

Birch, Caitlynn[1]; Scott, Michael D.[2]

(2) IATTC, La Jolla, California
Corresponding Author: CAITLYNN.BIRCH@GMAIL.COM

Tuna and dolphins swim together in the waters of the eastern tropical Pacific, and this association has long benefitted tuna fishermen and intrigued scientists. Much is known about the association. Yellowfin tuna (*Thunnus albacares*) are primarily caught with spotted dolphins (*Stenella attenuata*), and, to a lesser extent, spinner dolphins (*Stenella longirostris*); historically the spotted dolphin has borne the brunt of the bycatch mortality. We know the primary promoter of the tuna-dolphin association is the unique ETP oceanography: a shallow mixed layer, a thick oxygen minimum zone, and warm surface waters. We know that as the mixed layer deepens, the association begins to break down; first with spinner dolphins, then with spotted dolphins. Important ecological and management questions remain. What are the effects of season, El Niño Southern Oscillation (ENSO) cycles, and long-term climate change on the association? What will be the future effects on the association with the continued influence of climate change? And how will these changes affect the fishery and dolphin mortality?

We used the IATTC observer data from 1992-2015 for pure herds of spotted dolphins and spinner dolphins (n=482,557 sightings), the SODA oceanographic dataset (0.5°x0.5° resolution), GIS and species distribution models to investigate which oceanographic variables most influenced the association's distribution, and predictive models (R-based GAMs and Random Forest) to test our results. The mixed layer depth had the most influence on the distribution of the association, but SST, temperature at 25-m depth, and ENSO Index were also significant factors. The spatial distribution of the association expanded and contracted with season and ENSO events, overlaid on a long-term expansion caused by climate change. The conditions that promote the tuna-dolphin association are intensifying and the management implications are already apparent: sets on pure spinner dolphin herds have increased, and spinner dolphins have replaced spotted dolphins as the leading component.

A comparison of percent dorsal scar cover between populations of humpback whales (Megaptera novaeangliae) off California and the Western Antarctic Peninsula

Humpback whale populations are found around the globe, each influenced by a variety of natural and anthropogenic factors, including direct interactions with humans that can result in injury or mortality. Scarring rates in whales have been studied using photo ID images of the fluke and caudal peduncle to estimate prevalence of entanglement and ship strikes within a population. The present study compares percent dorsal scar cover between two populations (California and Western Antarctic Peninsula) of humpback whales exposed to different levels of human activity, derived from Unoccupied Aircraft System (UAS) imagery collected during foraging seasons from 2017-2019. Specifically, we use a semiautomated GIS algorithm to quantify percent scar cover by using a combination of high and low pass filtering and Jenks classification to determine the threshold used to identify scars from the image. This system extracts the scars and calculates percent scar cover on the portion of the whales back that is visible and available for assessment. We found that the California population (mean = 6.88%) had significantly higher percent scar cover than the Western Antarctic Peninsula population (mean = 3.21%) ($t = 3.02$, $df = 49.01$, $p = 0.004$). Our results indicate that there are behavioral or environmental factors related to scarring that vary between these two populations. Future studies should include classification of scar type and cause to better understand what drives this difference. Our approach provides new information on scarring rates of these two populations and presents a novel method for assessing scar cover adaptable to other species.

Saving whales, one smartphone at a time: The development of the WhaleReport Alert System.

Along Canada's west coast, marine transportation is an essential part of life, serving both Canadian import and export markets and supporting many coastal communities. These activities overlap with the habitat of at-risk cetaceans including a critically endangered population of killer whales. As a result, both industry and the conservation-sector are motivated to reduce vessel-associated impacts to these vulnerable cetacean populations. Here, we detail the development, testing and implementation of the WhaleReport Alert System (WRAS), a cetacean conservation tool that broadcasts pertinent details of whale presence to large commercial vessels in real time. Information on whale presence is obtained from sightings reported via a smartphone application to the B.C. Cetacean Sightings Network, a well-established citizen science project that collects cetacean sightings from a network of over 6,600 mariners and coastal citizens. Developed in partnership with local ports and a working group of marine industry professionals, the WRAS allows mariners to undertake mitigation measures in the vicinity of cetaceans – such as slowing down or diverting course – to reduce the risk of collision and disturbance. The WRAS project highlights how citizen science initiatives and collaboration between scientists and industry can effectively contribute to the conservation of vulnerable species.

New insights about the world's only known, predictable winter aggregation of dwarf minke whales (Balaenoptera acutorostrata subsp.) in the remote northern Great Barrier Reef (Australia) and their implications for sustainable swim-with-whales management.

The world's only known predictable aggregation of dwarf minke whales occurs at a remote shelf-edge, northern Australian location in the austral

winter. It supports a long-standing, swim-with ecotourism industry involving live-aboard dive vessels under permits from the Great Barrier Reef Marine Park Authority, designed to achieve sustainably managed interactions. The Minke Whale Project has been studying this unique phenomenon for >25 years.

We analyse multiple lines of evidence about the environmental characteristics of the aggregation area, its pattern of temporal and spatial use by this whale population, the life history stages and behaviour of the interacting animals in order to explore the significance of this location and its potential importance for the whales. We now know that individuals migrate from here to the Sub-Antarctic and return. Many whales have been resighted over periods spanning >10 years, with some individuals resighted almost annually. Recent genetic evidence from sloughed-skin sampling has shown that this population is identical with the South-West Pacific dwarf minkes killed by Japanese Southern Ocean scientific whaling.

Annual fieldwork has been conducted during June-July since 1996. Photo-identification data from researchers is augmented by tens of thousands of timed and dated underwater images donated annually by hundreds of passengers and crew from the commercial dive-fleet, providing a rich citizen-science-based source of sightings information. Four years of complete seasonal censuses of all individual whales identified (>500 in 2006, 2007, 2017 & 2018) are compared and their resighting patterns analysed to show their spatial and temporal use of the area. Data on mean (<10 days) and maximum (38 days) residence times are presented and satellite tracking data from 26 whales are used to refine the aggregation area use patterns from 2013-15.

The reasons for this unique aggregation area are explored and the extent of protection for the population and this very special location are discussed.

Fjords of Plenty: Herring overwintering superabundance as a seasonally important and accessible resource for humpback whales and fisheries in Northern Norway.

Superabundance of Norwegian Spring Spawning (NSS) herring overwintering in North Norwegian fjords in recent years have attracted large numbers of humpback whales, which probably utilize this resource to top up energy reserves prior to long-range migrations. We attempted to estimate the importance of these events to humpbacks, and assess the impact of whales and commercial fisheries on local herring biomass during the 2014-2016 winters. Monthly hydroacoustic surveys (using an EK60 scientific echosounder with 70 and 200 kHz transducers), combined with spatio-temporal point process modelling, were used to estimate herring biomass and distribution within a focal fjord system. Whales were tagged with high-resolution activity/GPS dataloggers, and feeding lunges were identified using specific patterns in swim speed and acceleration. 3D tracks were reconstructed to estimate position of lunges relative to estimated herring biomass, allowing us to estimate daily consumption rates. Robust Design Mark Recapture based on photo-ID was used to estimate local population size and residence time. Estimated herring consumption by whales was compared to commercial catch data and the acoustically derived biomass estimates. Results suggest that local herring biomass in focal fjords (99 km^2, mean depth: 100m) increases from October to a maximum of 1.5 million tonnes (equivalent to ~25% of the entire NSS herring spawning stock) in mid-December, before gradually declining towards February. Estimated individual consumption rate was 1.5 Tonnes per day, translating to a total seasonal consumption of 18,000 Tonnes for an estimated population size of ~400 and mean residence time of ~30 days. This represents roughly half of the 37,500 tonnes taken simultaneously by commercial fisheries, and 1,2% of the maximum observed herring biomass. The high estimated consumption rates strongly support the idea that these superabundance events are important, but transient, opportunities for predators. Our results also suggest that the high local concentration of commercial fisheries and whale foraging are

unlikely to negatively impact this seasonally superabundant resource.

What if...?: Population viability analysis of resident Bottlenose Dolphins (Tursiops truncatus) in the Shannon Estuary (Ireland) to help inform management.

Photo-identification is used to monitor the resident bottlenose dolphins (*Tursiops truncatus*) in the Shannon Estuary SAC (Ireland) as part of EU obligations to ensure Favourable Conservation Status. In 2015 a discovery curve using IWDG data collected during 77 photo-identification surveys suggested all animals in the population were captured providing an abundance of 145, which resulted in a mark-recapture estimate of 136 ± 18.03, CV = 0.13 (95% CI = 125-202). Concurrent in 2015, the NPWS funded an abundance estimate as part of their long-term monitoring strategy, involving 12 transects. We compared catalogues to identify any individuals not included in the IWDG data; there were none. We used this maximum abundance estimate with new demographic parameters to run Population Viability Analyses using Vortex in order to explore population status under potential management scenarios. Sensitivity analysis revealed adult and juvenile female mortality was the most influential parameter, followed by lifespan and reproductive rates, indicating the importance of female reproduction for population growth and persistence. Standard models showed stable dynamics (r = -0.007) and null probability of extinction (PE = 0) after 50 years projection. Reducing lifespan from 50 to 30 years (pollution effects) led to a decline (r = -0.033, PE = 0). Similar results were obtained when annual adult mortality increased from 3.8% to 7% (r = -0.032, PE = 0) due to by-catch. A single catastrophic scenario (oil spill) reducing survival and reproduction rates led to remarkable decline (r = -0.046, PE = 0.152). These results help managers to understand the implications of activities that may affect this small, genetically discrete bottlenose dolphin population. Current monitoring strategy may be insufficient to gain a proper understanding of population dynamics and we recommend higher annual survey effort as well as research on those population parametres which may affect long-term abundance trends.

Association patterns over thirty years and four generations of Bigg's (Transient) killer whales in relation to predation on gray whale calves in Monterey Bay, California

Bigg's (Transient) killer whales occur year-round in Monterey Bay, California, which is bisected by a submarine canyon. Gray whale cow/calf pairs must cross this canyon on their northward migration to Alaska from Mexico each spring, leaving the protection of shore which is advantageous to their predators. Killer whales periodically patrol the canyon in search of these calves. Over 30 years, we photo-identified 180 individual killer whales. Since 1992, we documented 81 predation events on gray whale calves, and identified the individual killer whales most involved in the attack. They primarily travel in core groups composed of matrilines: adult females with their offspring. As the daughters of matriarchs had their own offspring, they eventually separated from their mother's group and formed their own group. Males usually remained with their mothers for life, but in some cases the second son left for several years. If their mothers died, they usually travelled alone or joined up with other lone males. Twenty-eight matrilines were regularly sighted, which included four extended families. Usually 2-4 matrilines (range 1-10) were present during calf predations. In most attacks, a combination of 2-3 out of 5 key reproductively active females with offspring from different matrilines were intensely engaged in the attack, while others watched or participated to a lesser degree. In the last 10 years, there has been a shift in key females: now their daughters with offspring are most involved in attacks. Several original key females have died, and most adult males have died. Key females who have spent 20 plus years attacking calves could kill them within an hour, compared to younger key females with less experience that took several hours to kill calves. Cultural transmission is essential for passing on the necessary hunting techniques to new generations of whales.

Developing a health baseline for narwhals (Monodon monoceros) from the eastern Canadian Arctic

Rapid climate change is occurring in the Arctic and is potentially troubling for ice-dependent marine mammals such as narwhal (Monodon monoceros), that are likely to be sensitive to changes in sea ice and the marine environment. Multiple anthropogenic stressors related to climate change may cause deleterious health effects for this species. Environmental toxins, industrial activities, harvest, loss of sea ice, disease, ice entrapments, predation, commercial shipping and competing fisheries all have the potential to negatively impact narwhal populations. Healthy wildlife contribute to ecosystem health, a productive economy, and food safety and security in the Arctic. As apex marine predators, narwhal are part of the resilience of the Arctic marine ecosystem, yet very little is known about individual and population health or how they may adapt to a changing environment. Due to severe weather, darkness in winter, marine environment, and an extensive species range, the study of Arctic cetaceans is challenging. Narwhal health data have been collected from 2004-2018 during the ice free season using a transdisciplinary scientific approach. Health indices (hematology, serum chemistry, selected pathogen serology) were collected and analysed from over 50 live free-ranging narwhals from the eastern Canadian Arctic gathered through physical exams and sample collection conducted during live handling events. To date, these narwhal appear naïve to Cetacean morbillivirus (CeMV) and Influenza, and have varying levels of exposure to Toxoplasma gondii and Brucella sp. With the assistance of Inuit collaborators, thorough necropsy examinations were carried out on thirteen traditionally harvested narwhals to investigate disease caused by pathogens, toxins and neoplasia. Findings of interest included aural and pulmonary parasitism, pulmonary, endocrine and intestinal neoplasia, sarcocystosis and other mild inflammatory changes in myocardium and skeletal muscle. These findings comprise the groundwork for a health baseline for narwhals against which future changes can be measured.

Individual-specific calls in east Greenland narwhals – another type of signature whistle?

Blackwell, Susanna B.[1]; Tervo, Outi[2]; Conrad, Alexander S.[3]; Heide-Jørgensen, Mads Peter[2]

Individually distinctive vocal signatures, first described in bottlenose dolphins about 50 years ago, have more recently been suspected in several other odontocetes, including the narwhal's closest relative, the beluga. During the summers of 2013-2018, we instrumented narwhals from Scoresby Sound, East Greenland, with acoustic sound and movement tags (Acousonde™). The records provided continuous information on the whales' acoustic behavior during diving, foraging, and social interactions, over periods of up to eight days. The calls in 12 complete records (four females, seven males, one of which was tagged two years in a row) were manually classified by human analysts. Each acoustic record included a distinctive call type that was stereotypical, was used by the tag carrier from a few times to >100 times over a few days, was sometimes repeated several times in succession, and was unique to the tag-bearer, i.e., the call was not heard in other records. These calls therefore share similarities with signature whistles described in bottlenose dolphins. "Signature calls" (SCs) in narwhals were burst pulses, sometimes augmented by other sounds such as whistles. In contrast to the deep diving during foraging (up to ~1000 m in Scoresby Sound), about 70% of SCs occurred in the top 50 m of the water column, where most social interactions are thought to take place. A subset of >120 SCs were analyzed in detail in terms of their pattern of successive inter-click intervals (ICIs). While overall length could be somewhat variable, the succession of ICIs was unique for each whale, and was maintained for the male tagged in two consecutive years. Anthropogenic activities are on the rise in the Arctic, leading to noise level increases. Therefore, conservation efforts will need to rely in part on understanding narwhal communication and social behavior – vocal signatures are a first step in that direction.

Costa del Sol: A harbour porpoise (Phocoena phocoena) habitat in the Mediterranean Sea. A collaboration between OceanSea and CostaSol Cruceros.

The Costa del Sol waters are part of the Alboran Sea, which was recently identified as an Important Area for Marine Mammals (IMMA) by the IUCN (International Union for the Conservation of Nature). Between 2015 and 2019 the association OceanSea and Avistamiento Costasol Cruceros conducted a study in these waters on cetacean and marine turtle ecology as part of a project aimed towards their conservation. The data were collected between Benalmadena and Fuengirola and are a mixture of opportunistic and transect sightings. This study with over 500 recorded sightings has determined the presence and area preference of 6 different protected species in the coastal waters off the Costa del Sol; namely the bottlenose dolphin (*Tursiops truncatus*), common dolphin (*Delphinus delphis*), striped dolphin (*Stenella coeruleoalba*), fin whale (*Balaenoptera physalus*) and loggerhead turtle (*Caretta caretta*). This being said, the most important species identified was the harbour porpoise (*Phocoena phocoena*) as it is currently considered to be absent in the western Mediterranean Sea (reference). Sightings of this species have been recorded in the same area every year from 2016 to 2019. This recurring presence of the porpoise means that they are using this area on a temporary, potentially permanent, basis which is the first on scientific record in the western Mediterranean Sea. This study shows the importance of collaborations between scientists and whale watching companies and the usefulness of correctly recorded data.

Do polar bear ecotypes in the Barents Sea region have different energetic requirements?

Barents Sea polar bears *(Ursus maritimus)* are currently facing rapid environmental changes with loss of sea ice and changes in the distribution of their prey. Two distinct ecotypes exist in this region. Coastal bears remain within the Svalbard Archipelago year-round, whereas offshore bears follow the marginal ice zone (MIZ). We explore energy needs for these two ecotypes and how environmental changes may influence their energy budgets. Offshore bears travel longer distances on land and at sea, at a higher speed, and have a higher activity rate compared to coastal bears. This translates into higher overall energy expenditure. Offshore bears undertake longer and more distant swimming trips to the MIZ in rough weather that make these excursions energetically costly. Both ecotypes show similar seasonal patterns of activity and movement consistent with their life history linked to sea ice phenology. Despite higher energy expenditure, the offshore ecotype seems currently to be a more profitable strategy compared to the coastal one as females are in better condition likely due to their specialized high caloric diet of seals. However, both ecotypes are currently under stress as their respective habitats change. Coastal bears are losing glacial ice, and the degree of habitat overlap with their main prey the ringed seal is decreasing. Offshore bears are following the MIZ further away from land increasing their travel costs between fragmented suitable hunting and denning habitats. In addition, offshore bears have higher levels of persistent organic pollutants (POP) due to higher proportion of marine and high-trophic level food items in their diet and higher concentrations of pollutants in they prey. The latter strategy will remain profitable as long as the density of seals is sufficient to cover offshore bears' increase in energy needs and that the POP load does not affect the bears' physiology negatively.

Decreasing population trend and reproductive output in bottlenose dolphins (Tursiops truncatus) from the Aeolian Archipelago, Italy.

Blasi, Monica Francesca; Bruno, Chiara Anastasia; Boitani, Luigi
Filicudi WildLife Conservation, Lipari, Italy
Corresponding Author: blasimf@yahoo.com

Understanding the factors influencing population trends and reproductive patterns in wild bottlenose dolphin (*Tursiops truncatus*) populations is of strong importance for their conservation. A thirteen-year (2005-2017) photo-identification study have revealed complex societies and adapting behaviour to local environmental and anthropogenic conditions for a resident bottlenose dolphins' population in the Aeolian Archipelago (Italy; Blasi et al. 2012, Blasi and Boitani 2014, Blasi et al. 2015, Leone et al. 2019). In this area, the inshore occurrence of these dolphins is mainly related to fishery activities and, as fish stocks are generally declining, individuals are increasingly competing with coastal artisanal fishing. The encounter rate of the dolphin groups was drastically decreasing during the last few years. Only 7 reproductive females and their 16 calves were photo-identified during 272 focal follows. The mean number of calves for female was very low (2.3 ± 1.1 SD), ranging from 0 to 4 during the study period. The mean interbirth interval was 3.5 ± 1.6

(SD) years ranging from 2 to 7 years but it was between 2-4 for 5 females. Calf mortality was high (12.5% by age 1 for 2 calves) and 2 calves also died within 5 years. The 69.2% of epidermal marks on different body regions of dolphins were associated with traumata and gunshot wounds and/or mutilations were also frequently found. As 95% of bottlenose dolphins in this geographic area are resident (40 of 42 photo-identified individuals) and the 29% of reproductive females have died at the end of this study, we underline urgent conservation actions for this endangered bottlenose dolphin population.

Respiration-coupled heart rate changes in common bottlenose dolphins (Tursiops truncatus)

Respiratory sinus arrhythmia (RSA) describes fluctuations in heart rate (f_H) associated with breathing and is universally observed among vertebrates. In terrestrial mammals RSA is characterized by an increase in f_H during inspiration and a decrease during expiration. Marine mammals are known to exhibit respiration-coupled heart rate changes, but little has been done to understand the role of f_H and respiration coupling during resting and diving behaviors in fully aquatic, air-breathing taxa. Because marine mammals maintain comparatively lower respiratory frequencies (f_R) than terrestrial mammals and exhibit intermittent breathing rather than continuous breathing, it would be expected that respiration-coupled heart rate changes may be exaggerated in marine mammals. Likewise, mammals in a marine environment are more often oxygen-constrained and therefore a strong cardiorespiratory coupling may improve gas exchange and reduce cardiac work. Our aim was to quantify fluctuations in f_H in spontaneously breathing, resting common bottlenose dolphins (*Tursiops truncatus*) to determine the extent of f_H variation that may be attributable to respiration. We measured f_H for nine male dolphins resting at the surface using respirometry to record respiratory flow and end-expired O_2 and CO_2 concentrations while continuously recording the electrocardiogram waveform, from which instantaneous f_H (if_H) could be calculated. As expected, the maximum if_H above the mean (16.0 ± 6.2 bpm, n = 207 breaths) in breath-to-breath segments occurred closely following the start of a breath (5.5 ± 2.0 s), and the minimum if_H below the mean (16.7 ± 6.1 bpm) occurred shortly before the start of the next breath (6.7 ± 3.5 s). The strength of RSA scaled with f_R as: $RSA = 82.11\ f_R^{-0.58}$. These results suggest that, for all f_R's, respiration has a predictable and significant effect on f_H. We suggest the importance of respiration-coupled heart rate changes in understanding resting and, particularly, diving heart rates of marine mammals.

An affordable, hand-deployable, rope-less and acoustically silent mooring design for passive acoustic monitoring, TOSSIT.

Passive Acoustic Monitoring (PAM) in the ocean has become a standard technique across the oceanographic community, and is used for biological, geological and meteorological questions.

Current applications of PAM technology are: marine mammal population density studies, measures of anthropogenic noise in the ocean, soundscape measurements on coral reef to assess biological activities, monitoring and prediction of underwater earthquakes and tsunamis, in addition to several other military application.

During recent years, a plethora of different low-cost PAM recorders have been developed and made PAM available across a much larger scientific community, including smaller organizations and NGO's. Due to depth restrictions (~500m) of low-cost recorders most installations are conducted from smaller vessels and deployed by divers or on mooring lines with surface expressions, and not with elaborate mooring deployments. This limits the use of such devices to diving depth or, if simple mooring lines with surface expression are used, reduces data quality due to mooring induced noise like strumming and pulling, especially in high-current coastal areas.

Here, we present a low-cost, low self-noise and hand-deployable mooring design that can be used on up to 500m water depth and released by hand from a RIB. The TOSSIT modular mooring system consists of a light and strong modular non-metallic frame that can fit a variety of sensors including PAM instruments, acoustic releases, additional power packages, and environmental parameter

sensors. The rope less design avoids any risk of entanglement and keeps the self-noise very low.

We present noise data comparison of three different deployments in 10-160m water depth with adjacent deployments on traditional mooring setups.

Bowhead whale acoustic occurrence and vocal behavior in central Fram Strait

The Arctic Ocean provides critical habitat for various marine mammal species, including the endangered Spitsbergen bowhead whale (*Balaena mysticetus*) population. In the context of climate warming and sea-ice reduction causing rapid changes in the Arctic Ocean, understanding the spatio-temporal patterns in the distribution and acoustic behavior of marine mammals is crucial for developing effective conservation and management strategies. Passive acoustic data are collected at different recording sites in Fram Strait since 2012, contributing to the Arctic Observatory FRAM (**FR**ontiers in **A**rctic Marine **M**onitoring). Here, data recorded at 78°50 N, 0°E from July to November 2012 were analyzed for the daily acoustic presence of marine mammals. Bowhead whales were acoustically present only in October and November, which coincided with increasing sea-ice concentration within 50 km of the recording site. Downsweep song (three types) was present in October and November, while upsweep song (one type) was only present in October. Furthermore, automatic detection of bowhead whale hourly presence using the low-frequency detection and classification system (LFDCS) retrieved 85% of the manually annotated hours with bowhead whale acoustic presence (recall) at 73% precision, hence making LFDCS a promising tool to process large sets of (long-term) passive acoustic data. Besides bowhead whales, blue whales *(Balaenoptera musculus)* and fin whales (*B. physalus*) were acoustically present from July to October, sperm whales (*Physeter macrocephalus*) in July and September, narwhals *(Monodon monoceros*) in October and November, and harp seals (*Pagophilus groenlandicus)* were present during all recording months. Acoustic species interactions in terms of temporal and spectral overlap of biophonic (blue and fin whale vocalizations) and anthrophonic (airgun) signals were detected in the low-frequency (<100 Hz) spectrum. Our results emphasize the importance of Fram Strait as marine mammal habitat, possibly providing (summer) feeding opportunities for blue and fin whales and an overwintering ground for bowhead whales and narwhals.

Characterizing bycatch and depredation in northeast U.S. sink gillnet fisheries.

Fishery interactions are a critical concern for marine mammal population and ecosystem health. Fishery bycatch is currently the primary cause of mortality for marine mammals globally. Focusing on issues surrounding bycatch and depredation will help maintain sustainable fisheries and practices while addressing the impacts of conservation and management measures. We are using several methods to document interactions between gillnets and marine life, including underwater video cameras mounted on fishing gear, and on-deck documentation of depredation using scoring methods previously developed to identify predators of depredated catch. We are also documenting depredation using traditional hard-part analysis and prey DNA sequencing analysis of stomach contents from bycaught seals. Our objectives are to provide scientific support to commercial fishermen to allow for scientific ground-truthing of anecdotal evidence of depredation events. At the end of this project we will hold a forum to support community engagement and share details of findings and discuss mitigation methods based on findings. Through this approach, our overall objective is to build collaboration, trust, and community among local fishermen, researchers, and managers including documenting bycatch of marine mammals; and provide a platform for scientific research using commercial fishing operations. To date, we have obtained the first video footage of sink gillnet actively fishing in the northeast U.S., with documentation of depredation via this video analysis and from directly observed depredated catch. Preliminary results indicate that sub-adult gray seals (*Halichoerus grypus atlantica*) bycaught in gillnet were not engaged in

depredation of the net's target species at the time of capture. This was supported by prey DNA and hard part stomach content analysis. Ongoing video analysis is underway to quantify and characterize how and when these events takes place.

Deep diving cetaceans of the Mediterranean basin: The vessel survey component of the ACCOBAMS Survey Initiative (ASI), summer 2018.

The ACCOBAMS Survey Initiative (ASI) is a major international collaborative effort to establish a coordinated regional monitoring system for cetaceans in the Mediterranean Sea. As part of the ASI, acoustic and/or visual vessel surveys were planned for those areas where aerial surveys could not be conducted in summer 2018. Equal spaced zigzag transects were designed and 21,829 km of track-lines were surveyed by R/V *Song of the Whale* in the western basin, Hellenic Trench and Libyan waters with a global acoustic coverage of 22% realised for sperm whales. R/V *CANA-CNRS* covered 1,055 km track-line off Lebanon, with Egyptian and Syrian coastal blocks to be surveyed during the summer 2019. As part of the vital capacity building aspects of the ASI, 30 participants from 10 countries across the region joined the team on *Song of the Whale* and four cruise leaders attended a vessel survey training course.

Nine species of cetacean were encountered including fin, sperm, Cuvier's beaked, long-finned pilot whales, Risso's, rough-toothed, bottlenose, common and striped dolphins. Turtle, fish and marine debris sightings were also logged. During the *Song of the Whale* surveys, towed hydrophone arrays were used to detect 152 groups of sperm whales and 18 groups of beaked whales (in small clusters of < 4 animals). Dolphins were detected throughout the survey, with group size decreasing towards the eastern areas of the western basin, and largest aggregations in the contiguous Atlantic waters. Ship, seismic and military noise were also documented. Abundance estimates from the vessel-based surveys will be presented.

The ASI vessel surveys provide substantial new datasets that can be compared with previous studies that have identified that the Mediterranean sperm whale subpopulation is alarmingly small. In addition, the ASI provides an update on the status of all cetaceans, establishing a baseline for future monitoring and conservation efforts.

Assessing the relationship between residency and population parameters in bottlenose dolphins off the southwestern Gulf of Mexico

The presence of transient/temporary individuals in capture-mark-recapture studies may tamper the assumption on equal catchability, and thus yield biased estimates. We investigated for the first time the effects of individual residency in population parameters for bottlenose dolphins inhabiting the coastal waters off Alvarado, Veracruz, Mexico. We hypothesized that known sexual differences in access to the study area will result in lower recapture probability (C), (apparent) survival (Phi), and abundance (N) for male nonresident individuals. Between 2006-2010, we conducted 76 photo-id surveys and recorded 276 sightings, in which 235 dolphins were identified. A composite residency index (IH4) was computed for each dolphin, and transient individuals (recorded one time) were not included in the analyses. We split the sample (N=135 individuals) into three *a priori*-defined groups: residents (n=52), visitors (n=48) and temporary (n=35) via the *k*-means clustering method (k =3) using IH4 values. Population parameters were estimated for each group with the Cormack-Jolly-Seber model (C and Phi) and the Pollock´s Robust Design (N). There were 75 sexed individuals, including 60 putative females (residents 34, temporary 18, visitors 8) and 15 were putative males (residents 11, temporary 3, visitors 1). No difference was found in the expected proportion of sexes by residency degree (chi2 = 1.4, p=0.49, df=2). Significant differences amongst the median monthly C (H=43.6, p<0.001) were observed for all groups (residents 0.37±0.23, temporary 0.15±0.12 and visitors 0.09±0.11) supporting differences in habitat use, although unrelated to sex. Phi was 1.00 (± 0.00) for all groups, suggesting a similar impact by local

conditions on all groups. Finally, the median for N was only different (H=19.04, p<0.001) between visitors (16±15.4) and residents (48±6.5), being 33 (±16.2) for temporary individuals. These results highlight the importance of considering residency when dealing with failures in the goodness of fit because of heterogeneity in capture rates.

Perfusion requirements of the organs in large vs. small cetaceans.

Corresponding Author: marco.bonato@gmail.com

Perfusion of the viscera of the bottlenose dolphin (*Tursiops truncatus*) (and possibly other small cetaceans) is relatively like the human. Available information on the comparative weight of organs (brain, heart, lung, liver, spleen, stomach, kidney) or systems (skeleton and muscle) allow some speculations on the dynamics of blood circulation. Given the mass of a specimen, and the blood volume inside the body (7.4 % of the total body weight), the minimal specific perfusion flow rate for each organ can be calculated based on compari-sons with human or other small cetacean data. The dolphin brain is 0,8% of the total body mass and needs at least 50 ml/min of oxygenated blood for 100 g of tissue. Therefore, a 200 kg bottlenose dolphin whose brain weighs approx. 1.6 kg requires a minimal perfusion flow rate of 0.8 l/min (human: 0.75 l/min). However, correlations based on the said assumptions become hazardous with middle-sized cetaceans, and utterly im-possible with large whales including blue (*Balenoptera musculus*), humpback (*Megaptera novaeangliae*) and sperm whales (*Physeter macrocephalus*), and their like. The major changes are due to brain weight and blood volume, which are not increasing proportionally to body mass. Application of the encephalization quo-tient shows that the brain weight of the large blue whale is markedly inferior to what is expected for a mam-mal of such size (approximately 6.5 kg instead of 800 kg), and consequently the minimal perfusion flow rate remains well below the predicted 400 l/min. According to studies performed in whaling times, the weight of the blood in a sperm whale is only 3.9% of the whole mass. Here we investigate how the relationship be-tween vascularization and blood perfusion changes with the increase of body mass and the reduction of the expected brain weight in large whales, and the potential implications for diving.

Automatic detection of fin whale calls: Is available software good enough?

Bonilla Garzon, Andrea[1]; Romero-Vivas, Eduardo[2]
(1) Universidad Autónoma de Baja California Sur, La Paz, Mexico

Corresponding Author: nabonillag@unal.edu.co

Vocalizations studies are helpful to understand whale's ecology, population structure, distribution and links among individuals. Autonomous recording equipment generates vast amounts of data which in turn require a great effort for analysis. Although visual inspection is considered the gold standard, the time investment makes, in some cases, this option unfeasible and calls for autonomous detection methods. Software available is generally designed for specific taxa, but their use is often extended to other taxa without being properly evaluated. Moreover, when autonomous methods are used, detection rate is usually not specified in published literature. In this study three detection algorithms (Spectrogram correlation, bandwidth energy and energy sum) used in some of the most cited software (XBAT, PAMGUARD and Raven Pro) are compared to visual detection. Their sensibility and specificity within the context of fin whale (Balaenoptera physalus) call detection is presented. Audio files from an autonomous system deployed in the Gulf of California are used for this analysis. Field recordings include single pulses, call series, distorted signals, pulses of different intensity, noisy segments, and clear calls, so the algorithms are tested for real scenarios. In the best case only half of the signals were correctly detected. Since the fine tuning of the algorithms, parameter selection, and learning curve are also factors that contribute to the performance of the algorithms, they were also evaluated. PamGuard was considered the hardest to learn due to its modularity, followed by XBAT which is poorly documented, while Raven Pro was considered the friendliest environment. Parameter selection was most critical for XBAT: it presented the highest sensitivity values for all software tested upon a right selection, but sensitivity decreased to half with in other cases. Despite low sensitivity values obtained in this study, automated detection could still be useful in studies of marine mammal detection when sensibly used.

Long-term photo-identification of a data deficient species, the Indo-Pacific bottlenose

dolphin (Tursiops aduncus), reveals populations with distinct habitat use and social behavior in New Caledonia lagoons.

Understanding the population structure and habitat use of poorly-known cetacean species is a first step towards scientifically informed management decisions. Due to their strictly coastal distribution and isolated populations, Indo-Pacific dolphins are particularly vulnerable to global changes and direct anthropogenic impacts. In New Caledonia (South Pacific), photo-identification and genetic data have revealed several distinct populations of this species around the main island, which precarious status and isolation are alarming. Here, we used a long-term dataset (20 years, 178 groups) to investigate the social structure and habitat use of Indo-Pacific bottlenose dolphins in the southern part of their New Caledonian range. A total of 928 individual observations were recorded, among which 310 unique individuals were photo-identified. Resighting histories revealed three distinct populations spread over a 100 km axis displaying variable levels of anthropogenic activities: the highly frequented southwest lagoon around Nouméa, the UNESCO world heritage site of the South Lagoon and the remote Isle of Pines. Individual home ranges computed with Kernel Density Estimates showed contrasting movements, from roaming (range: 32 km wide) to highly sedentary (range: 50 m wide). Among the latter, sedentary dolphins mostly confined to inner bays and isolated reef patches of the South Lagoon. Both at individual and populational levels, this diversity of habitat use patterns will be interpreted in relation to extrinsic factors (shark predation assessed from scarring) and intrinsic factors (cultural preferences assessed from social networks). Finally, anthropogenic threats will be comparatively assessed over the distinct populations in the southern waters of New Caledonia. Indeed, in a context of growing human impacts from maritime traffic, fishing and recreational activities, further investigation of collision and by-catch risks is warranted to evaluate the current conservation status of Indo-Pacific bottlenose dolphins in New Caledonia.

New Zealand sea lion pup behaviour around natural terrain traps and effectiveness of ramps for mitigation on Campbell Island

New Zealand (NZ) sea lions (Phocarctos hookeri, NZSL), endemic to NZ, are currently listed as Endangered (IUCN Red List). Early pup (i.e. up to January) mortality, particularly on Campbell Island (Motu Ihupuku, the second largest breeding colony) is high (40 – 60%) where a considerable proportion of pups become trapped and die in natural mud holes/channels (hereafter terrain traps; TT). Previous mitigation efforts have included ramps to allow pups to self-rescue from the TTs. However, limited research has been done on Campbell Island due to its remoteness and there is uncertainty of the ramps' effectiveness in the long-term and their usage by pups. The aim of this project was to track movements of young pups in the breeding colony to assess how they are using the terrain and spatially quantify the risk of the TTs to pups. The study was conducted over 2-3 weeks in January 2018. We tracked the movements of pups (n = 20) using GPS trackers and placed remote camera traps around TTs. There was considerable movement of pups within the main colony and a 5m buffer zone of all TTs, indicating the TTs were in a highly used part of the colony and all pups are at risk of entering one. We found that when a pup was near a TT, there was a 14% chance of it entering the trap. However, this varied considerably among different TTs and the chances of falling into one increased when conditions were wet. Monitoring of pup behaviour in relation to TTs proved useful in better quantifying the impact of TTs on pup mortality vs other potential causes, e.g. extreme weather events, and the potential interaction between these. This information can guide appropriate mitigation options for known causes of mortality to reduce the overall high mortality observed at this site.

Augmenting fieldwork: Accessible deep learning for satellite-based whale detection.

Many marine mammals, including most cetaceans, are wide-ranging and highly mobile, complicating efforts to collect reliable data at biologically-reasonable spatial and temporal scales. This has resulted in vast areas of ocean remaining never or rarely surveyed and has hampered our ability to describe habitat and population parameters. We used very high-resolution (sub-meter) satellite imagery and trained a convolutional neural network (CNN) to partially automate whale detection as a means to solve part of this problem. Our CNN was trained using down-scaled aerial imagery and tested on 31 cm-resolution imagery from the WorldView-3 sensor. The trained model correctly classified 100% of whales and 90% of image tiles that contained only water. This approach removes the need for tedious manual image classification and potentially opens up vast areas of the ocean that are infeasible to survey at sea. Moreover, it can augment existing field protocols to potentially improve temporal resolution and spatial extent. Such an approach can easily be adapted to different regions and iteratively improved as more whales are detected.

Developing a diagnostic tool to assess respiratory health in bottlenose dolphins (Tursiops truncatus) through spirometry

Current methods to diagnose respiratory health in marine mammals do not provide information about functional changes associated with illness, which is often masked until the animal is severely affected. Our preliminary results suggest that spirometry is a useful, non-invasive method to diagnose lung health in dolphins and could be used to assess respiratory health in wild dolphins. Spirometry is used in human medicine and defines respiratory health by evaluating deviations from normal flow-volume (F-V) patterns. The present study was aimed to assess whether airflow limitations could be determined using F-V data in bottlenose dolphins (*Tursiops truncatus*) in managed care. Spirometry was performed through operant conditioning on 3 unrestrained dolphins (body mass: 196 ± 34 kg) resting in water each 6 months for one year. A pneumotachometer was placed over the blowhole and the dolphin instructed to perform 3-4 maximal expiratory efforts. The forced expiratory flow between 25% and 75% (FEF_{25-75}) of the forced vital capacity of each breath was determined. Lung health was validated through radiographs and standard clinical testing. One dolphin (D1) had chronic bronchitis while another dolphin (D2) developed pneumonia before the last testing date. The F-V loops showed a consistent shape between trials in the healthy dolphin (D3) with an average FEF_{25-75} of 35 ± 4 l · s^{-1}. A consistent F-V relationship was also seen in D2, but for the last trial with emerging pneumonia the F-V loop indicated airflow limitation at lower lung volumes, and the FEF_{25-75} decreased from 54 ± 2 to 30 ± 1 l · s^{-1}. The average FEF_{25-75} for D1 was 18 ± 1 l · s^{-1}, indicative of consistent airflow limitation during all testing periods. Consequently, our results suggest that spirometry is a diagnostic tool for cetacean lung health and helps improve knowledge of basic respiratory physiology.

Life in the fast lane: Foraging behavior of Antarctic fur seals (Arctocephalus gazella) at the edge of their southern most breeding distribution.

At its most southerly breeding range, the Antarctic fur seal (AFS) operates at its highest field metabolic rate in an environment challenging the physiological limits for energy acquisition. Currently, we have little understanding on how edge colonies, already coping with high environmental variability, may deal with additional

variation contributed by specific atmospheric events. By using a combination of diet estimates and biologging we evaluated how additional environmental variability (2014/15 EL NINO year against regular years) may affect the behavior of these colonies. Foraging behavior was compared between all years using 18 variables that represent five categories: trip duration, recovery time (time ashore and surface time), diving effort, habitat use and diet. Differences were found in trip duration (longer trips), recovery time (shorter time ashore) and habitat use between 2014/15 and normal years. No differences were found in diving effort since colonies are already operating at their physiological maximum. Diet was no different between years but prey consumed changes throughout the breeding season from an specialist diet to generalist feeding behavior. This suggest that, in critical years, individuals will not take decisions that may risk the success of capturing prey (longer but close to shore trips and shorter time ashore) differing from other AFS colonies under critical conditions. Adaptive mechanisms may be shaping the behavior of these colonies highlighting the importance of research on evolutionary patterns in colonies living constantly in the fast lane of life.

Feeding ecology of the Ross Sea killer whale

The fish-eating killer whale ecotype (C-type), also known as the Ross Sea killer whale (RSKW), is a top predator in the Ross Sea, Antarctica. It is mainly distributed along coastal areas, especially along dense pack ice. Knowledge about the diet of RSKW is scarce; it is not fully understood to which extent RSKW is dependent on Antarctic toothfish *(Dissostichus mawsoni*) which has been described as its primary prey species. Toothfish is also targeted from commercial fishery in the Ross Sea and this may have led to its decline and forced RSKW to compete with other predators for smaller and most abundant fish species such as Antarctic silverfish (*Pleurogramma antarcticum*). This might alter the foodweb delicate balance in the area. The aim of this study was to investigate the diet of RSKW by means of stable isotope analysis through a mixing model. Seven killer whales were skin biopsied, in Terra Nova Bay (Ross Sea) during austral summer 2015. Stable ratio isotopes of C and N were determined in the samples and a list of RSKW potential prey species in the area, with their stable isotope ratios, was compiled to run the model. The results suggested that diet of the sampled killer whales was mostly based on Antarctic toothfish, which represented about 35% of the biomass ingested, followed by Jonah's icefish (*Neopagetopsis ionah*) (33%) and by striped rockcod (*Trematomus hansoni*) (19%), while all other seven species identified, including Antarctic silverfish, showed less than 13% contribution to the diet. A better understanding of the trophic role of RSKW in the Antarctic food web represents a key research priority to inform management measures to be adopted in the Ross Sea Region Marine Protected Area as also recommended by CCAMLR.

An epigenetic clock for aging endangered cook inlet beluga whales

A method for aging living whales and dolphins from biopsy samples could improve estimates of life history parameters and population viability. Until recently, however, estimates of age have relied on counting growth layers in teeth or ear plugs extracted from carcasses. Over the past decade, advances in mammalian genomics have revealed correlations between chronological age and DNA methylation, the addition of a methyl group to cytosines in cytosine-guanine di-nucleotide sequences (CpG sites). Our current research focuses on beluga whales (*Delphinapterus leucas*) from the Cook Inlet, Alaska, USA. Using a custom hybridization array developed from genes conserved across many mammal species, we have measured the methylation levels at over 30,000 CpG sites in the beluga whale genome. In parallel we have also implemented a candidate gene

approach to identify gene regions containing age-correlated CpG sites that can be used for targeted sequencing in future studies. Data from both methods reveal differential methylation at a subset of CpG sites that correlate with a calibration dataset of know-age individuals (n = 72). Using this relationship, we have built an initial 'epigenetic clock' for the endangered population of Cook Inlet beluga whales ($r = 0.9$, $p < 0.0001$, median age error ~2.8 years). Our methods and results contribute to the larger search for a solution to estimating the age of living whales.

Updating the assessment of southwestern Atlantic humpback whale population status

Humpback whales from the population breeding in Brazilian waters were exploited by commercial whaling almost to the point of extinction in the mid-nineteenth century. The population increased once whaling ceased, but the historical carrying capacity is unknown; hence we do not know how close the population is to full recovery. We fitted a Bayesian population dynamics model to survey data and historical whaling records, and estimated carrying capacity (K), maximum population growth rate (r_{max}), maximum level of depletion ($Nmin/K$) and current level of depletion (N_{2019}/K). The model was based on a previously published study (Zerbini et al., 2011, J. Cet. Res. Man. Special Issue 3:131-144). Our goals were 1) to replicate the "base case scenario" presented in that study using a different fitting method (Markov chain Monte Carlo vs Sampling Importance Re-sampling), and 2) to update that model with newly-derived abundance estimates for 2008 and 2012 and information on rate of population increase. The base case was successfully reproduced. The updated model provided more precise estimates for population sizes and suggested that that carrying capacity and maximum level of depletion were lower than previously estimated (although posterior 95% credible intervals overlap those from the previous analysis). Results suggest the population will reach carrying capacity sooner than previously expected. We propose further developments of the model, such as using a more informative prior for maximum growth rate and less informative prior on carrying capacity to better capture scientific understanding of the system.

Escorting of mother-calf pairs of humpback whales (Megaptera novaeangliae) in the Gulf of Tribugá, northern Colombian Pacific, during the breeding season.

Humpback whales (*Megaptera novaeangliae*) from the Breeding Stock G stock reproduce off the northwest coast of South America and southeast of Central America. The association between cows and escort(s) was examined with photo-identification and behavioral/spatial methods at the Gulf of Tribugá, northern Colombian Pacific, in 2010 and between 2013-2016. Groups were classified as mother-calf pair (Mc), mother, calf and escort groups (McE), and mother, calf, and multiple escorts groups (McME). Flukes and dorsal fins were used for individual identification. Positioned sightings were processed using ArcMap v10.3 along with public database layers (ERDAP y GADM) to calculate depth and distance to the coastline. Spatial variables were processed with a multivariate analysis. Chi-squared tests examined the presumed variation of surface behavioral frequencies among groups. A total of 108 groups with calves were encountered (22.4% of total). Despite obtaining fifteen re-sightings during the study period, there was no evidence of long-term association between cows and escorts. Additionally, four individuals identified as maternal escorts were also identified as members of competitive groups. Significant differences were found regarding the behavioral frequencies of unescorted vs. escorted mother-calf pairs. Mc pairs spent significantly more time resting and diving when compared with escorted pairs. On the contrary, McE and McME groups spent significantly more time traveling and executing surface-active and social/agonistic behaviors when compared with Mc pairs ($\chi^2_8 > 15.51$, $p < 0.05$). No significant differences when comparing depth and distance to the coastline data between groups $F(4, 208) = 0.564$ ($p > 0.05$). In conclusion, the association between cows and escorts appears to be transitory in the Gulf of Tribugá, occurs with no apparent spatial distribution pattern and, has a behavioral impact on Mc pairs, all consistent with a male mating strategy.

Geographic and individual-based differences in the trophic ecology of the Cape fur seal

Information on resource use and trophic dynamics of marine top predators is important towards developing a holistic understanding of ecosystem structure and functioning. Where separate populations of conspecifics experience different local environmental conditions, geographic variability in niche use is expected. Individuals within populations may also vary in morphology, physiology and experience, resulting in individual-level differences and specialisation in resource use. In this context, isotopic compositions of incrementally grown tissues such as keratinous hairs offer valuable insights into individual-level variance in resource use. The Cape fur seal (*Arctocephalus pusillus pusillus*) is the only pinniped endemic to southern Africa. The breeding distribution of the species spans across a broad geographic range which is largely influenced by two contrasting oceanographic regimes, namely the Benguela and Agulhas currents. In this study, we investigated the trophic ecology of female Cape fur seals using isotopic signatures of serially sampled whiskers collected at four breeding sites along the coast of South Africa. Drawing on over 900 individual isotopic measurements, we assessed geographic variability in trophic niche width between colonies as well as the degree of individual specialisation. Individuals from colonies located within the Benguela current region exhibited higher δ15N compared to individuals elsewhere, while δ13C values were similar across the distributional range. Despite these marginal geographic differences, a large overlap in total trophic niche width between the four colonies was apparent. Indices of individual specialisation (WIC/TNW index) were generally low for both δ15N and δ13C. However, moderate levels of variation along the length of the whisker were observed for several individuals. Overall, our study suggests that while Cape fur seals are predominantly generalist foragers, within certain populations, specialisation at the individual level does occur. Results are further discussed with regard to individual foraging strategies, ecological opportunity and observed changes in prey availability.

Three-dimensional ecological niche of two endemic coastal dolphins from the Western South Atlantic

The ecological niche of sympatric marine mammals has been studied through its proxy, the isotopic niche, in order to evaluate their degree of resource overlap and partition. Defining the ecological niche of species is important in order to understand their role within and ecosystem and to describe species-specific niche interactions. In this study, the ecological niche of two sympatric dolphin species that are endemic to coastal waters of the Western South Atlantic Ocean, the Lahille's bottlenose dolphin (*Tursiops truncatus gephyreus* n=22) and the franciscana dolphin (*Pontoporia blainvillei* n=12) was evaluated in order to characterize their resource use and overlap. We used $\delta^{13}C$, $\delta^{15}N$ and $\delta^{34}S$ values in muscle of stranded specimens found along the Southern Brazil (31°21'S–33°04'S) to determine their niche region (95% probability region in the three-dimensional space) through the 'nicheROVER' package. We also estimated the probability of isotopic niche overlap (95% region) between species, defined as the probability that an individual from one species is found in the niche of the other species. Mean $\delta^{13}C$ and $\delta^{15}N$ in Lahille's bottlenose dolphins (-14.7±0.3‰ and 18.3±1.1‰) were higher than in franciscanas (-15.1±0.6‰ and 17.2±0.4‰) ($p<0.05$), while $\delta^{34}S$ values were similar (16.2±1.0‰ and 16.9±1.4‰, for bottlenose dolphins and franciscanas, respectively, $p=0.06$). The probability of niche overlap (mean [credible interval]) between those dolphin species was higher (57.65 [33-81]) in the case of the probability of a franciscana being found within the niche of the bottlenose dolphin than the latter being found inside the niche of the former (32.62 [18-53]). These preliminary results showed how these two sympatric dolphin species coexist by partitioning their spatial (e.g. $\delta^{13}C$ and $\delta^{34}S$) and trophic ($\delta^{15}N$) dimensions of their niche. Our results will help to understand the mechanisms that allow the coexistence of these endangered cetaceans and also predict changes in marine community structure.

Practical tools for assessing extrapolation in models of cetacean abundance.

Bouchet, Phil[1]; Miller, David[1]; Roberts, Jason[2]; Mannocci, Laura[3]; Harris, Catriona[4]; Thomas, Len[4]

Density surface models (DSMs) are clearly established as a method of choice for the analysis of cetacean line transect survey data, and are increasingly used to inform risk assessments in remote marine areas subject to rising anthropogenic impacts (eg. the high seas). However, more and more DSMs are being applied well beyond the boundaries of the study regions where field sampling originally took place, leading to both uncertain and error-prone extrapolations that may mislead on-the-ground management interventions and undermine conservation decision-making. Building upon recent advances in extrapolation detection, we present a new R package for quantifying, summarising and visualising various forms of extrapolation within novel, multivariate environmental space. Although designed with traditional line transects in mind, the package is suitable for use with other data types, and optimised to be computationally fast on datasets of varying sizes. We illustrate our methods by revisiting previously published predictions of sperm whale (Physeter macrocephalus) and beaked whale (Ziphiidae spp.) abundance in the Northwest Atlantic, and evaluating them in light of several extrapolation metrics. We also use Monte Carlo simulations to demonstrate how ignoring extrapolation can lead to misguided management recommendations. Very early in their training, ecologists are warned against extrapolating, as model predictions made in data-deficient contexts rely heavily on assumptions that may not hold outside the range of sampled conditions. A transparent and consistent approach to identifying extrapolation is therefore a critical prerequisite to better understanding how models may behave outside the realm of values from which they are built, and knowing how much trust we can ultimately assign to their outputs. Our approach offers a user-friendly means of evaluating extrapolation a priori in order to guide model development and selection.

From seismic to science: Using passive acoustic monitoring data to enhance the knowledge of marine mammals off Brazil.

Boutros de Mello, Aline[1]; Anzolin, Daiane[2]; Viana, Laura[3]

Corresponding Author: liboutros@gmail.com

Passive acoustic monitoring (PAM) has been implemented during seismic activities in Brazilian waters since 2012. Despite the growing amounts of PAM data being collected along the coast, information has been used mainly as a tool for mitigation purposes. Aiming to use the information for scientific studies, we analyzed PAM data collected during 3D seismic surveys carried out by CGG in the Espírito Santo and Campos basins between July 2017 and July 2018. Acoustical detections were made by Seiche PAM System, consisting of a linear array with two pairs of hydrophones placed 97 m apart, towed approximately 235 m behind and to one side of the seismic vessel. Monitoring effort was conducted 24 h a day and total number of acoustical detection events was 416 (> 191 hours), of which 120 (> 114 hrs) were mysticetes and 296 (> 77 hrs) were odontocetes. Raven Pro 1.5 was used for acoustical analyses focused primarily on the overall quality of sound recordings. Considering the signal-to-noise ratio, recordings were rated as excellent (n=24, 7%), good (n=143, 38%) and poor (n=207, 55%). Acoustic recordings were not available for 10% (n=42) of the detections. Excellent and good quality recordings were obtained for humpback whales, sperm whales, pantropical spotted dolphins and false killer whales. Although species identification through acoustic methods remains a challenge, it is achievable when animals are detected both visually and acoustically. Acoustic characteristics of oceanic cetaceans in South Atlantic waters are still poorly known and, in this regard, we are now measuring acoustic parameters of whistles and clicks from odontocetes and tonal sounds from mysticetes in order to characterize vocalizations of the identified species. We are confident that the results will help fill in the gaps in the knowledge of vocal behavior of marine mammals off Brazil.

The first assessment of social organisation of the Indian Ocean humpback dolphin (Sousa plumbea) along the south coast of South Africa.

Corresponding Author: tbouveroux@gmail.com

The Indian Ocean humpback dolphin (*Sousa plumbea*) is the most endangered marine mammal species in South Africa, and the overall decline of its abundance and group size may affect the social organization of the species, potentially accentuating its vulnerability. Understanding the social organization is therefore particularly relevant to conservation efforts. From photo-identification surveys along the south coast of South Africa from March 2014 to June 2015, we quantified association patterns and investigated the social organisation of humpback dolphins using the Half-Weight-Index, social cluster and network analyses. During the 101 surveys conducted and 553h of survey effort, 98 sightings of dolphins were recorded, and 65 individuals identified. Using individuals seen at least three times, this study reveals that the social network is well differentiated, as strong social divisions exist between individuals that seem to be split into four distinctive social clusters. Network strength was low; approximately half of the associations were low to moderate, while some individuals were strongly associated, especially between four pairs of individuals. Although this study is based on a limited number of individuals, our study nevertheless suggests that the atypical strong social bonds recorded here could result from behavioural responses following the decline in group size and abundance.

Abundance of ice-associated seals in the eastern Bering sea in spring of 2012 and 2013: A cause for concern?

Boveng, Peter[1]; Moreland, Erin[2]; Cameron, Michael[1]; Conn, Paul[1]; London, Josh[1]; McClintock, Brett[3]; Ver Hoef, Jay[4]
(1) Marine Mammal Lab / NOAA, Seattle, WA

Corresponding Author: peter.boveng@noaa.gov

Ice-associated seals in the Arctic are likely to be vulnerable to long-term declines in sea ice and other effects of climate warming, but are difficult to monitor given their remoteness and expansive ranges. In 2012 and 2013, we used a combination of thermal imaging and digital photography to study the abundance and distribution of 4 species of seals (bearded seals, *Erignathus barbatus*; ribbon seals, *Histriophoca fasciata*; ringed seals, *Pusa* (or *Phoca*) *hispida*; and spotted seals, *Phoca largha*) from aircraft in the eastern (U.S.) Bering Sea. Applying species distribution models accounting for zero-inflation, overdispersion, incomplete detection, and species misclassification, we estimated that abundance and 95% confidence intervals of bearded, ribbon, and spotted seals were 275,443 (250,626-302,717); 56,485 (37,957-84,057); and 297,394 (249,721-354,169), respectively in 2012. In 2013, abundances were estimated as 247,218 (220,296-277,430); 39,476 (31,351-49,708); and 161,865 (140,310-186,732), respectively. We do not report on ringed seal abundance, which will require additional, specific analyses. Although we cannot rule out extreme differences in haul-out behavior from 2012 to 2013, the estimated 46% decline for spotted seals and 30% decline of ribbon seals is concerning. We note that the estimated decline coincided with an unusual mortality event associated with skin lesions and documented deaths of ice-associated seals in the Bering Sea and other Alaska waters between 2011 and 2014.

Repeatability and reproductive consequences of birth-site selection in grey seals (Halichoerus grypus).

Bowen, Don[1]; Allen, Sydney; den Heyer, Cornelia[2]

Corresponding Author: wbowen@dal.ca

Selection of birth-site habitat can have important effects on the reproductive success of females and the survival of offspring. We studied birth-site habitat selection by grey seals (*Halichoerus grypus*) on Sable Island, Nova Scotia, and its consequences for body mass of pups at weaning. Birth-site habitat was determined in 584 known-age, females during the 2006 to 2016 breeding seasons. Over this period, these females produced 3,347 pups. We identified a mosaic of eight habitats using orthorectified imagery from a digital photographic aerial survey of the Island in January 2016. We then compared the distribution of birth sites in 2014-2016 with the available habitat in 2016. Vegetated dunes, beach under tidal influence and sandy areas inland of the beach accounted for 86% of the available habitat. Females selected beach and inland sandy habitats that were not floodable and avoided the same habitats were flooding occurred. Females also avoided vegetated dunes, hummocks and the heath community. Using longitudinal data for the entire study period and generalized linear mixed-effects models, we found that younger and inexperienced females pupped in different habitats than older and more experienced females. After accounting for maternal age, parity and pup sex, we found that pups born in inland sand habitat that did not flood averaged 1.5 kg heavier (3%) than those born on vegetated dunes or tidally influenced beaches. Although individual

females exhibited little evidence of site fidelity within the colony among years, they showed high repeatability in their selection of birth-site habitat. This along with boldness, birth date, lactation performance and milk composition suggest the selection for consistent individual differences is strong in this species.

Estimating seasonal movement and distribution patterns using animal tracking data: Application to Cook Inlet belugas.

Cetaceans and other highly mobile species are often characterized by seasonal variation in movement and distribution patterns. The goal of this study was to estimate seasonal utilization densities for an endangered population of belugas (*Delphinapterus leucas*) in Cook Inlet (Alaska) using Argos telemetry data. A previous study using the same dataset described contrasting distribution patterns in June-November and December-May based on kernel densities of interpolated hourly positions. We used new analytical tools and methods (including the crawl() and ctmcmove() packages in *R* and a customized hidden Markov model) to extract more information on seasonal distribution patterns than was previously possible. We combined these tools to (a) estimate maximum likelihood locations of tracked animals after accounting for Argos measurement error and land barriers; (b) objectively partition tracks into seasonal modes; (c) estimate seasonal movement patterns as a function of environmental covariates; and (d) predict seasonally structured utilization densities. Analyzed tracks were characterized by three distinct seasonal modes: (i) summer/fall movements (e.g., June-December) restricted to coastal areas of northeastern upper Cook Inlet; (ii) fall-only movements (e.g., September-December) by some individuals, extending along the coastal areas of western Cook Inlet; and (iii) winter movements (e.g., November-March) expanding away from coastal areas throughout the upper Inlet and into the lower Inlet. The seasonally structured habitat selection patterns that emerge from this analysis provide new insights into the foraging ecology of Cook Inlet belugas, highlighting the importance of rivers mouths and bays of western Cook Inlet in fall. Understanding fine-scale habitat utilization of Cook Inlet belugas is important as this endangered population, with fewer than 250 mature individuals, is subject to increasing disturbance from activities such as construction, shipping, oil and gas development. Information on the belugas' seasonal distribution patterns could be used to minimize this disturbance and improve prospects for population recovery.

Estimating age and growth of West Greenland humpback whales through aspartic acid racemization and eye lens bomb radiocarbon methods

Humpback whales of the North Atlantic were subject to an intense hunt for centuries and declined dramatically. In West Greenland, the population was estimated to constitute less than 200 individuals by the time the whaling moratorium was enforced. The years after with no hunt led to an increase in population size and an estimated annual rate of increase in West Greenland humpbacks was 9.4% yr^{-1} for the period 1984-2007 and a population size of 2,100 individuals by 2007. With the increase in numbers, followed a reopening of the subsistence hunt on humpback whales in West Greenland in 2010.

To decrease the risk of unsustainable harvest of marine mammals, there is a need to obtain knowledge on key life history parameters including age and derived attributes such as longevity, age at sexual maturity and age distribution within a population. The re-opening of hunt on west Greenland humpbacks offers a unique opportunity to sample individuals and gain knowledge on the biology and life history. Here, we use the eye lens from 12 humpback whales taken in the subsistence hunt to obtain age and growth estimates through aspartic acid racemization (AAR) and bomb radiocarbon dating combined. Furthermore, a Gompertz growth curve was fitted to the data.

Based on AAR, five individuals were between 0-9 years, six between 10-19 years and one was ~46 years. Radiocarbon dating showed that all individuals had elevated pMC values between 103 and 106 and therefore estimated to have been born

in the post-bomb period (i.e. after 1963), thus backing up the AAR ages. Whales reached their asymptotic length at approximately age 10.

The results indicate a young population of humpback whales following the many years of overexploitation. Also, radiocarbon dating in combination with AAR age estimation provides a valuable tool and steps towards age validation in difficult-to-age animals.

Deathly silent: Exploring the lack of peer-reviewed literature relating to euthanasia methods and efficacy.

Euthanasia is key to minimising welfare concerns, yet is seldom straightforward. Safety as well as the need for trained personnel and specialist equipment are always essential considerations. Socio-economic, indigenous and/or religious beliefs can further influence decision-making. To understand current international best practice for marine mammal euthanasia, we examined the English language peer-reviewed literature to address (i) types of euthanasia applied and (ii) efficacy of methods. A total of 2,113 articles included marine mammals in the context of 'euthanize' or derivative words in either the title, abstract, keywords or text. A replica search for 'hunt' revealed a further 2,647 articles. Notably, only 3.2% (n=67) of the euthanasia literature detailed the actual method applied. Chemical euthanasia was most prolific (72%, n=48), followed by ballistics (13% n=9). Within the hunt search, only 2.7%, (n=71) of papers detailed methodology - the majority involving hand-held harpoons/spears (52%, n=37) or ballistics (45%, n=32). Most hunts reported using multiple techniques in unison. Efficacy of methods, determined by time to death (TTD), was detailed in very few euthanasia articles (0.5%, n=10), and even less in a hunt context (0.4%, n=11). TTD varied from instantaneous to 49.7h (mean=4.4h) and instantaneous to ca.3d (mean=7.1h) during euthanasia and hunting, respectively. Pinnipeds were the focus of euthanasia literature (53.7%, n=36), followed by delphinids (17.9%, n=12) and mysticetes (16.4%, n=11). In contrast, efficacy of euthanasia primarily focused on mysticetes (60%, n=6) and delphinids (20%, n=2). Similarly, most hunt studies involved pinnipeds (26.8%, n=19), followed by sirenians (21%, n=15). Whilst, efficacy of hunts focused on mysticetes (54.5%, n=6), with few pinnipeds (27%, n=3) reported. Our results highlight a disconcerting lack of scientific literature detailing marine mammal euthanasia, and an urgent need for comprehensive quantitative studies to address this void.

Excretion of Dehydroepiandrosterone Sulfate (DHEAS) in polar bears

Brandhuber, Monica[1]; Curry, Erin[2]; Roth, Terri[2]; Atkinson DeMaster, Shannon[3]

Polar bears (*Ursus maritimus*) are under threat due to climate change and habitat disruptions, and experience poor reproductive success in both wild and zoo settings. Polar bears are a seasonally polyestrous species that exhibit embryonic diapause and pseudopregnancy, complicating characterization of reproductive function. Whereas excretion of testosterone and progesterone has been studied extensively in female polar bears in zoos, many questions remain about their reproductive endocrinology. Dehydroepiandrosterone (DHEA) is a steroid hormone precursor that has been correlated with reproductive success, age, and body condition in other species. However, it has not been characterized in the polar bear. This study aims to validate a commercial enzyme immunoassay kit to quantify the sulfated form of DHEA, DHEAS, in dried polar bear feces to determine if there are differences in DHEAS concentrations between juveniles and adults in the breeding versus non-breeding season. Fecal samples were collected from juvenile (n = 4) and adult (n = 6) female polar bears housed in zoos. Steroids were extracted from 0.1g of lyophilized feces using 90% ethanol with overnight agitation. Four pooled samples representing juveniles and adults during the spring and fall seasons were tested for parallelism with the standard curve. A 1:10 to 1:160 range of serial dilutions produced a curve with a slope that fell within 10% of the commercial kit's standard curve for each group. Preliminary results suggest that adult females exhibit elevated DHEAS concentrations during the spring breeding season (mean: 923 ng/g, p value = 0.033) when compared to adult females in the fall (mean: 405 ng/g), or juveniles during either of the seasons (mean: 131 ng/g spring, mean: 324 ng/g fall) tested. This indicates that DHEAS may be a useful marker of sexual maturity in this species.

Assessment of online information as a tool to improve the documentation of aquatic wildmeat in Asia.

Brannan, Naomi[1]; Porter, Lindsay[2]; Yeung, Niki[3]

Aquatic wildmeat is defined as products derived from aquatic mammals and reptiles that are used for bait, subsistence food and traditional uses. Aquatic wildmeat is obtained through unregulated, and sometimes illegal, hunts as well as from stranded and/or bycaught animals. Regular, high-volume take of multiple marine mammal species occurs in Asia, however, the vast coastlines of the region make monitoring efforts extremely challenging. Online media has become a valuable alternative source of data for terrestrial wildmeat but has never been explored for aquatic species. The objectives of this study were to assess if searching online information was a useful means to document aquatic wildmeat in Asia. Between 2015-17, searches of web platforms Baidu and Sina Weibo were conducted using various keywords. These searches identified 85 incidences between 2003 and 2017. These incidents involved 6 species of small cetacean (4 *Delphinidae* and 2 *Phocoenidae*). From these data, geographical areas were targeted for in person visits to fish markets, to ground truth online information. Further, interviews were also conducted in areas where there were no regular reporting. Shandong Province, China, was identified online as area where cetaceans commonly occurred in markets, especially finless porpoise (*Neophocaena* sp.). In general, online sources indicated only single animals were available, suggesting that catch was opportunistic rather than deliberate. Interviews in Shandong corroborated this. In contrast, in Vietnam where online accounts were relatively few, interviews indicated that marine mammal availability was relatively common. From the information extracted, species, the quantity of carcasses and intended use could be readily identified in 81.2%, 95.7% and 89.4% incidents, respectively. Further, relative trends in online media reflected trends published in systematic reviews of national strandings documents. In addition, online searches identified undocumented incidents. This study showed that online information, when carefully scrutinised, can improve the documentation of aquatic wildmeat in Asia.

Partial breeding migration of harbour seals in the southern North Sea

Brasseur, Sophie[1]; Reijnders, Peter[2]; Kirkwood, Roger; Aarts, Geert[2]
(1) WMR, Den Burg, Netherlands
(2) WMR, Den Helder, Netherlands
Corresponding Author: sophie.brasseur@wur.nl

Migration plays a central role in the spatial dynamics of many mobile species, though until now migration had not been demonstrated in the harbour seal (*Phoca vitulina*). In the Wadden Sea however, regional differences in pup production led to the hypothesis of an annual breeding migration. Seasonal migration of pregnant females between areas with low pup numbers (the Netherlands and Denmark) and high pup numbers (Germany) could explain the elevated pup production in Germany.

Between 2007 and 2016, 225 harbour seals were tracked using GPS data-loggers in the Dutch Wadden Sea. A total of 44 females were tracked during the breeding period. Based on movement and behaviour 27 females were identified as breeding. Twelve (44%) breeding females remained within 10 km of the catch site, but thirteen (48%) females migrated in an easterly direction towards Germany prior to the breeding season. Some feamales migrated 200 km to pup. After the breeding period most (78%) adult females moved in the opposite direction, (i.e. westerly), suggesting a return migration to the feeding grounds. These results suggest partial migration in this species. Migration distance varied significantly among individuals and may explain why such migrations have not been noticed previously. Further study of the movements of these highly individual animals may provide new insights in the population development and genetics.

Dams, Freshwater Flow and Climate Change: The future of the world's river dolphins

Braulik, Gill
University of St. Andrews, Fife, United Kingdom
Corresponding Author: gillbraulik@downstream.vg

Freshwater ecosystems host remarkable biodiversity including one third of all vertebrate species. Globally there are eight river systems, all in Asia and South America, that are inhabited by freshwater dolphins or porpoises. Every freshwater cetacean is listed as either Endangered or Critically Endangered on the IUCN Red List and it is these species that are likely to be at the forefront of the extinction crisis for marine mammals in the coming decades. Immediate threats to freshwater cetaceans are from high levels of pollution, fisheries bycatch, hunting, changing land-use and destruction of

forest in the river catchment, and construction of dams that change and deplete the natural river flow regime. In India and Pakistan water stress is so great that rivers are dammed and diverted such that they are barely flowing and dolphins have very little water to survive through the dry season. Predicted climate change related impacts on the large Himalayan river systems are linked to changing monsoon patterns, reduced rainfall, and depleted glaciers that will change river flow, and these changes will be exacerbated by increasing human populations and warmer air temperatures that will place even further demands on finite freshwater resources. Despite the concerns, in several cases, where a specific threat was identified and it could be removed, freshwater cetacean species have started to recover. For example, the Indus dolphin in Pakistan has been increasing in abundance since hunting was banned despite its severely fragmented habitat. The Mekong dolphin population is also increasing slowly since the removal of fishing nets from its core habitat. Some freshwater cetaceans have shown remarkable resilience in the face of overwhelming threat and this gives some hope that many may be able to persist despite the challenges.

Conservation of African manatee (Trichechus senegalensis. Link, 1795) in the SouthWestern Periphery of Campo Ma'an National Park. An ethno ecological and attitude survey.

Bridget Akume, Eduke
The university of yaounde 1, Yaounde, centre, Cameroon
Corresponding Author: eduke_bridget@yahoo.com

Of all sirenians, the African manatee (Trichechus senegalensis Link, 1795) is the least studied Species. The present study is a survey of ethno-ecology and attitude towards the species and is the first research on the African manatee along the coast of Campo Ma'an National Park, Cameroon.

It looks into the importance of understanding human attitudes associated with the manatee and its habitat in order to develop effective conservation strategies for the species and its habitat. During August 2015 to December 2016, a survey on manatee presence and distribution, as well as attitude and perception by local people was undertaken by conducting surveys both on land and water along the campo coast. The study area was stratified into ecological zones (coastal, river, estuary and mangrove). This allowed the survey of 99 fishers and 18 local authorities in six villages with landing ports using structured and semi-structured questionnaires. This work confirmed the presence of manatees in Campo. Institutions in charge of wildlife will gain much, as they do for other threatened species, if the population is sensitized to the conservation of manatees. Indigenous fishers consider the manatee as a deity, while foreign fishers consider this species as food and/or raw material for rituals. Manatee-fishers conflict is not very evident as compared to other areas were manatees also occur (Korup and Lake Ossa). However, fish marauding is the main cause of conflicts. Water survey conducted in three strategic points indicated the presence of the manatee (grazed vegetation, and floating faeces). It was reported that there has been a progressive reduction in the manatee population in recent years. Conclusively, this study has indicated that the manatee is still present in campo and fishers have a good understanding of this elusive species and its ecology.

Bottlenose dolphin (Tursiops truncatus) social structure and distribution changes following the 2008 unusual mortality event in the Indian River Lagoon, Florida

Brightwell, Kristy[1]; Titcomb, Elizabeth[2]; Mazzoil, Marilyn[2]; Gibson, Quincy[3]

Corresponding Author: kkbrightwell@gmail.com

In fission-fusion societies, environmental disturbances can influence the social and spatial structure of the population. Within the Indian River Lagoon (IRL), Florida, bottlenose dolphins (*Tursiops truncatus*) have experienced recurrent unusual mortality events (UMEs) providing an opportunity to examine post-disturbance restructuring within the same population. This study investigates the impact of the non-epidemiological 2008 unusual mortality event (UME) on the IRL dolphin population. Photo-identification surveys conducted from April 2006 to May 2010 were stratified into pre- (April 2006–April 2008) and post-UME (May 2008–May 2010) time periods. Analyses were limited to individuals sighted 6+ times (Pre-UME=163, Post-UME=138). Half-weight indices (HWIs) and network values were calculated via SOCPROGv2.8, while univariate kernel density estimates (KDEs) were calculated within ArcGISv10.4.1 and SASv9.4. Community associations were highly variable (Pre-UME range: mean=0.04±0.06–1.00±0.00; Post-UME range: mean=0.04±0.09–0.80±0.00), with a small subset of males (Pre-UME=6, Post-UME=10) who formed first-order alliances. Mean HWIs decreased between time periods (Pre-UME Md=0.02, Post-UME Md=0.01, U=9335, $p<0.05$), while mean non-zero HWIs increased (Pre-UME

Md = 0.12, Post-UME Md=0.15, U=5365.5, $p<0.05$) indicating fewer associations among individuals. Further, network analyses showed a decrease from 12 to 9 social communities in combination with increased community clustering post-UME (Pre-UME Md=0.05, Post-UME Md=0.07, U=7786, $p<0.05$). Univariate spatial analyses showed a disconnect between the northern Mosquito Lagoon communities and the rest of the IRL population during both time periods. However, there was no change in KDE overlap among communities following the UME (95%: Pre-UME Md=0.46, Post-UME Md=0.38, U=34, $p>0.05$: 50%: Pre-UME Md=0.19, Post-UME Md=0.14, U=49, $p>0.05$). These results illustrate the social resilience of IRL bottlenose dolphins to environmental and demographic changes despite impairment in adaptive immunity related to anthropogenic and natural stressors present within the estuary. Future studies on the effects of the larger, and more recent 2013-2015 UME will determine if this population continues to be resilient to multiple disturbances.

Prey abundance and habitat type are characteristics of 'hotspots' in the distribution of the endangered Hector's dolphin

Brough, Tom[1]; Rayment, Will[2]; Slooten, Liz[3]; Dawson, Steve[4]

Marine species generally show hotspots in distribution, yet the habitat characteristics that underlie these features are unknown for many species, particularly at fine scales. Understanding what drives hotspots is important for identifying and protecting high quality habitat, and is thus vital for species and ecosystem management. Between 2015 and 2018, we conducted 187 systematic visual surveys for Hector's dolphins in nearshore habitat at Banks Peninsula, New Zealand, while simultaneously collecting a broad suite of data on the dolphins' habitat (including habitat type, bathymetry, oceanography and epipelagic prey). Surveys were carried out at four known hotspots in the dolphins' distribution and at six randomly selected 'reference areas'. Relationships between dolphin relative abundance and habitat characteristics were modelled using generalised additive mixed models. The best model (54% deviance explained) for describing dolphin distribution included data on the coverage of mud and reef habitat types, depth, tidal current velocity, surface chlorophyll and salinity, and prey abundance. Among all biophysical characteristics, the relative abundance of epipelagic prey had the strongest influence on dolphin distribution. Hotspots had more shallow, sandy habitat with higher current velocity and prey abundance, compared to reference areas. Knowledge on the habitat types that support high density of dolphins and their prey provides valuable new insights into the ecology of this nearshore ecosystem. Further, identifying the importance of these environmental features allows for management of habitat related threats to this endangered species.

Changes in gray whale foraging occurrence in the eastern Chukchi Sea, 2009-2018.

Foraging gray whale (*Eschrichtius robustus*) occurrence in the eastern Chukchi Sea (67°-72°N, 154°-169°W) increased from 2009 to 2018 based on visual data collected during annual line-transect aerial surveys conducted from July to October. These systematic surveys, part of the Aerial Surveys of Arctic Marine Mammals (ASAMM) project, have been conducted since 2009 to document marine mammal relative density, distribution, and behavior. The Chukchi Sea serves as important foraging grounds for the eastern North Pacific gray whale (ENPGW) and is the northernmost extent of their geographical range. Foraging gray whale sighting rates (# feeding gray whales per km flown) in the northeastern Chukchi Sea (> 69°N) were higher in 2018 than any previous year. Sighting rates here typically decline in September as gray whales begin migrating south; however, in 2018, September sighting rates were three times higher than in September of any previous year. Gray whale preferential foraging habitat also shifted geographically between 2009-2015 and 2016-2018 in the northeastern Chukchi Sea. In the southcentral Chukchi Sea (< 69°N), gray whales were observed feeding in dense aggregations in a benthic hotspot during most years from 2014 to 2018, when survey coverage included that area. In 2018, sighting rates in the benthic hotspot were high in July but lower in August to October,

compared to previous years. Gray whales may be depleting benthic prey in some previously preferred foraging areas and moving to other areas that may have less nutritional value. Understanding gray whale foraging habits and habitats in the Chukchi Sea are key to understanding the health of the ENPGW population.

Using Unmanned Aerial Vehicles (UAVs) to estimate availability and group size error for aerial surveys of coastal dolphins.

The precision of marine mammal abundance estimates based on aerial surveys relies upon accurate estimates of availability (the probability of animals being visible for detection) and group size. Here, we present a novel method of using small, vessel-launched, multi-rotor UAVs to collect aerial video of coastal dolphins to estimate availability and group size error, applicable to surveys conducted from aerial platforms. We collected 20 hours of aerial video of the dive-surfacing behaviour of Australian humpback dolphins (*Sousa sahulensis*) off north-western Australia. Estimates of availability based on 60 focal follows of consistent group composition ranged between 0.22 and 0.88, with a mean availability of 0.48 (CV=0.04). Availability was higher for follows with calves (0.53, CV=0.05) than without (0.31, CV=0.10), and trended higher with increasing group size. There was a downward bias in group size estimation, with true group size typically one individual more than would have been estimated by a human observer during a standard aerial survey. The variability of availability estimates between follows highlights the potential for bias, and the need to sample across a variety of group compositions, behaviours and environmental conditions. Furthermore, we undertook truncation/resampling exercises on these data to investigate how availability estimates and resultant precision varied with the number and duration of follows, with results providing an indication of target sample sizes to minimise bias in future research. We show that UAVs can provide an effective and relatively inexpensive method of estimating availability for coastal dolphins, with several advantages over existing approaches, including a visual perspective which is representative of the visibility of the animals from the air. These humpback dolphin availability estimates are within the range of values obtained for other shallow-water delphinids, and directly inform a program of aerial surveys in the region.

A polyphasic approach to determine ecological and toxilogical consequences of a new and cryptic species of cyanobacteria (Komarekiella delphini-convector) recovered from bottlenose dolphin epidermis

On January 15, 2015, an adult bottlenose dolphin (*Tursiops truncatus*) was found dead with a thick, epidermal mat in low salinity habitat. The animal was matched to the University of North Florida's St. Johns River dolphin photo-identification catalog as Makena, whom had a history of skin lesions. Toxin analyses of Makena's hepatic tissue revealed the presence of either cyanotoxin microcystin or nodularin, both of which are produced by cyanobacteria. The composition of the epidermal mat was then investigated to determine if any species within this mat could have been the source of toxins found within the hepatic tissue. A species of cyanobacteria was grown in culture from the epidermal mat. Preliminary morphologic investigations revealed that this species had major phenotypic plasticity, obscuring identification. Further genetic (*i.e.,* 16S-23S ITS, full genomics) analyses revealed that this was a new species of cyanobacteria. This new species was the second member of the newly described genus *Komarekiella*. *Komarekiella* is a sister-taxa to the microcystin-producing genus *Nostoc*, highlighting the potential of this species having the ability to synthesize microcystin. Two types of toxin analyses (ELISA and the MMPB technique) were conducted on both the original epidermal mat and subsequent cultures, producing conflicting and inconclusive results. The full genome was then sequenced, and novel genome mining processes were conducted to determine the biosynthetic

capabilities of this species. Results showed that this species is very biosynthetically active (48 unique biosynthetic clusters identified), though the function of most of the biosynthetic clusters were not defined due to lack of sequence similarity. Further genomic analyses will be conducted to determine if any of these biosynthetic clusters are related to the synthesis of microcystins.

Deep trouble: Investigation into an unprecedented number of beaked whale strandings, eastern Atlantic, July-October 2018.

Between July and October 2018, 100 beaked whales were reported dead stranded in advanced stages of decomposition in countries bordering the NE Atlantic. The majority of cases (n=73) were *Ziphius cavirostris* strandings along the west and north coasts of Ireland (n=24) and the west of Scotland (n=49) in August and early September, with a smaller cluster of *Hyperoodon ampullatus (*n=8) reported in northern Scotland in October (other species or regions=19*)*.

At an individual country level this represented an unprecedented strandings incidence for these species, and together comprised the largest unusual mortality event of beaked whales recorded globally, with impact likely at a population level. *Ziphius cavirostris* are a deepwater species known to be highly susceptible to noise, in particular mid-frequency active sonar. Identification of potential aetiologies was however challenging, as carcases were in an advanced state of decomposition and logistics restricted detailed necropsy examination of several cases.

Here we present the multidisciplinary integrative approach taken to investigate this event and suggest its relevance and implementation to future cases of mortality events where standard investigative methods aren't possible. The following results were integrated to identify plausible source regions and aetiologies for mortality:

1. Health and pathological data derived from cases recovered for necropsy;

2. Species and sex identification using short mitochondrial DNA fragment analysis of sampled cases;

3. Drift simulations for potential carcase origins, incorporating modelled ocean surface currents with effect of prevailing wind;

4. Acoustic analysis of broadband static and towed acoustic arrays operational in the NE Atlantic contemporaneously with this UME.

Cases examined exhibited pathology not inconsistent with acoustic trauma, for example fat emboli in lung parenchyma. Drift models suggested a focal source in the Rockall Trough and Porcupine Bank west of Ireland in July 2018. This investigation highlights how a multidisciplinary, collaborative approach can reduce the uncertainty and data-gaps often intrinsic to atypical mass stranding events, particularly of cryptic species such as beaked whales.

Amazon river dolphin abundance at an area of high touristic interest and implications for its management

Brum, Sannie[1]; da Silva, Vera[2]; Valle, Marcele[3]

The boto, *Inia geoffrensis*, was recently considered endangered and robust population information is required to guide effective management measures. In the lower Rio Negro, AM, Brazil, since 1998 a tourism interaction activity has been developing in which wild botos are habituated to remain close to tourists in the water, but no information on the impacts of this activity for the botos exists. Here we present the first population estimates of botos in this area and discuss the tourism impact. We surveyed 992km between

Manaus and Novo Airão municipalities (an area of 1.666km^2) in April and October 2016. Boat-based surveys were performed with double observer configuration. Data was analyzed with R software ('mrds' package), in a mark-recapture distance sampling (MRDS) model, with trial configuration and full Independence assumption. The biological removal potential (PBR) was calculated according to Wade (1998). The abundance was estimated as 2.666 botos (IC 95% 1.499 - 4.831, CV = 0,3) and PBR indicated an annual withdrawal limit of 16 botos. Hipothetising that interacting botos are withdrawn from their ecological functions, PBR can be used as a basis for monitoring the impact of this activity on botos population and this is the first index produced in this area. In the last five years, the estimated number of interacting animals remains at around 50-60 botos and the PBR indicates that for this time a withdrawal of 80 botos from the population would not cause population decline. Monitoring and inhibiting the increase in the number of interacting animals is an easy-to-use management measure. We conclude that the touristic activity with botos, if correctly managed, should not be considered a threath to this species at a populational level. Population monitoring to obtain accurate PBRs indexes and close inspection of this activity are relevant management measures for boto conservation in the region.

A photoidentification study reveals a sex-related skin mark pattern in bottlenose dolphins (Tursiops truncatus) interacting with artisanal fishery.

Skin marks occur frequently in many cetacean species across the globe revealing a broad spectrum of causes, including social interactions, infectious diseases and injuries produced by anthropogenic factors. The current study used photo-id data from 2005–2014 to estimate the skin mark pattern on resident bottlenose dolphins (*Tursiops truncatus*) from the Aeolian Archipelago (Italy). Thirteen skin mark types were identified and their origin, prevalence and permanence time were examined. The pattern of skin marks was assessed for the abundance, richness, distribution and severity in six body regions and compared among age classes, sex and degree of dolphins' interaction with trammel nets (DIN). Our results showed higher prevalence, abundance, richness and distribution of skin marks in adults than in the younger age classes, with the exception of black marks and white ring lesions. The prevalence and abundance of skin marks were higher in males than females, with the exception of scratches and white patches. Moreover, gunshot wounds, mutilations and irregular dorsal fin edges were found only on adult males. Since males showed higher DIN than females and, in dolphins with higher DIN, skin marks were more abundant and frequently distributed in different body regions, the skin mark pattern in regard to DIN seems to be sex-related. The more severe marks were observed on adults, males and dolphins with higher DIN, namely skin disorder, tooth rake marks, small shallow indentations, deep indentations and mutilations. On the contrary, the severity of scratches, white patches and dark ring lesions was higher in females than males, but not significantly related to DIN and age of the individuals. Our results showed that photo-id data provide an efficient and cost-effective approach to document the occurrence of skin marks in free-ranging bottlenose dolphin populations, a critical step toward understanding the cause and supporting the conservation strategies.

Ringed, bearded, and spotted seal productivity in Alaska using harvest-based monitoring, 1960s–1980s and 2000–2018.

Declines in sea ice are predicted to negatively affect ice associated seals (ringed, *Pusa hispida*, bearded, *Erignathus barbatus*, and spotted, *Phoca largha*), important to Alaska Natives for food and materials, by reducing their time to rest, pup, nurse, and molt on sea ice. Concurrent with declines in sea ice are predicted reductions in snow depth used by ringed seals to construct pupping lairs. This is expected to lower productivity and pup survival by providing less protection from weather and predators. Estimates of ice seal abundance cannot be used to detect population trends in Alaska; however, data from the subsistence harvest can be used as an index of population health and status. We compared seal productivity during the 2000s to the 1960s and 1970s, before sea ice decline. Pregnancy rate from 2010–2016 (2010s) was higher for bearded (99%) and spotted (97%) seals than the earlier periods, and although slightly lower

now for ringed seals has remained relatively high (80%). A decrease in annual pregnancy rate was detected for ringed seals during an Unusual Mortality Event (UME) in 2010 (63%) and 2011 (47%), however, it recovered to 80% by 2012. The average age of maturity for all three seal species was lower in the 2010s than the earlier periods; with ringed seals at 3.6 (vs. 4.6) years old, bearded at 2.8 (vs. 3.4), and spotted at 3.2 (vs. 3.6). Additionally, a high proportion of pups were harvested in the 2010s indicating that pups are being produced, weaned, and surviving to be harvested. As of 2016, we had not detected negative effects in ringed, bearded, or spotted seal reproduction as was predicted with declining sea ice, however, record low winter sea ice extent in the Bering Sea in 2017 and 2018 may affect productivity. Here we update our results through 2018.

Exploring the genetic basis of boldness in female grey seals.

Researchers have begun paying increasing attention towards the study of behavioural variation within a population or species, and furthermore towards the study of animal personality. Personality, defined as inter-individual behavioural differences that are consistent across time or contexts,influences various evolutionary and ecological processes including life-history characteristics, interspecific interactions, and responses to changing environmental conditions and anthropogenic pressures.Unfortunately, many investigations of personality end prematurely at the descriptive stage without further exploring proximate mechanisms underlying the behavioural variation. We have previously described evidence of a personality signal in a free-ranging population of female grey seals (*Halichoerus grypus*) on Sable Island National Park Preserve in Nova Scotia, Canada. High repeatability estimates suggest that boldness may have an underlying genetic basis. As such, we are now using molecular genetic association methodologies to gain insight into processes shaping and maintaining variation in personality. With boldness scores for over 450 females, we aim to perform a genome-wide association study (GWAS) using thousands of single nucleotide polymorphism (SNP) markers to identify genomic regions contributing to the observed behavioural variation in the Sable Island population. In addition, we aim to use a candidate gene approach as a complementary analysis to the GWAS. We have sequenced five candidate genes (dopamine receptor D4, serotonin transporter, oxytocin receptor, and the melanocortin 1 and 5 receptors) that have previously been shown to influence various aspects of behaviour in passerine, non-human primates, and domesticated species. Our sequencing efforts led to the discovery of genetic polymorphisms in each gene (35 total SNPs), facilitating genotype-behaviour statistical association analyses. Results from our study will contribute knowledge of the genetic architecture underlying natural behavioural diversity, and in doing so, will provide a basis for investigating the rate and direction of selective forces driving population adaptation in marine mammals.

Blue, sei and humpback whale acoustically-inferred distribution in relation to oceanographic features in Northern Chilean Patagonia using gliders and fixed timeseries data

Northern Chilean Patagonia (NCP) is an extensive estuarine system (S 41°35-46°35) and known feeding ground for blue (BW), sei and humpback whales. Understanding whale distribution in this dynamic and heterogeneous habitat is a challenge. We seek to determine the distribution of baleen whales in relation to oceanographic features in the Corcovado Gulf to better understand underlying drivers. This is the first study of whales and in situ oceanography over the meso-spatial scale in Chile, and the first glider-based survey of cetaceans in Latin America. Slocum gliders were deployed in April 2018, and April-May 2019. Gliders were equipped with a Digital Acoustic Monitoring instrument (DMON) to detect whales acoustically in near real time, and chlorophyll-a/turbidity and temperature/salinity sensors. A mooring was deployed January-December 2016 and since March 2018 including: a SM3M hydrophone, an Acoustic Doppler Current Profiler (ADCP), an Acoustic Zooplankton and Fish Profiler (AZFP), and chlorophyll-a and temperature/salinity sensors.

Stratified zooplankton samples to validate ADCP/AZFP data were collected (n=20); zooplankton (n=20) and fecal samples (n=12) were used to infer/determine prey of foraging whales. Backscatter/oceanographic data were analyzed using standard techniques; passive acoustic data were analyzed using the Low Frequency Detection and Classification System (LFDCS). Acoustically-inferred occurrence of BW (most commonly detected species), was associated with thermal fronts, and intermediate/oceanic water masses versus estuarine water. Clear diel variation in BW calls was found, which was associated with zooplankton diel migration. Synoptic variation over a 16-20-day period was also observed. Seasonally, we observed a 1-month lag between chlorophyll-a and zooplankton maxima in March, and peak BW calls in April. Patterns were less marked for sei and humpback whales. Blue and humpback whales appear to feed on euphausiids (*Euphausia vallentini*), while sei whales feed on lobster krill (*Munida gregaria*). We discuss the possible processes that drive spatial/temporal distribution of these species, and make conservation and management recommendations.

Living at the limit: Distribution of small cetacean along Abu Dhabi waters, Arabian Gulf, UAE.

The Emirate of Abu Dhabi is strategically located within the Arabian Gulf in a combination of geographical, oceanographic and ecological conditions which enable the presence of a rich cetacean fauna. Although the preservation of suitable habitats is necessary, the persistence of cetacean species in Abu-Dhabi waters cannot occur without a better understanding of their distribution, demography and use of habitat. Here we report the distribution patterns and group dynamic of cetacean species as integral components of the information needed to manage human impacts on marine mammals in Abu Dhabi waters. Overall, 13 days were spent at sea in April 2017, totaling 107 hours and 1 145 km of boat-based observations. During this time there were 57 encounters with cetaceans (35 with Indo-pacific bottlenose dolphins, 14 with Indian Ocean humpback dolphins, and 8 with finless porpoises). During these encounters 268 Indo-pacific bottlenose dolphins, 92 Indian Ocean humpback dolphins, and 37 finless porpoises were observed. These surveys confirm Abu Dhabi waters as an important foraging habitat for all these cetacean species. Indeed, behavioural data confirm Abu Dhabi waters as a breeding/nursery zone for Indian Ocean humpback dolphins and Indo-pacific bottlenose dolphins. Although the Abu-Dhabi humpback dolphin population is considered one of the largest in the genus Sousa in the world, based on previous studies, the observed decline in presence of humpback dolphins could be cause of concern. A number of interacting factors may have played a role in this decline, ranging from natural fluctuations to the potential impact of human activities such as oil and gas exploration (including seismic surveying) in the Central region during the surveys period. Therefore, further surveys are needed to confirm if this decline is result of a short-term seasonal variation in presence or on the contrary, is due to a real decline in the occurrence of this endangered species.

Stranding records of marine mammals in Kuwait

Buhadi, Yousef
The University of Iceland
Corresponding Author: y.bohadi@gmail.com

As attempts to survey the cetacean populations in the Arabian/Persian Gulf increased in recent years, so does the need to raise public awareness regarding these animals and their current state. While most cetaceans tend to avoid areas with high human activity, stranded carcasses tend to catch the public's eye, and at the same time provide scientists with valuable data such as the cause of death, the animal's dietary consumption, the amount of pollution it might have in it's system, and even the stress levels in a fresh sample. All these insights can better help us understand the reality these animals face and better equip experts to give more crucial advice to the authorities to better insure their future in these waters. Our aim here is to provide a recored of the stranding events that took place in Kuwait from 2013 to 2018, we do so by examining public records as well as personal documentation of stranding events. We were able to put together a recored of 16 Strandings spanning 6 years in Kuwait waters. Some of these records were published online in press releases while others were individual sightings personally documented, or reported from fishermen. Of these carcasses, 2 were identified as finless porpoises, one as a humpback dolphin and one bryde's whale. We were not able to identify the other 12 carcasses, apart from one clearly belonging to a baleen whale

due to its size and general morphological features. A good step to take from here is to get in contact with local fishermen and engage them in surveys to gather better information on stranding incidents as well as raise their awareness to better document these events to the best of their abilities, to ultimately serve as a good tool for population assessment.

Environmental drivers of grey seal (Halichoerus grypus) pupping phenology in the Irish Sea.

The causes and consequences of phenological shifts resulting from climate change has become a major area of interest in recent years, across many ecosystems and geographic regions. In communities that are strongly regulated by top-down processes, climate change-driven shifts in predator distributions and dynamics are likely to have disproportionate effects on whole assemblages of species and ecosystem function. Here we focus on grey seals (*Halichoerus grypus*), as a well-studied example of the marine predators. They are an iconic focal group in their own right as well important indicators of the wider effects of climate change. Using multi-decade data sets from major pupping sites in the Irish Sea, we set out to quantify how changes in the timing and progression of the grey seal pupping season are dependent on climatic drivers. We developed a logistic population growth model and estimated shifts in the timing and speed of within-season pup accumulation. We tested hypotheses on local and regional scale environmental drivers of these changes. Sea surface temperature was found to influence pupping season timing, and local winds affected the length of the season. We explore differences in these findings between pupping sites and consider implications for marine spatial planning.

Photo-identification of the Mediterranean monk seal sub-population in the central Ionian Sea, Greece

Since March 2018, a systematic monk seal photo-identification project was launched in the central Ionian Sea, Greece. From May onward, 8 important marine caves suitable for resting and reproduction which were identified in earlier studies (1985-2002) were equipped with infrared cameras, thereby strategically covering the entire area of study. The pictures were analyzed from July onward; the process is still ongoing. Morphological characteristics of the fur distinguishing animals in pup, juvenile, subadult/adult, adult male, as well as individual scars were used to identify the animals. Animals were classified as adults only if evidence of sexual maturity was recorded (female with pup or adult male fur). The gender was attributed only to those individuals where the ventral part was clearly visible (ventral patch for pups; nipples, penis opening for the other categories, or the typical coloration of adult males). In the pictures up to November 2018, we identified and catalogued 18 individual seals: 3 adult males, 1 adult female, 9 sub-adult/adult seals (6 identified as females), 1 juvenile and 4 pups (1 identified as a female, 2 as males). Gender was evident only in 13 cases. Several pictures seem not to relate to the 18 already photo-identified animals but more data are undoubtedly needed in order to fully identify the animals. Seals not fully identified yet were not included in our catalogue in order to avoid an over-estimation of the actual numbers. Nevertheless, this fact indicates that the monk seal sub-population in the study area is composed of more than 20 animals, at least confirming previous minimum estimates. These findings outline the relevance of the central Ionian Sea for the conservation of this endangered species. The analysis of new material will reveal additional information on the size and other relevant parameters of the sub-population in the Greek central Ionian Sea.

Developing non-invasive fecal biomarkers to monitor Florida manatee health

Over the past decade, seven mass mortality events of the Florida manatee (*Trichechus manatus latirostris*) have been documented, resulting in the deaths of more than 1000 animals. One *unusual mortality event* (UME) of undetermined cause in the Indian River Lagoon (IRL) remains under investigation but appears to be related to dietary shifts following the drastic loss of seagrass. Although carcass necropsy is invaluable, there remains a need for a non-invasive tool to detect changes in the health of wild manatees at the population level to better inform management. We developed enzyme-immunoassays to monitor manatee health by measuring glucocorticoids (e.g., cortisol; adrenal stress hormone) and triiodothyronine (T_3; thyroid metabolic hormone) in feces collected during live health assessments (n = 90) and post-mortem investigations (n = 29). Cortisol and T_3 have profound influences on energy mobilization and metabolism and are particularly responsive to nutritional deficits and extreme temperature insults. We found that apparently healthy wild manatees had elevated fecal cortisol and T_3 during spring-summer likely related to heightened metabolic demands due to breeding activity and increased food availability. Adult males, who often pursue a single female in competitive breeding herds, showed the greatest metabolic activity during this time of year. Both fecal cortisol and T_3 levels were lower in winter, when food becomes scarcer and manatees possibly conserve their energy reserves. Interestingly, manatees with access to naturally-warmed artesian springs had reduced metabolic activity compared to manatees overwintering in secondary warm-water sites, such as powerplant outflows. Manatees with signs of cold-induced stress or manatees that died during the IRL UME showed significantly elevated thyroid activity in winter compared to healthy manatees. This non-invasive tool could be useful to enhance manatee health monitoring during environmental perturbations, which are increasing in frequency and often challenging to investigate.

Long-term trends in Steller sea lion abundance in the Commander Islands, Russia.

Steller sea lions (SSL) breed and pup on the Commander Islands (CI) of Russia, at the westernmost edge of the Aleutian Island chain. The CI are adjacent to the area of the greatest decline of SSL in the United States (US), the Western Aleutian Islands. Management of SSLs and fisheries interactions/competition is contingent upon accurate trend analyses in the CI as well as the US. We used published data and our own surveys conducted since the late 1980s to analyze long-term SSL population trends on the CI. SSLs were abundant in the CI in the late 1700's and bred on the archipelago until the mid-1800's when overharvest almost led to extinction. The population recovered by the mid 1900's when non-pup abundance in winter was >10,000 and breeding was observed. In contrast to the decline of the species in the Aleutian Islands, non-pup abundance on the CI in the early 1980s fluctuated around 2,000 individuals while pup production grew steadily to 280 pups in 1998. The high non-pup abundance and a steady positive trend in pup production have been attributed to a 30 nm no-fishing conservation zone surrounding the CI since the late 1950s. However, in 2000 pup numbers abruptly decreased to 180 pups (-33.6%). Pup abundance increased slightly during the next five years but never recovered and the long-term trend was negative through 2018 (-1.9%/year). Non-pup abundance declined >70% in the late 1980s and early 1990s from over 2,000 to 544 individuals in 1994. Abundance has continued to decline, and the 2015 count was 490 non-pups (-6.2%/year). Our studies suggest that the current negative trend is due to poor reproduction rather than any other causes and it is more likely that current declines in SSL numbers are more related to global oceanic environment changes than any local human-related causes.

Fin whale (Balaenoptera physalus) acoustic presence off Elephant Island (South Shetland Islands) Antarctica

Summertime visual observations suggest that the region around Elephant Island may serve as an important feeding area for fin whales. To explore its year-round relevance, passive acoustic recordings collected northwest of Elephant Island (61°0.88'S, 55°58.53'W) from January 2013 to February 2016 were analysed for seasonal and diel patterns of fin whale 20 Hz calls. Calls were detected year-round, although in some years calls were not present during all months. For all years, fin whale calls were consistently present from March to July for more than 90% of days per month. From August to January, percentage of days with calls varied between years, with presence exceeding 75% of days per month throughout 2014, whereas in 2015 calls were absent in October and November. In 2013, fin whale calling dropped in August and increased again towards October and November. Quantitative analyses of power spectral density for the 20-Hz and 89-Hz fin whale bands, showed that fin whale acoustic power in both frequency bands followed a Gaussian-like temporal pattern, increasing in late January, peaking during April-May and decreasing in late August for all years. A second shoulder peak in PSD seemed to occur during the second part of July showing strongest for the upper fin whale band, followed by a rapid decrease, after which SNR for both bands dropped to zero. Diel patterns in call activity were analysed for a 10-month subset of the data from 2013. Fluctuations in call rates did not follow a diel pattern nor correspond to local insolation.

The observed peaks in fin whale call activity correspond to the periods during which fin whale super groups have been observed visually in this region. Our year-round acoustic analysis indicates that the Elephant Island region likely carries an important role for fin whales throughout the entire year.

Remote sensing and mapping the habitat features important to the large whale assemblage off Vancouver Island.

A key issue in cetacean research is understanding the effect of anthropogenic influences. However, basic knowledge of many of the large whales, including presence, number, and habitat use is lacking. We used ocean gliders to survey regions once described as productive whale habitat, and focus on the continental shelf break and areas of bathymetric relief, such as submarine canyons. Passive and active acoustic measures, as well as habitat variables such as conductivity and temperature, were collected to compare ocean and prey-scape features coincident whale presence.

Whale calls in the passive acoustic data is a proxy to presence. Use of the call repertoire guides our interpretation the whales' behaviour and area use. Tying habitat variables to this can further strengthen conclusions as well as outline important habitat areas over space and time.

Large baleen and toothed whales were located off the west coast of Vancouver Island, with most calls heard along the shelf break. We recorded blue, fin, humpback, sperm and possible sei whales, all of which were heavily targeted by whaling. Call type suggests the presence of feeding, socialising, and breeding/calving behaviours. Spatial analysis shows distinct zoning in horizontal and vertical space between on- and off-shelf and relief areas. The comparison of multiple deployments in the region allows comparison of winter to spring-like conditions, and the prey aggregations derived from upwelling. Creating surfaces from point data allows us to start to reconcile the spatial mismatch between the scale at which the habitat data is collected and the area over which whale calls are propagated. Establishing patterns in habitat variables helps predict the importance of these areas to a variety of large whales species, and the effect that human activities could have on their use.

Understanding diet, past and present: Insights into the foraging ecology of Falkland Islands Sei whales using DNA metabarcoding and stable isotope analysis.

Despite being the third largest of the iconic baleen whales, little is known about the diet of the sei whale (*Balaenoptera borealis)* in the Southern Hemisphere. Here we provide the first assessment of sei whale diet using DNA metabarcoding and stable isotope analysis of both contemporary and historical material. Specifically, we analyse skin, faecal and bone samples collected during the austral summer of 2017 to 2018 alongside historical bone samples gathered from the start of the modern whaling era (~1910) from New Island whaling station, Falkland Islands. Bone collagen and its intrinsic isotopic values are stable over millennia and can be used to infer dietary preferences of historical populations. Ratios of stable isotopes found within contemporary tissues of varying turnover rates (e.g. skin vs. bone) can provide insight into foraging preferences over different temporal scales. DNA metabarcoding of scats can be used to taxonomically identify prey from recent foraging bouts. Our dataset permits three questions to be addressed: (1) what is the current diet of sei whales in the Falklands Islands? (2) are stable isotope analyses comparable over a multitude of tissue types and time periods? and (3) has diet changed since whaling occurred in this region? Our results from 35 contemporary and 12 historical samples suggest (1) a presence of fish and crustacea in modern sei whale diet as inferred using DNA analysis. We also find that (2) nitrogen isotope ratios do not differ between bone, blubber and skin tissue types, making it possible to compare trophic levels between historical bone samples and modern bone, skin or blubber samples; analyses of these suggest that (3) whaling has not impacted the trophic ecology of sei whales over the past century. Further results based on ~40 contemporary and ~40 historical samples are currently being analysed.

The role of sociality in the response of killer whales to an additive mortality event

In highly social top-predators, group-living is an ecological strategy that enhances individual fitness, primarily through increased foraging success. Additive mortality events across multiple social groups in populations may affect the social structure, and therefore the fitness, of surviving individuals. We examined this hypothesis in a killer whale (*Orcinus orca*) population that experienced a 7-year period of severe additive mortality due to lethal interactions with illegal fishing vessels. Using both social and demographic analyses conducted on a unique long-term dataset encompassing periods before, during and after this event, we found a decrease of both the number and the mean strength of associations of surviving individuals during the additive mortality period. A positive significant correlation between association strength and apparent survival suggested that the fitness of surviving individuals was impacted by the additive mortality event. After this event, individuals responded to the loss of relatives in their social groups by associating with a greater number of other social groups, likely to maintain a functional group size that maximized their foraging success. However, these associations were loose; individuals did not re-associate in highly stable social groups, and their survival remained low years after the mortality event. Our findings demonstrate how the disruption of social structure in killer whales may lead to prolonged negative effects of demographic stress beyond an additive mortality event. More importantly, we show that sociality has a key role in the resilience of populations to human-induced mortality; this has major implications for the conservation of highly social and long-lived species.

Monitoring the population of the South American sea lion in southern Chile from 1998 to 2018: A methodology for population estimation at large-scale.

The South American sea lion, *Otaria byronia*, has a wide distribution in South America. The species has an estimated abundance of about 500,000 individuals, 192,000 of which inhabit the Chilean Coast (between 17º30'S and 55º58'S): northern (95,000), central (28,000), and southern (67,000) Chile and Magallanes (2,000). The aim of this study is to analyze the population trend of *O. byronia* in the five main breeding colonies of southern Chile and to estimate the total population on a large scale. Aerial photographic surveys were conducted in Isla Doña Sebastiana, Isla Metalqui, Punta Chaiguaco, Isla Guafo and Isla Guamblin during the austral summers (1998, 2007, 2012, 2013, 2016 and 2018). The individuals in the colonies were counted and categorized in age classes by three independent observers. The overall abundance during the surveyed years was: 30,581±1,223; 32,155±1,286; 48,990±1,960; 55,585±509; 56,310±958 and 38,664±386 individuals, respectively. Isla Metalqui is the main breeding ground in Chile, with 56% of the population observed in these colonies during 2013 including 14,331±68 newborn pups. If we analyze the abundance of the five colonies during the years 1998, 2007 and 2012 (with available abundance data for the entire Chilean territory) we find that these colonies accounted for 90%,91%,90% and 41%,31%,34% of the total pups born in southern Chile and in the entire country, respectively. Moreover, 56%,64%,74% of the total population in southern Chile was concentrated in the five colonies in those years (from 139 colonies). A linear regression was the best-fitting model, which can be used in the future to predict the target species abundance (colonies vs. overall abundance, r=0.942). This methodological proposal contributes to the goal of obtaining a large-scale population estimate with a high level of certainty, reducing the costs of aerial surveys to provide scientific information for conservation, potential biological removal estimations (MMPA) and global protection measures.

Combining citizen science and automatic identification system to monitor marine mammals' distribution patterns

albuquerquecris@gmail.com

Monitoring marine mammals' distribution is essential for marine spatial planning. However, systematic data acquisition is expensive, time-consuming and usually associated with trade-offs of sampling effort, spatial scale, and ecosystem representativeness. Citizen Science (CSci) has the advantage of valuing citizen participation and increasing the volume of data. Here, we illustrate the advantages of the combined use of CSci protocol and Automatic Identification System (AIS) data to the monitoring of large whales' occurrence and distribution patterns within the Saguenay–St. Lawrence Marine Park, QC, Canada. CSci data collection took place from 2012 (pilot study) to 2018 on board a whale watching boat with the participation of naturalist guides. Each time the whale watching boat reduced the speed to approach a targeted species, the sighting was reported with an approximate time. AIS data were stored throughout the season, and in order to maximize its use, an algorithm was developed to define the boat's activity (observation versus travelling/searching) based on its speed, which has been validated by a systematic and independent data set. Besides providing information on survey effort, the combined use of CSci-AIS allowed positioning the sightings, estimating the time spent in observation of each species over the season and mapping of the main observation areas. CSci provided almost daily information on the occurrence and distribution of Minke (*Balaenoptera acutorostrata*), Fin (*B. physalus*), Blue (*B. musculus*) and Humpback (*Megaptera novaeangliae*) whales. Since the beginning of the monitoring 1545 excursions were sampled on 790 days covering up to 93% of the whale watching season. More than 3000 sightings of these species were reported, from which 62% were located. CSci-AIS allows fine-scale and long-term spatial data collection at low cost, provides support for marine spatial planning and conservation efforts and, additionally, empower naturalist guides and engages whale watching companies in the monitoring of the targeted species.

Comparative genomics of Sotalia guianensis and Sotalia fluviatilis: Divergence and adaptation to a riverine environment.

Dolphins belonging to the genus *Sotalia* are endemic to Central and South America and two species have been recognized: *Sotalia guianensis*, found in coastal environments along the Caribbean and the Atlantic as well as in Maracaibo Lake and the Orinoco River, and *Sotalia fluviatilis* is found in the Amazon River and in most of its tributaries. These dolphin species are an interesting model to study adaptation and evolutionary processes in marine and freshwater environments.

Previously, a comparative analysis of the mitochondrial genome provided evidence of positive selection, suggesting differences in their energy metabolism in each environment. In order to further investigate adaptive selection of the nuclear genome, we performed whole shotgun genome sequencing on two samples from each *Sotalia* species, using Illumina short read technology. We obtained an average 90,644,338 short reads (150 bp, paired-end) per sample. Genome assembling is currently underway using different platforms and algorithms (i.e Unicycler) and read mapping has been done with Bowtie2 on Galaxy against the recently published genome of the Indo-Pacific Humpback Dolphin (*Sousa chinensis*), with an overall alignment rate of 94% for *Sotalia guianensis* and of 88% for *Sotalia fluviatilis* and also against the annotated genome of the Yangtze finless porpoises *Neophocaena asiaorientalis,* resulting on an overall alignment rate of 82% for *Sotalia guianensis* and of 84% for *Sotalia fluviatilis*. These results are preliminary, but additional analyses will allow evaluation of genomic regions related to convergent adaptation to freshwater environments in these species.

Urinary parameters of the Antillean manatee (Trichechus manatus manatus) in the Caribbean

The urinalysis is an easy, rapid, inexpensive and non-invasive tool that allows the documentation of renal and systemic functioning through the increased or decreased elimination of certain metabolites. For this reason, urinalysis can help monitor the health status of manatees. However, there are no reference values for this analysis in Antillean manatees (*Trichechus manatus manatus*). The following work aimed to know the physical, chemical and microscopic characteristics of the urine of 23 manatees belonging to this manatee subspecies under human care in four Caribbean facilities. The samples were obtained through the implementation of operant conditioning; the analysis of the chemical and microscopic characteristics was carried out through the use of multiagent chemical test strips, pH reagent strips, refractrometer, and sediments were analyzed using a compound microscope. The physical characteristics found revealed that the urine of the Antillean manatees presents a straw yellow pigmentation with a clear appearance and a urinoid odor. The chemical test determined that glucose, bilirubin, ketones, proteins, blood, leukocyte and nitrites were negative and constant in all the samples analyzed. However, the urine was found to be alkaline with an average pH of 8.1 ± 0.80, and a low specific gravity of 1.010. Urinare sediment included, few squamous cells (78.3%), erythrocyte cylinders (8.3%), calcium oxalate crystals (26%), amorphous urates (4.3%), and triple phosphates (4.3%). Sperm cells were also found in 6.6% of the cases. The characterization of the urinary parameters obtained in this study constitute the first reference data for this subspecies, which, when implemented along with veterinary physical examination and other diagnostic aids, can help monitor the health status of animals that are under human care, rescued, and in rehabilitation programs for later release.

Making fish feeding possible: How humpback whales avoid dispersing schools of maneuverable prey.

Corresponding Author: davecade@stanford.edu

All rorqual whale species feed on krill, but humpback whales are generalist foragers that regularly forage on larger, more maneuverable and more energy-rich fish of various species. This foraging flexibility has likely been an important factor in their 21st century recovery from 20th century whaling. While video evidence suggests that krill feeding has very low escapement, fish are highly maneuverable and will flee oncoming predators. The proportion of a school that can be caught has not before been calculated, nor has it been shown how humpback whales using whole body acceleration avoid rendering lunge-feeding inefficient by dispersing the school. In a first of its kind study we deployed combined video and accelerometer tags on anchovy-feeding humpback whales (n = 10), then used the engulfment and kinematic data to parameterize a looming-stimulus playback to anchovies in the laboratory. Anchovies were found to respond to the changing stimulus at a mean value (1.66 rad/s) that gives sufficient chance to escape from a sea lion-sized predator. Lunge-feeding humpback whales, however, can capture 40-50% of a school because they do not reach this threshold before engulfment begins close to the prey. Using field observations of humpback whale approaches from tags and the experimentally derived anchovy escape responses, we calculated how catch percentage, and thus foraging efficiency

(energy in/energy out), is determined more strongly by the timing of engulfment in relation to the school than by the timing of engulfment in relation to whale speed. These experiments both explain why humpback lunges on fish are not always kinematically efficient and also explain why lunge feeding on fish – which we found to have ~ 7x the efficiency of feeding on krill – is worth the extra costs of the pursuit and herding behaviors commonly observed in humpback whales.

Bottlenose dolphins (Tursiops truncatus, Montagu, 1821) and underwater noise pollution: Simulate the exposure of three Mediterranean groups..

Underwater noise represents a relevant threat to marine mammals. Bottlenose dolphins (*Tursiops truncatus*, Montagu 1821) is a cetacean species categorized as "vulnerable" according to the International Union for Conservation of Nature Red List criteria as well as listed in Annex II of the Habitat Directive. This species inhabits coastal waters, which are notoriously subject to intense human use. This work focuses on the assessment of the anthropogenic noise disturbance on bottlenose dolphins in the surrounding area of the Port of Civitavecchia (northern Tyrrhenian Sea, Italy). The vocal plasticity of bottlenose dolphins in the study area was evaluated comparing recordings coming from other two Mediterranean areas (Pianosa Island and Sicilian Channel) representing two different scenarios: the first is closer to the study area and quieter due to the lower marine traffic, the second is far from Civitavecchia and characterized by an intense marine traffic.

The analysis of the whistles features together with an exposure simulation of local and foreign whistles datasets to the soundscape characterizing the Civitavecchia coastal area allowed to evaluate the noise pollution effect on bottlenose dolphins in terms of potential masking. Our data suggest a vocal behavior compensation, in terms of frequencies and intensity to the ambient noise, among the resident bottlenose dolphins. Bottlenose dolphin communications appeared to be masked by the ambient noise recorded in the main research area. Comparison obtained with the two datasets, suggests that they used to adjust some vocal behavior features to compensate the environmental noise. The results obtained from this analysis suggests that differences found in the vocal plasticity of bottlenose dolphins whistles seem to be directly proportional to the underwater noise of the area they inhabit even if geographical influences cannot be excluded.

Differential vulnerability to ship strikes between day and night for blue, fin, and humpback Whales based on dive and movement data from medium duration archival tags

We examine the dive and movement behavior of blue, fin, and humpback whales along the US West Coast in regions with high ship traffic where ship strikes have been identified as a major concern. All three species are known to feed in coastal waters near areas of high ship traffic:1) the Southern California utilized by ships using the ports of LA/Long Beach, 2) the Gulf of the Farallones west of the ports in San Francisco Bay, and 3) the Strait of Juan de Fuca, the main access for ports in Vancouver and Puget Sound. We analyzed data from 33 archival tag deployments representing over 3,000 of data that were attached with suction cups or short darts for periods >24 hours and recorded depth (≥1 Hz), fast-lock GPS positions and other deployment-specific sensors. There were clear differences among the three species but all showed a distinct diurnal difference in diving behavior. While dive depth varied among animals based on where prey was located, whales spent a high proportion of their time closer to the surface where they would be more vulnerable to ship strikes at night than in the day. This was most pronounced for blue whales where vulnerability was twice as high at night compared to the day. We also found differences in movement patterns of whales between day and night. Movements were more localized to specific areas in the day near prey resources while at night these movements often involved directional movements (though sometimes circling back to the same area by the end of the

night). We show how in several specific areas like the Santa Barbara Channel, these differences in movements and locations translate to a very different overlap with shipping lanes at night compared to the daytime locations, which is the basis for most sighting data.

Working together to reveal the bigger picture: Tursiops truncatus truncatus movement patterns along the U.S. Florida east coast.

East coast Florida common bottlenose dolphins, *Tursiops truncatus truncatus,* are distributed in a longitudinal continuum within inland waterways. Seven regional studies have identified local populations with resident and seasonally transient dolphins. However, study area boundaries limit understanding of distribution and movement patterns between these geographically separated regions. To reveal the bigger picture, a multi-organizational consortium conducted semiannual photo-identification surveys from the Florida-Georgia border to Titusville, Florida (331 km). The area was divided into segments to allow a one-day sampling period: S1 (FL-GA border to S2), S2 (St. Johns River), S3-5 (connecting waterways), and S6 (Mosquito Lagoon). During 28 surveys between August 2011 and January 2016 a total of 6,896 dolphins, including 196 neonates, were observed. Of the 222 distinct dolphins sighted in ≥5 seasons, 78% exhibited significant regional and seasonal fidelity to one or more segments. Habitat preference and spatial autocorrelation (SAC) analyses identified five main discoveries that no single study could elucidate. First, more dolphins avoided S1 (92%) than any other region; additionally, dolphins exclusive to S1 exhibited random distribution patterns and year-round site fidelity with sightings clustered seasonally. Second, small populations of year-round residents with significantly clustered seasonal sightings were identified in S2 (n=14) and S6 (n=48). Third, 87 dolphins utilized multiple segments. SAC analyses revealed that while these dolphins were randomly distributed within their range, their sightings were significantly clustered seasonally. Fourth, preference analyses, SAC analyses, and resight rates, coupled with the limited number of dolphins exclusive to each segment, suggest that S3 and S4 are passage zones and that S5 encompasses only part of individual dolphin ranges. Finally, resights among S2, S5 and S6 suggest that S5 is a key mixing area. Further collaborative studies of habitat use and behavior will help to explicate the year-round importance of these passage and mixing areas.

"Broken Heart Syndrome" in Cetaceans: Histological, histochemical and immunohistochemical study.

Both humans and other animals, like cetaceans, have evolved mechanisms to cope with stressful situations in their lives. However, it is possible to develop different diseases when the stress is excessive or prolonged over time. An example is the Stress Cardiomyopathy (SCMP), also known as

"Takotsubo disease", "Broken Heart Syndrome", or "Apical Ballooning Syndrome", which is a reversible cardiomyopathy (CMP) in humans, most often occurring after an emotional or physical stress. Free-living cetaceans are threatened, daily, by a wide variety of stressful situations that affect their well-being and previous studies suggest that cetaceans would be especially predisposed to develop stress cardiomyopathies due to the characteristic of their cardiovascular adaptations. Different pathological entities have as central in its pathogenesis the acute stress so for this study we examined heart samples, from sixty-seven ashore cetaceans (48 stranded alive, 7 died from ship collision and 12 from bycatch) on the coast of the Canary Islands from 2000 to 2016 and on the coast of Andalucía from 2011 to 2014. As it occurs in the SCMP, all the above mentioned pathological entities share the same microscopic findings, characterized by acute or subacute cardiac degenerative necrotic lesions, presenting a perivascular pattern and consisting of: contraction band necrosis (49.25%), wavy fibers (43.28%), cytoplasmic hypereosinophilia and pyknotic nuclei (100%), perinuclear vacuolization (97.01%); vascular changes illustrated as congestion (67.41%), interstitial edema (38.81%) and hemorrhages (22.38%); infiltration of inflammatory cells (25.37%) and presence of interstitial myoglobin globules (43.28%). Immunohistochemically, it is also characteristic the depletion of cardiac troponin I, cardiac troponin C and myoglobin, besides the expression of fibrinogen in the degenerated/necrotic cardiomyocytes. Likewise, we intend to provide more knowledge about the pathologies and their implications in the conservation of cetaceans, through the reduction of mortality of these animals, their treatment and subsequent rehabilitation to the marine environment.

Observations during a springtime Bering Sea research cruise in a year of record-low sea ice extent.

michael.cameron@noaa.gov

A warming climate is predicted to reduce the volume, extent and duration of Arctic sea ice. Ribbon, bearded, ringed and spotted seals ('ice seals') use sea ice in the spring as a platform for pupping, nursing and molting. In April 2014, 2016 and 2018, we conducted research surveys at the Bering Sea ice edge to collect samples and measurements from ice seals and to deploy seal-borne satellite-tags to record the seals' movements. In April 2018, the southern ice edge was 375 km farther north than in previous years, approximating conditions predicted by climate models after 2050. 2018 might therefore prove useful as a case-study for a future Bering Sea.

In 2014 and 2016, most of our sightings in the marginal ice zone were of ribbon seals, but we observed almost none at the more northerly ice edge in 2018. There were no reports of ribbon seals hauling out on shore in numbers that would explain their very low abundance at the ice edge, so ribbon seals may have moved west to occupy sea ice in Russian waters. April is the peak of pupping for ribbon seals and they are not known to pup or nurse in the water. If instead they remained in their typical breeding areas near the shelf break, they would likely have suffered a significant pup production failure.

There is evidence for a decline in the body condition (mass/length) and blubber thickness of spotted seal pups over the period 2014-2018 ($p<0.05$). The reasons for these declines are not yet known, but a more northerly ice edge would require nursing mothers to occupy areas farther from their usual foraging zones near the shelf-break. Reduced access to preferred prey could in turn, induce spotted seal mothers to produce less milk of sufficient quality, affecting the condition of their pups.

Bad management and vertical decision-making are tied with failure in the reduction of bycatch of Lahille's bottlenose dolphins (Tursiops truncatus gephyreus) in a protected area in southern Brazil

In this work we investigated the artisanal fishermen's perceptions about Lahille's bottlenose dolphins and the gillnet fishing exclusion area in the Patos Lagoon Estuary and coastal areas, southern Brazil. This protection area (PA) was established by the Brazilian Government in 2012 aiming at reduce dolphin bycatch. Between April 2016 and December 2017, 49 artisanal gillnetting

fishermen were interviewed using a snowball approach and semi-structured questionnaire. During the interviews, fishermen were asked to draw the areas they use to fish and the geographic coverage of the PA in a map with known local references. Maps were digitalized and georeferenced in a grid of 20mx20m pixels, from which a series of information were obtained. None fishermen interviewed perceived dolphins as competitors nor reported bycatch. Most fishermen stated, "other fisheries, allowed to operate inside the protected area, incidentally capture bottlenose dolphins". According to the interviews, all fishermen are aware about the existence of a PA, but are ignorant about the reasons why this area was established and its boundaries. Maps analysis revealed that the mean fishing area (226km2) is much larger than the extension of the PA (95km2). This PA represents 38% of the mean gillnet fishing area. When operating inside the PA, fishermen uses 62% of its range, concentrating fishing effort where density of dolphins is highest. Therefore, we have verified that the artisanal gillnet fishing fleet continues to operate illegally within the PA and that other types of artisanal fisheries contribute to the bycatch – an information corroborated by recent records of bycatch during beach gillnetting and trawling activities. We diagnosed that the main reasons for the failure of the PA would be a top-down decision-making and the subsequent failure of the Brazilian government in the management process, which has caused serious social conflicts in the area where the environmental problem

Approach to a predictive model of habitat selection by blue whales (Balaenoptera musculus), based on satellite oceanographic measurements, between Chiloense Ecoregion and Corcovado Gulf, Chile (42° - 45°S).

ccantergiani@fundacionmeri.cl

Blue whales, categorized as "*endangered*", frequent the inner sea of Chiloe (ISC) waters in Chile, intensifying their presence during the austral summer, associated with high productivity levels, being a key site for population recovery. Considering the spatio-temporal difficulties to register cetacean sightings, an alternative is the SDM studies through remote sensing. This research develops approximations to a predictive model for habitat selection by blue whales, through satellite oceanographic measurements.

Presence data were recorded from 2014 to 2017 during the summer of the southern hemisphere, between the Chiloense eco-region and the Gulf of Corcovado. Environmental satellite data was obtained from MODIS-Aqua. Spearman test was applied to determine correlation between parameters and presence data. To develop the predictive model, a species distribution model of maximum entropy (SDM-MaxEnt) was used.

Spearman's test indicates that the association of PAR + POC (r = 0,785), turns out to be the greater correlation that explains the habitat selection. Besides, MaxEnt model provides that the highest percentage contributions for environmental parameters was POC=45,1%, SST=33,5%, and Chl-a=11,2%. For this research, the habitat selection model places the highest probability of encounter in the Northeast area of the ISC.

Due to the high variability of the marine environment, determining habitat selection is a significant contribution to the ecology and distribution knowledge of blue whales. This allows us to develop a predictive model for habitat selection by blue whales, associating field observations with environmental parameters as predictors of habitat selection and the probability of encounter, in this intense climate change scenario.

Home and away: The importance of the Wild Coast of South Africa as a habitat for Indo-Pacific bottlenose dolphins.

The Wild Coast of South Africa is characterised by the annual sardine (*Sardinops sagax*) run which attracts large numbers of top predators including cetaceans, fish, and birds during the austral winter. Adverse sea conditions and limited infrastructure have largely restricted research on cetaceans to aerial surveys during this sardine run. The importance of the region as a habitat for cetaceans is therefore, poorly understood. Here we present the main findings of boat-based photographic identification studies of Indo-Pacific bottlenose

dolphins (*Tursiops aduncus*) in the Wild Coast over the period 2014-2016. The study was conducted in three marine protected areas (MPA's), visiting each at least once per year and selected physico-chemical variables were measured. During this study, 2149 individual bottlenose dolphins were identified. The majority of animals (90%) were only observed once, with 225 (10.5%) re-sighted on 2-4 occasions, with an average of 305 days (range: 88-705) between re-sightings. However, 162 individuals (7.5%) were re-sighted within a 3-week field trip with an average of 3.7 days (range: 1-13) between these re-sightings. Importantly, 12 individuals were re-sighted in one MPA during all three surveys suggesting some degree of residency within the region. Environmental factors had minimal effect on individual and sighting density. Sea conditions limited surveys/time at sea leading to insufficient effort to estimate population size. Indeed, the discovery curve never reached an asymptote, indicating that a large portion of individuals remain to be identified. However, the number of individuals reported here is the largest for *Tursiops spp.,* suggesting that waters off southeastern South Africa are sufficiently productive to support huge numbers of dolphins. Moreover, findings suggest that the presence of sardines off the Wild Coast is not the only mechanism attracting these animals here and further research is necessary to understand bottlenose dolphin movement along the southeastern coastline of South Africa.

Influence of sample location on blubber cortisol concentration in striped dolphins (Stenella coeruleoalba)

Given that hormone analysis can provide valuable insights into the animal physiology and the overall health status, considerable interest is focused in the measurement of cortisol as a physiological indicator of stress. In wild cetaceans, blubber sampled from projectile biopsies is one of the main matrixes used for cortisol analysis. The body location from which blubber is collected could potentially influence the levels of the hormone, but to date, no studies have yet addressed this issue. Therefore, the aim of the present study was to evaluate whether blubber cortisol is affected by the body region in striped dolphins (Stenella coeruleoalba). Subjects used were stranded dolphins found either dead or alive throughout the Catalan coast. Blubber samples were collected from 10 individuals at five different locations during necropsy: cranial and caudal areas in relation to the dorsal fin, and dorsal, central and ventral areas in relation to the pectoral flipper. Cortisol was extracted from blubber following an adapted organic-solvent extraction method and determined by enzyme immunoassay. Differences in cortisol concentrations across anatomical regions were tested by using a Friedman test. Mean (± SD) cortisol values obtained were as follows (values are reported as ng cortisol/mg blubber): cranial 7.45 (± 6.26), caudal 7.38 (± 5.69), dorsal 8.22 (± 7.31), central 8.53 (± 7.48) and ventral 10.31 (± 9.18). Cortisol levels did not vary with sampling location on the body (Friedman test: $X2(4) = 7.84$, $p = 0.098$), suggesting that hormone concentrations are uniformly distributed throughout the whole body blubber. In free-ranging marine mammals, blubber samples are usually biopsied by remote methods. This approach can be affected by the ability and training of the operator, likewise by the animal body size and swimming speed. Therefore, these results provide new evidence that potential inaccuracies of projectile biopsy sampling may not influence blubber cortisol concentrations.

Cuvier's beaked whales of Guadalupe Island: A possible resident population in a "natural laboratory" of México.

Cuvier's beaked whale (*Ziphius cavirostris*) is one of the most abundant and widespread species of beaked whale in the world, and yet its natural history remains very poorly understood. A pilot

study undertaken at Guadalupe Island, México in 2009 revealed a high encounter rates of this species, as well as the presence of mother-calf pairs. Due to its low levels of human disturbance, as well as its protection as a Biosphere Reserve, Guadalupe Island represents a "natural laboratory" to research a rarely seen species in a relatively pristine environment. Recent field trips to Guadalupe Island were undertaken from October 2016 to November 2018. The search effort was conducted in a non-systematic manner. During 397.53 hours of search effort we recorded 210 sightings of Cuvier's beaked whales. Although surveys were conducted all along the east coast of the island, and a two-day circumnavigation around the island was also performed, beaked whales were exclusively sighted within Bahía Norte and Campo Lima, both with presence of submarine canyons. Group size ranged from 1 to 12 individuals, with a mean of 2.82 (SD = 0.44, N = 210). Only six of the total sightings included mother and calf pairs. The photo-ID catalog from Guadalupe, started opportunistically in 2006, now contains 76 unique individuals, including some whales with a sighting history spanning more than 10 years and recaptures of 33 whales across various time scales. These include a number of associated mom/calf resightings, which are critically important to understanding weaning in this species. A comparison of photo-ID catalogs to date has resulted in no matches between the Guadalupe population and the Southern California population. Therefore, results suggest a high degree of site fidelity among some of the sampled animals, and thus raise the possibility that this is an island-associated resident population of Cuvier's beaked whales.

Haul-out behavior of male Antarctic fur seals Arctocephalus gazella during late summer and early fall at the South Shetland islands

Male Antarctic fur seals aggregate at male only haul-out sites in the South Shetland islands after the breeding season. We conducted visual census at Deception Island in early March 2019 to assess the demographic structure and population density at three haul-out sites (Collins Point, Whalers Bay, Baily Head). We also instrumented 14 subadult males at Collins Point and satellite tracked them from late summer to early fall to assess site fidelity and the duration of feeding and resting bouts. Demographic structure was rather homogeneous at the three sites and subadult males represented 46-63% of the population everywhere. Furthermore, males concentrated in the first 80 m above the water limit at the three sites, although adults concentrated in the first 40 m and subadults from 40 to 80 m above the water limit. Population density declined markedly 80 m inland, but some males moved as much as 220 m inland. Population density in the preferred part of the beach was much higher at Baily Head (10 males 400 m^{-2}) than at the other sites (Collins point: 6.2 males 400 m^{-2}; Whalers Bay: 4.7 males 400 m^{-2}), probably because of an easier access from the ocean. On average, the foraging bouts of subadult males lasted 5.7 ± 1.0 days and they rested at haul-out sites for 2.1 ± 0.6 days. Subadult males usually shifted haul-out sites between foraging bouts, which resulted in an extremely low site fidelity: only 5 out of 14 subadult males returned to Deception island at least once during the first 40 days after tagging and only 1 of them returned to Collins Point. Furthermore, 5 males leaved the Bransfield Sea to move south.

Population biology and abundance of Common Bottlenose Dolphins (Tursiops truncatus) in the Cap de Creus Marine Protected Area, North-western Mediterranean

Cardona-Barreña, Alicia[1]; A. Chicote, Carla[1]; Álvarez de Quevedo, Irene[1]; Gazo, Manel[2]

alicia.cardona.b@outlook.com

Common Bottlenose Dolphin (CBD), *Tursiops truncatus*, presence in the Cap de Creus Marine Protected Area (MPA) has the highest density for this species in the Catalan coast. However, no dedicated survey had yet been done in the area, which represents an important habitat for Mediterranean CBDs, classified as 'Vulnerable' by IUCN, due to underwater canyons present within two European Sites of Community Importance (including Cap de Creus canyon). In 2017 we started a two-year CBD study here to investigate this population through photo-identification surveys. 1183 nm of effective effort during 25 surveys days were carried out in 2017 and 1952 nm during 33 surveys days in 2018. 12 CBD sightings were recorded in 2017 and 36 in 2018. Average group sizes recorded were 8.3 (2017) and 10.3 (2018), however maximum group sizes were 25 (2017) and 46 (2018). Presence of calves was detected in 67% (2017) and 62% (2018) of the encounters. A total of 6897 photographs in 2017 and 21481 in 2018 were taken, from which best good-quality pictures were selected to be processed. Photo-ID efficiency was of 85% (2017)

and 100% (2018). 77 individuals (including 7 calves) were identified in 2017 and 388 (including 46 calves) in 2018; from these 71 (2017) and 337 (2018) were marked individuals. 4 recaptures were identified within 2017, 3 within 2018 and 4 between 2017-2018, resulting in 300 marked individuals being registered in this MPA's Bottlenose Dolphin Catalogue. Closed population capture-recapture models were used to assess abundance from left and right catalogues separately. 2017 left-catalogue data (n=45) resulted on a preliminary population abundance estimate of 239 (SE = 110, 95% CI 113-594). Results suggest this MPA could represent important breeding and feeding areas for the Mediterranean CBD population and, as fisheries interaction has been detected, also stress the need for further investigation.

Connecting conservation policy and marine mammal science: A survey of attitudes and trends in publications.

Carini, Roxanne[1]; O'Donnell, Brady[1]; Cornish, Vicki[2]; Daniel, Raychelle[3]

Understanding attitudes about engagement in conservation policy within the marine mammal scientific community may help non-governmental organizations, federal agencies, and other management entities develop and enhance partnerships with scientists. To assess current attitudes and levels of engagement and how they have changed over time, we re-administered a survey and extended a literature review that were conducted in 2007 (Cornish and Daniel, Ocean Conservancy). In the 2007 survey, of the 305 respondents who were marine mammal researchers, 90.5% said their work had conservation implications and 59.3% believed they should engage in actions to promote marine mammal conservation. However, only 28.5% had engaged with federal, state or local government officials or agencies. In the twelve years since the initial study, social media use, the availability of science communication training, and public awareness and action around climate change and ocean degradation issues have increased significantly. Due to these and other influences, we expect the re-administered survey to reveal that the level of engagement has increased. We provided modern methods of science communication as survey response options and included questions about how researchers receive conservation policy information. In the previous literature review, of the 591 Marine Mammal Science journal articles reviewed from 1985-2007, less than 4% explicitly referenced conservation. However, almost 15% of the roughly 880 articles reviewed from the same journal for the shorter and more recent time period of 2008-2018 explicitly connect research to conservation. Our full literature review included other journals, such as Marine Policy and Aquatic Mammals, and considered keywords related to conservation, like 'policy' and 'management'. The results of this study will be shared broadly with survey respondents and with interested stakeholders looking to improve communication efforts for the conservation of marine mammals.

Do harbour porpoises (Phocoena phocoena) in the Baltic Sea prefer certain areas for foraging?

Protecting foraging areas is essential in the protection of a species. The harbour porpoise population in the Baltic Sea is listed by the IUCN as critically endangered, and in this study we aimed at identifying areas important for foraging within its distribution range. Foraging buzzes, defined as parts of click trains with short inter-click-intervals (ICIs), were identified in the acoustic dataset from the SAMBAH project, which collected passive acoustic monitoring data from the Baltic Sea. The proportion of buzz ICIs to total ICIs was calculated per station per day per diel phase (dawn, day, dusk and night), and a general additive model was constructed to investigate if foraging areas could be identified within the harbour porpoise distribution range. Two main clusters of animals were evident in the data: one in the southwestern Baltic Proper and one in the Central Baltic Proper, with the sample size in the Central Baltic Proper being small compared to that in the southwestern Baltic Proper. Results show that on the scale of the 304 sampling stations (placed in a grid with 23.5 km between stations) no specific foraging areas could be identified. However, a significant difference could be seen in foraging activity between the two clusters, with a higher proportion of buzz ICIs in the Central Baltic Proper. Buzz ICIs were present in all diel phases, but the proportion of buzzes was significantly higher during night and dawn. Results are interpreted to agree with previous studies suggesting that harbour porpoises need to eat

almost constantly, meaning that foraging should occur in the entire distribution range and throughout the day. The higher buzz ratio in the Central Baltic Proper could indicate differences in porpoise foraging behaviour, prey species, and/or prey quality between the two porpoise populations.

The curious case of hairless seals.

Ahola, Markus[1]; Carlsson, Anja[2]

Corresponding Author: anja.carlsson@nrm.se

Hair loss has been observed in several marine mammal species and can have consequences for thermoregulation, impacting on metabolic rate and nutrition. Phocids spend a significant time on-land to breed, pup and rest, during which time fur contributes to an estimated 30% of thermal insulation. Alopecia, a condition of localized hair loss, has been observed in a number of seal species. Complete hair loss in seals has, however, rarely been reported in the wild. Here, we present, the first observations of apparent completely hairless grey (*Halichoerus grypus*) and harbour seals (*Phoca vitulina*) in Swedish waters. Hairless seals were identified from photos taken in august during the annual Harbour seal aerial surveys in 2015-2019. Each photo was combined with a GPS coordinate allowing us to pinpoint the locations of the hairless seals. The etiology of this condition is currently unknown and needs to be confirmed by close-up observations and sampling. As top predators marine mammals are ecosystem sentinels and the emergence of a hair loss syndrome may be an indicator of an ecological or biological disturbance in the marine environment.

Variation in ringed seal habitat use and feeding across a latitudinal gradient of sea ice.

Ringed seals are vulnerable to rapid climate-driven sea-ice decline given their dependence on ice for subnivean lairs, moulting, and ice-associated prey. Ringed seals have a broad latitudinal range that experiences large variation in sea-ice coverage from transient coverage in their southern limits to persistent coverage in the north. Therefore, ringed seals likely adjust their habitat use and feeding to varying regional sea-ice conditions. Our objective is to investigate how the density, occurrence, and diet of ringed seals varies with sea-ice conditions across their latitudinal range. We conducted aerial surveys using infrared and digital imagery to obtain density estimates of ringed seals in Alert (82.5°N), Pond Inlet (72.7°N), and Arviat (61.1°N), Nunavut in May-June from 2016-2018. Pairing georeferenced sighting positions with high resolution remote sensing imagery allowed for novel investigation of fine scale habitat selection of ringed seals. Stable isotopes were used to infer trophic dynamics and highly branched isoprenoid (HBI) lipids identified the relative contribution of sea-ice carbon in ringed seal diets using muscle and liver from Arviat, Pond Inlet, and Grise Fjord, Nunavut (76.4°N), and Qaanaaq, Greenland (77.5°N) from September-November in 2015-2018. Ringed seal densities were highest at mid-latitude Pond Inlet (0.46-0.92 seals/km^2), intermediate in Arviat (0.45 seals/km^2), and lowest at high-latitude Alert (0.05 seals/km^2). Seals also selected limited first-year ice in the multi-year ice dominated Alert. Muscle samples (n=41) significantly increased in δ^{15}N from 15.61‰ to 16.48‰ ($t=2.88$, $p=0.0063$) and decreased in δ^{13}C from -21.15‰ to -19.76‰ ($t=11.26$, $p<0.0001$) between Arviat and Pond Inlet, respectively. Liver samples (n=44) similarly increased in δ^{15}N ($t=3.23$, $p=0.0024$) and decreased in δ^{13}C ($t=15.62$, $p<0.0001$) between Arviat and Pond Inlet. Results from HBIs will also be discussed. As sea-ice decline continues, our results provide insights into how a key Arctic species adjusts to regional sea-ice conditions and inform co-management with northern communities.

Human influence on common bottlenose dolphin (Tursiops truncatus) strandings in the northern Gulf of Mexico

Corresponding Author: rcarmichael@disl.org

Human interactions (HI) with marine mammals pose a threat of increasing global concern for conservation, but human activities can also benefit stranding response through enhanced monitoring and reporting of stranded animals. The net effect of these human influences on stranding demographics is not well studied but has potential to influence stranding numbers and how we manage and conserve populations. To quantify human influence on stranding events in terms of direct contributions to strandings and stranding response effort, we determined the number and proportion of total and HI-related bottlenose dolphin (*Tursiops truncatus*) strandings normalized to shoreline length in each northern Gulf of Mexico (nGOM) state. We used the Deepwater Horizon oil spill (DWHOS) as a benchmark to compare periods of lower (pre-) and higher (post-DWHOS) response effort. Alabama was used as a case study to define potential interannual and spatial variation in human influences on strandings because sufficient data were available to make comparisons for this state. Our findings indicate a region-specific increase in strandings along the nGOM coast from Louisiana through Alabama, with the greatest proportion of HI strandings in eastern nGOM (Alabama, western Florida). While the overall increase in stranding numbers is likely due to a combination of increased stranding occurrence and response effort following the DWHOS, HI-related standings increased independently from the DWHOS. Alabama was identified as a hotspot of HI strandings, having the highest density and percentage of (non-oiled) HI strandings since 2010, primarily fishery interactions. This study highlights the: 1) value of high-quality local and regional data to support analysis of patterns in marine mammal stranding events, 2) need for sufficient monitoring and stranding network operations, and 3) importance of understanding negative and positive human influences on stranding demographics to support targeted conservation efforts.

New kids on the block! Studying stereotyped whistles in a resident population of common bottlenose dolphins

The Sado estuary, Portugal is home to a small, resident population of common bottlenose dolphins (*Tursiops truncatus*) that have been the focus of multidisciplinary research. The long-term occurrence of stereotyped tonal calls has been documented for more than 20 years, and these emissions with stable frequency modulation contours have been hypothesized to be signature whistles. These whistles are thought to broadcast individual identity, and are considered important vocalizations to maintain cohesion in bottlenose dolphin groups. In order to support the attribution of signature function to stereotyped whistles, the SIGID criterion has been applied to field recordings. This study attempts to document the occurrence of new signature whistles in a well-known, stable population where newborns were observed recently. From 2016-2018, bottlenose dolphins' underwater emissions were recorded and the composition of groups was assessed using photo-identification. The complete census of this population during this study was at 31 individuals: 25 adults, 2 juveniles, 4 calves. Based on the acoustic analysis, 169 good-quality whistles were identified, and classified into categories by four independent judges, through visual inspection of spectrograms. A total of 11 stereotyped whistle contours were identified, of which 4 were detected for the first time. Interestingly, during the same period of time 4 new calves were observed. Only three whistle types were validated as signature whistles by the SIGID method: two previously identified contours and one of the new additions. Work is in progress to explore the link between recorded stereotyped whistles and identified individuals in the groups of these resident bottlenose dolphins.

Monitoring marine mammals in Brazil: Beyond the legal commitments.

North Atlantic right whales (NARWs; *Eubalaena glacialis*) and blue whales (*Balaenoptera musculus*) are listed as endangered under the Canadian Species at Risk Act. NARWs were recorded in the GSL as early as 1976, but not observed in large numbers until surveys began in 2015. Surveys have reported consistent blue whale presence in the GSL since they began in 1979 and individuals have been recorded in elevated vessel traffic areas including the GSL shipping lanes. Shipping traffic has been identified as a threat to both these species in their respective recovery strategies.

Since the 2017 NARW unusual mortality event where 57% of necropsied carcasses showed evidence of vessel collision, vessel-strike mitigation in much of the GSL has consisted of seasonal speed restrictions aimed at reducing the probability of lethal vessel strikes for NARW. Necropsy evidence has not initiated protection for blue whales as their carcasses sink after death and are less likely to be necropsied.

Despite the NARW (est. 411 individuals) and Northwest Atlantic blue whale populations' (est. <250 adults) endangered statuses, current GSL vessel strike mitigation focuses exclusively on NARWs. Though blue whales are sighted in the GSL shipping lanes, speed restrictions are not triggered by their presence. Additionally, the extent of the speed restriction zone does not include high density blue whale aggregation areas such as the Saint Lawrence Estuary.

This study aims to evaluate the efficacy of the static speed restriction zone and dynamic shipping sections in reducing lethal vessel strike risk to blue and right whales using Automated Identification System (AIS) vessel traffic information, whale sightings and visual survey effort data. This is achieved through identifying areas of elevated risk for each species, evaluating changes in risk, and assessing whether risk to blue whales increased as a result of the current management scheme for NARWs.

Characterization of degenerative diseases on marine mammals of Peru: Increased incidence over 10 years.

Carrington, James[1]; Yaipen-LLanos, Carlos[2]

Corresponding Author: carrington@orca.org.pe

Research and data on marine mammal health in Peru has been recorded over the past 18 years by the Organization for Research and Conservation of Aquatic Animals (ORCA). This presentation provides a clear description of degenerative diseases currently affecting marine mammal in the Peruvian waters. Seven species were recorded stranded between 2008 and 2018. Samples collected included skin, blubber, liver, heart, lymph nodes, intestines, stomach, bladder, lung, and blood. Characterization of degenerative disease included external clinical signs before death: emaciation, bone projected lumps from hips, lumbar vertebrae, shoulders, ribcage, chest and rostrum; transparent discharge from nose, weakness, limping, pale mucous or cyanosis, lethargic behavior, dyspnea, hypoxia, and dehydration. Necropsy abnormalities showed ascites or hydrothorax, abnormal coloration of intestines, hyperplasic bladder, heart with hyperplasia on left or right side, hemoprotein liquid in abdomen or thorax, lung collapse with veins constricted and hemorrhoidal white structures, and white solid structures around thoracic or abdominal organs. Formalin fixed samples with H-E stain confirmed neoplasm in 83% of the cases (N=103). Acquired data has shown the significant increase of degenerative cases between 2008 and 2018. from 1

to a median of 12 per year, with a peak of 36 cases recorded in 2017. The impact of oncogenic pollutants on marine mammals plays a critical role in understanding population dynamics and disease risks. As oceans continue to increase in pollutant levels, marine mammals are playing a critical role as sentinel species for possible physiological effects that could occur in humans, as occurrences of neoplasm originating in the lymph nodes and lungs correlated with mercury toxicity. An analysis of known effects of pollutants and areas of needed research will be outlined based on these cases. Understanding the impact of focalized pollution will be a strong aid in determining the next steps towards restoring the ocean's health.

Circumpolar southern right whale foraging ecology and population recovery: Insights from isotopes.

Southern right whales (*Eubalaena australis*) are slowly recovering from several centuries of exploitation. While extensively studied on coastal wintering grounds, the species' foraging ecology on offshore summering grounds remains poorly understood. This knowledge gap needs to be addressed, as there is a growing body of evidence that environmental conditions on high-latitude foraging grounds shape population dynamics, and behavioural mechanisms may limit the ability of the species to adapt to predicted shifts in prey distribution linked to climate change. Therefore, it is likely that the quality and predictability of food resources will be a major factor in population recovery. This hypothesis has formed the basis for a Southern Ocean Research Partnership (SORP) theme entitled 'The right sentinel for climate change', which aims to link foraging ground variability to population recovery in the southern right whale. We will present progress on a SORP-funded global initiative based on a large carbon (δ13C) and nitrogen (δ15N) isotope dataset derived from skin samples collected from Argentina (n = 250), Australia (n = 84), Brazil (n = 49), Chile (n = 1), New Zealand (Auckland Islands n = 460), and South Africa (n = 131). A validation study to account for variation in lipid-extraction procedure by different primary labs is underway using a subset of samples. The standardised dataset will be analysed to investigate differences in skin isotope values related to region, sex, and collection era. The skin isotope data will then be compared to Southern Ocean δ13C and δ15N isoscape values. By matching whale skin isotope composition to isotopically distinct regions within the isoscape, after adjusting for trophic discrimination and accounting for sources of error, we aim to identify the most likely locations for an individual's summer foraging grounds. Ultimately, habitat models will be generated to describe the

environmental characteristics of these foraging grounds.

Predicting the at-sea distribution of sympatric grey and harbour seals in the United Kingdom using habitat preference models

The United Kingdom hosts globally important populations of both grey and harbour seals. While grey seal numbers have increased steadily over the last 60 years, harbour seals are experiencing dramatic population declines in some regions, with no causal factor identified. The distribution of both species overlaps in many areas. Grey seals have been reported to predate harbour seals, and their similar diets suggest that they may also be competitors. These factors, coupled with increasing potential for anthropogenic disturbance due to offshore construction and habitat modification, mean that there is a growing need to understand the drivers of at-sea distribution for both species. Previous studies have predicted at-sea distribution based on patterns of space use derived from telemetry data. However, this approach does not allow robust predictions of distribution emanating from haul-outs for which there are no associated telemetry data. Using high-resolution GPS tracking data from 95 grey and 280 harbour seals, we modelled regional habitat preference as a function of environmental covariates in a use-availability framework. Environmental drivers of at-sea distribution varied between the species and among regions, highlighting the complex spatial dynamics of phocid seal ecology in the UK. Spatial predictions of seal distribution were scaled by population estimates at each known haul-out site, and merged to create a UK-wide distribution map for each species for use in marine spatial planning.

Gender-based differences in body condition in humpback whales on the Hawaiian breeding grounds during a period of reproductive decline

Cartwright, Rachel[1]; Venema, Amy[2]; Garlington, Stacy[2]; Yarborough, Sarah[3]; Shapiro, Nathan[4]; Jaeger, Alan[3]

Between 2013 and 2018, as three potent climatic disruptions impacted the North Pacific, we documented a steep decline in the reproductive rate for the newly designated Hawaiian Distinct Population Segment of humpback whales, *Megaptera novaeangliae*. Encounter rates for mother-calf humpback whale pairs within our study area on the Hawaiian breeding grounds fell by 75% during this period. Additionally, while numbers of adult whales stayed relatively constant, anecdotal reports of malnourished whales increased during this time. Here, we provide regional encounter rates for the 2019 season, along with quantitative details of body condition for maternal females and likely males during this period of disruption. Beginning in 2016, we collected aerial imagery of samples of all cohorts using a small UAS. To address the limitations of the onboard altimetry included in the UAS, standardized calibration data were collected within each flight. Using still images extracted from aerial video and standard photogrammetry software, we collated details of body morphology and calculated the ratio of the dorsal surface area to body length to provide a condition estimate for each individual. Results highlight gender-based differences over this period. For maternal females, body condition remained consistent throughout the aerial study period (2016-2019). In contrast, for likely males (i.e. escorts to mother-calf pairs and adults seen in multiple groups, presumed mostly males), body condition estimates increased by 16% in the 2019 season compared to previous years ($t = -2.940$, $p = 0.007$). Combining these findings with our sighting data suggests a gender-specific response in migratory behavior during this time. Potentially, males, albeit in lesser body condition, migrated to the breeding grounds throughout this period of nutritional stress. In contrast, female reproductive activity and associated migratory behavior may have been constrained by body condition during these challenging times.

Passive acoustic platforms to investigate spatiotemporal patterns in distribution and acoustic behavior of Indo-pacific humpback dolphins southwest of Hainan island, China.

Passive Acoustic Monitoring (PAM) offers a non-invasive and reliable method to survey acoustically marine mammals and provide information on their distribution and activities at high spatiotemporal resolution. Indo-Pacific Humpback dolphin (*Sousa chinensis*) is a species inhabiting the tropical and warm-temperate waters of the eastern Indian Ocean and Southeast Asia and a new record was logged in 2014 in the coastal waters southwest of Hainan Island (South China Sea). The significant recent increase in coastal development in this area, related to economic growth linked with touristic business, has resulted in several activities (e.g. seashore construction, coastal urbanization, artificial islands) that could impact the dolphin habitat. We are investigating the long-term distribution of this population using an array of underwater platforms installed in shallow waters (10-20 m depth). In each PAM site, an acoustic stationary recorder (SoundTrap) is installed periodically from Feb 2018. A sampling frequency of 288 kHz with 16-bit quantization was chosen. We established a recording sampling protocol of 5 min every 30 min, with about two months of data acquisition with no-battery recharge. The PAM survey that we are applying with multiple platforms encouraged us to use automatic analyses methods. A detection algorithm was developed in MATLAB to identify echolocation signals (clicks) of Indo-Pacific humpback dolphin. Here, results on species distribution are presented across multiple temporal and spatial scales. Moreover, the accuracy of click detection process was examined through the different locations and compared with an acoustic click data logger (A-tag) installed in each platform. The acoustic presence of dolphins was checked via manual approach (spectrogram visualization and listening, Raven Lite software) and other signals of interest (natural, biological and anthropogenic sources) were identified in correspondence with dolphin vocalizations.

Spatio-temporal characterization of cetacean strandings and main causes of mortality along Western Southern Iberia, 1978-2017

Cetacean strandings data can provide insights into the long-term dynamics of populations, and threats they face. This work investigated cetacean strandings collected along the southern Portuguese coast (Algarve) between 1978 and 2017, seasonal and annual trends in the number of strandings for all strandings identified to specie level (N = 887), and for the five most frequently reported species: common dolphin, *Delphinus delphis* (39.0 % of records), striped dolphin, *Stenella coeruleoalba* (9.8 %), minke-whale, *Balaenoptera acutorostrata* (7.7 %), bottlenose-dolphin, *Tursiops truncatus* (7.4 %) and harbour porpoise, *Phocoena phocoena* (4.2 %). Analysis showed that the relative frequency of strandings on the overall and for the five most stranded species increased significantly recently in the most recent period (2010-2017). Seasonal peaks in strandings frequencies were only significant for minke-whale, between March and June. Strandings of all species, but especially bottlenoses and porpoises, occurred more frequently on the leeward (eastern Algarve) side of the coast. Of the 887 cetaceans strandings registered, it was possible to investigate the cause of stranding for 450 cetaceans (50.7%) and about 50 % of these individuals died of anthropogenic causes, mainly due to bycatch in fishing gear (31 %). The main factor we suggest that could be responsible for the increases in cetacean strandings in southern Portugal in recent years is mainly increased survey effort. Fisheries interactions, especially with coastal gears (gill and trammel nets, purse seine) are in significant part responsible for mortality patterns for smaller delphinids and porpoises and worthy of more detailed investigation. These results highlight the ecological significance of strandings data from long term databases as a valuable monitoring strategy in the region.

Ontogenetic and sex-related diet variation in Amazonian manatees (Trichechus inunguis) from central Amazon, Brazil

Variation in resource use among ontogenetic classes and sexes have been reported for many aquatic mammals. For species that inhabit areas of difficult access, as the endemic Amazonian manatee (*Trichechus inunguis*), there are few studies focused on feeding ecology, these ecological questions remaining unanswered. Therefore, the aim of this study was to assess variation in the diet of Amazonian manatees from Amanã and Mamirauá Sustainable Development Reserves, Amazonas, Brazil. Amazonian manatee's dentin and the potential food sources (algae and macrophytes) were analyzed for carbon and nitrogen stable isotopes. Mixing models were used to estimate the proportion of each food source that contributes to the diet and simulated mixing polygons were created to verify the adequacy of the trophic discrimination factors used. Sex and ontogenetic-related variation in $\delta^{13}C$ and $\delta^{15}N$ values were evaluated through generalized linear models. For all the adults and male adult groups the highest dietary contributor was C_4 plants, while for juveniles and adult females, C_3 aquatic plants contribute more. However, differences in contribution between C_4 and aquatic C_3 plants were small for all groups (0.04 to 0.18). The best model (lower AIC) for $\delta^{13}C$ included only the variable ontogenetic class and for $\delta^{15}N$, sex and ontogenetic class. Adults showed higher $\delta^{13}C$ values (-16.1‰), followed by juveniles (-18.2‰) and nursing calves (-20.5‰). The lowest $\delta^{15}N$ values were observed in juveniles (8.5‰) and females (8.9‰), and the highest values in nursing calves (9.9‰) and males (9.7‰). In conclusion, the differences in stable isotopic values among ontogenetic classes are probably reflecting the distinction between nursing calves' milk diet and adults' solid diet, which is commonly reported for other aquatic mammal species. Sex-related variation were attributed to different habitat use patterns due to distinct energetic reproduction demands, where males would travel larger distances searching for a receptive female.

Emerging contaminants in humpback whales (Megaptera novaeangliae) foraging in Antarctic waters, and their impact on whale fibroblast cell viability

valeria.casa@griffithuni.edu.au

The marine environment is susceptible to contamination by both natural and synthetic persistent organic compounds, with long-lived cetaceans at the greatest risk of accumulating lipophilic chemical burdens. The physico-chemical properties of most persistent organic pollutants (POPs) favour their transport to high latitude or altitude environments, with the poles of the Earth representing important environmental sinks for these compounds. In this study, a number of modern POPs, namely polybrominated diphenyl ethers (PBDEs) and short-chain chlorinated paraffins (SCCPs), as well as the naturally occurring brominated compound, 2,4,6-tribromoanisole (TBA), were detected in the blubber of southern hemisphere humpback whales, known to feed almost exclusively in Antarctic waters. BDE-47 and BDE-99 were present at the highest concentration and were the most frequently detected, confirming their ubiquitous presence in the global environment and their bioaccumulation potential. TBA, a compound that has raised concern due to its structural similarity to PBDEs, was similarly detected in the majority of samples. SCCPs were detected for the first time in any baleen whale species, and any Antarctic foraging mammal, providing valuable information regarding the distribution of these newly listed POPs. Selected congeners of these chemical groups were exposed to the newly established immortalized humpback whale fibroblasts cell line ($HuWa_{TERT}$) to evaluate their toxicological effect on species-specific cell viability. A dose-significant effect was observed for BDE-99, with a dose-dependent increase in cell metabolic activity and decrease in membrane integrity. Interestingly, this trend was the reverse for the positive control (*p,p'*-DDE). Clear dose-dependent trends were not observed for BDE-47, TBA or SCCPs. This *in vitro* effect-assessment model provides valuable insight into species-specific toxicological sensitivity and should be further applied to a broader range of known and emerging chemicals of concern and their mixtures to help fill the knowledge gap surrounding cetacean sensitivity to accumulated chemical burdens.

Results of diagnostic activities on stranded cetaceans, Italy, 2017-2018

Thanks to the surveillance activity of the Istituti Zooprofilattici Sperimentali network, coordinated by the National Reference Centre for Diagnostic Activities on Dead Stranded Cetaceans (C.Re.Di.Ma.), the examination of cetaceans stranded in recent years along the Italian coastline has shown that infectious diseases play an important role as cause of death (CD). During the two-year period 2017-2018, 184 out of the 386 cetaceans stranded along the Italian coastline (Italian National Stranding Database) were necropsied (47.6%). The necropsy and the panel of diagnostic investigations were either complete or partial, depending on the conservation status of the carcass. Based on gross and microscopic pathology and ancillary testing, the most probable CD was determined and categorized as anthropogenic (sub-classified into interaction with fishing activities/vessel collisions), infectious (sub-classified into viral/bacterial/parasitic/mycotic), by other causes (including metabolic and degenerative disorders, neonatal/perinatal pathology, etc.), and undetermined. The CD was determined for 120 animals (65%). Infectious diseases were the most common CD, involving 72 cetaceans (60%), while 40 specimens (34%) were diagnosed with an anthropogenic CD, consisting in interaction with fishing activities in most cases, and 8 (6%) were considered as affected by other CDs, mostly perinatal pathology. Noteworthy, the diagnostic activities allowed to detect well known cetacean-specific viruses like *Dolphin Morbillivirus*, cetacean *Alphaherpesvirus* and *Gammaherpesvirus,* as well as significant pathogens like *Salmonella* 1,4, [5], 12: i: - and *Salmonella* Enteritidis*, Listeria monocytogenes*, *Erysipelothrix rhusiopathiae, Brucella ceti* and *Toxoplasma gondii.* These results, integrating novel findings and published reports, are valuable for a baseline knowledge of cetacean pathology and mortality trends in the Central Mediterranean Sea and may be helpful to diagnosticians and future conservation policies.

Preliminary mark-recapture analysis of striped dolphins (Stenella coeruleoalba) photo-identification data in the Aeolian Archipelago, Italy.

A long-term photo-id study was performed on Mediterranean striped dolphins (*Stenella coeruleoalba*) inhabiting the Aeolian Archipelago (Southern Italy). Data collected through 412 focal follows on April-November from 2007-2018 were used to investigate striped dolphin distribution, habitat use, degree of residency and pattern of skin marks. A photo- ID catalogue of the photo-identified individuals was produced (DARWIN) and a high re-sighting rate was found in mark-recapture analysis. The prevalence of skin mark types found on dorsal fin and the other body regions (head, flanks, back, tail and flukes) was assessed and classified according to traumata or other causes. The distribution of striped dolphin groups varied with season, i.e. a more homogeneous distribution was found in the summer whereas more localized feeding habitats in spring/autumn, suggesting that the dolphin groups may move according to prey availability but also to anthropogenic factors such boat traffic. The offshore occurrence of the dolphin groups was related to a mean depth of 420.6 meters and a mean

distance to coast of 2455 meters. These results suggest that the Aeolian Archipelago is an important feeding area for Mediterranean striped dolphins and contribute to implement appropriate management actions for the conservation of cetacean species in this area.

Integrating remote sensing methods to measure social delphinid baseline behavior and responses to navy sonar

Oceanic delphinids are not endangered and typically have not been observed in mass-stranding events associated with military sonar, but include common protected species (*e.g.,* common, bottlenose, Risso's dolphin*s*) that are exposed in high numbers to sonar in some areas. We integrated existing research methods in novel ways to: (1) measure broad and fine-scale group and individual baseline behavior; (2) conduct the first-ever controlled exposure experiments (CEEs) to measure group-level responses to mid-frequency (3-4 kHz) active sonar (MFAS); and (3) obtain measurements of potential physiological stress responses arising from noise exposure. Our approach consisted of complementary sampling methodologies to measure the behaviour and physiology of several dolphin species, including shore- and vessel-based visual sampling, a long-endurance (>30 min) octocopter unmanned aerial system (UAS) for photogrammetry and behavioural sampling, drifting passive acoustic recorders, and biopsy sampling to detect stress response from blubber cortisol levels. During three field efforts, over 100 different groups were sampled. Shore-based theodolites generated tracks and speeds of overall group movement and social dynamics. UAS-based photogrammetry analysis measured the location and body length of > 335,000 individuals to describe group structure. Individual animal positions were then mapped in high spatial (cm) and temporal (s) resolution, enabling a detailed evaluation of individual heading, spacing, and speeds. Acoustic measurements of group vocal behavior were analyzed to compare vocal rates before, during, and after CEE exposure periods. CEE sequences were conducted (n=20 total across all focal species) in both no noise (control) and MFAS exposure conditions. The resulting data is categorically different from previous CEEs on single tagged individuals, appropriately so given the gregarious social nature of these species. Preliminary results demonstrate temporal changes in stress hormone levels following exposure and strong group-level responses in some, but not all conditions, with some indication of species and context-dependent differences.

Parameterizing dolphin behaviour with animal-attached tags to study acoustic communication

Many studies of acoustic communication classify vocalizations and examine how call categories are used in relation to behavioural states and events. Acoustic parameters of signals can also convey information independent of what call type is used, and can grade within or across call categories thus encoding information on a continuous spectrum. This offers complementary study approaches to call classifications. While animal movements are also frequently resolved into discrete classes, animal-attached tags enable continuous sampling of high-resolution behavioural data, which is valuable for testing how continuous acoustic parameters relate to the graded patterns of animal motion. Here we illustrate this approach through case-studies on

wild common bottlenose dolphins (*Tursiops truncatus*). We used data from sound-and-movement recording tags (Dtags) deployed in Sarasota Bay (FL), and parameterized dolphin vocalizations and motion to investigate how senders and receivers modified movements as a function of signal parameters (centroid frequency, modulation rate, spectral occupancy, duty-cycle). We used vectorial dynamic body acceleration (VeDBA) as a proxy for activity intensity during agonistic social interactions, and found that: 1) VeDBA of a female during reproductive consortships had a negative relationship with the frequency of male calls (-0.21 (m/s^2)/log(Hz)); 2) VeDBA of four males had a positive relationship with the modulation rate of their pulsed vocalizations (3.24 (m/s^2)/kHz). When comparing our acoustic parameters across sound categories of bottlenose dolphins (747 sounds from 11 deployments), we found that categories could not be clearly distinguished on the basis of these parameters combined (DFA correct-classification rates: 9% to 90%). Altogether, our results suggest that our chosen parameters are less involved in defining call categories, but help encoding information independent of what category is produced. Tags allow studying behaviour through analyses of multivariate quantitative patterns. Our study illustrates the value of these analyses to shed light on the communicative role of acoustic parameter changes.

Getting way too close to wild dolphins and manatees: Challenges of marine mammals watching tourism in Sian Ka'an Biosphere Reserve (SKBR), Mexican Caribbean.

castelblanco.nataly@gmail.com

Marine mammal watching is becoming an important non-consumptive use of wild megafauna in Mexico, mainly in the Pacific and Gulf of Mexico. Here, we present the first report of watching tourism targeting dolphins (Tursiops truncatus) and manatees (Trichechus manatus manatus) in the Mexican Caribbean (SKRB). We applied 64 semi-structured interviews to tourism operators and fishermen of Punta Allen and Punta Herrero communities, in order to compilate information about the offered tours, watching protocols and local perception. Based on this, we selected key localities to observe and describe watching activities and when possible, the animals' reaction to the boats. For manatees, two zones near sinkholes located in Caapechen and Bocapaila lagoons were selected, and observations were video-recorded using a drone DJI Phantom 3 Advanced. A locality known as 'El Faro' was visited to conduct boat-based observations of dolphin watching activities, assessing surface dolphin behavior by focal group sampling over two-minute intervals. Manatee watching tourism is conducted by two methods: stationary observations and active chasing, the latest representing a potential risk of collision for the manatees. Likewise, during dolphin watching activities we observed concerning boat operators behaviors: direct and close approaching to the dolphins, aggressive chasing, and excessive number of boats interacting with the same group. Five local tourism cooperatives and two private operators offer manatee/dolphin watching tours to visitors, showing that this is an important source of income to community stakeholders. However, our observations raise a concern as it could be detrimental to the target species. After several workshops/meetings with the local tourist operators and SKBR authorities, we propose guidelines for watching activities in order to reduce the risks of marine mammals' behavioral changes, habitat use modification and boat collisions. Likewise, establishing temporal or spatial refuges protecting biologically important areas (e.g., feeding grounds) where watching activity is prohibited, could be an appropriate strategy.

Improving our understanding of Cook Inlet beluga disturbance by anthropogenic noise

Following a dramatic decline, the Cook Inlet beluga (CIB) population was listed as endangered in 2008. A decade later, this population, currently estimated at 328 whales, has shown no sign of recovery, with the cause of this lack of recovery unclear. One major threat to this population is anthropogenic noise. CIB critical habitat is concentrated near Anchorage, which is the largest urban area in the state and home to the majority of Alaska's human population. CIB are exposed to a wide variety of potential noise stressors including fishing, mining, dredging, military operations, oil and gas development, air and water transportation, and residential and industrial shore development. Many of these activities are intensified during the belugas main foraging season when ice is absent (May-October). NOAA Fisheries regulates noise exposure under both the U.S. Marine Mammal Protection Act and the U.S. Endangered Species Act. However, noise impact mitigation is limited to close-range effects defined by the onset of injury (i.e. temporary and permanent hearing threshold shifts). Previous acoustic monitoring data showed how noise levels regularly exceed behavioral harassment thresholds in CIB critical habitat. To address this concern, an acoustics research project was initiated in 2017 to identify foraging areas based on foraging behavior documented with suction cup multisensor tags, and examine the potential disturbance by anthropogenic noise in these ecologically important areas, using year-round acoustic moorings. This presentation will summarize our current understanding of the temporal and spatial overlap between anthropogenic noise and beluga foraging behavior, and our initial results on potential displacement from foraging grounds.

Friendly whales? Unusual behavior of humpback whales that are possibly accustomed to tourism.

Castro, Cristina[1]; Kaufman, Gregory[2]

Corresponding Author:
cristinacastro@pacificwhale.org

Whale watching is one of the fastest growing tourism industries in the world. In Latin America whale tourism is in constant growth. In 2014, the fishing community of Puerto Lopez received more than $3,000,000 USD between direct and indirect profits and 60,000 tourists from June to September. Our main research objective is the population study of the humpback whales *Megaptera novaeangliae* and our research question is to know the impact of tourism on whales.

Our study area is located in Puerto Lopez, Machalilla National Park, Ecuador, which included Isla de la Plata. From 2016 to 2018, 180 research trips were realized, of which 15 (8%) instances of ´´friendly whales´´ have been observed. Pod sizes varied between one to fifteen animals. The most common behaviors observed: the competitive, travel and rest groups.

Friendly whales are curious whales that during the whale watching tours come close to the boat and stay around it, from five minutes to one hour. There are reports of whales touching the boats without moving, allowing the tourists to touch them. There are others that on various occasions will stay next to the boat doing spy hops and traveling around it.

This study aimed at understanding the behavioral reactions of individuals to these interactions with whale watching boats. Observing the behavioral events performed by individuals during an interaction can help define the short-term reactions elicited by the boat presence. We recorded the behavioral events performed by all individuals. The frequency of occurrence of all events was compared depending on the presence of vessels, their behavior, and the structure and composition groups.

This document proposes the naming of "friendly whale" as an unusual behaviour of the humpback whales in the presence of humans and whale watching boats. We suggest more studies on the behaviour, in other breeding areas, to determine if the growth of tourism is changing the behaviour of the whales and accustoming them to human presence.

Assessing the impact of drones on the behaviour of small dolphins

Unmanned Aerial Systems (UAS), commonly known as drones, have recently emerged as an inexpensive and accessible alternative to study marine wildlife. The Vertical Take Off and Landing (VTOL) are probably the best UAS type for behavioural studies. They provide cheap, stable, non-intrusive and highly maneuverable platforms to study single individuals or small groups of animals. Although studies with VTOL UAS have been done with various species of marine mammals

very few behavioural responses specific to these types of devices have been recorded. Considering the wide accessibility of UAS's, it is essential to understand their impacts on these animals. This study intends to determine the behavioural response of two different species of Delphinidae, the common dolphin (*Delphinus delphis*) and bottlenose dolphin (*Tursiops truncatus*) to a VTOL UAS at different altitudes. For this work we used a multi-rotor (quadcopter) UAS type with a Go Pro camera attached. Once the dolphin group was found, the starting height of UAS was 50 m , subsequently dropping 5 m every 30 sec until reaching 5 m. Three variables were considered to analyse the immediate response of the group at different UAS heights: changes in direction, increase in speed and diving behaviour. Responses by *D. delphis* (n=15) and *T. truncatus* (n=10) groups were analysed separately. Cochran's Q test revealed no significant responses of *T. truncatus* to any of the studied variables. However, changes in direction were statistically significant ($Q=18.000$; $p<0.05$) for *D. delphis*, with increased changes in direction apparent at altitudes of 5 m. We strongly recommend that VTOL UAS's fly above small cetacean groups at a minimum height of 20 m. To summarise, the use of VTOL UAS in small cetacean studies seems a very good option with minimal impact on the animals.

Automated pixel-based tool for assessment of body condition in large whales.

Marine ecosystems around the planet are undergoing unprecedented change and its species are facing increasingly variable and potentially inhospitable habitats, as evidenced by large-scale die-offs of numerous marine species. In order to keep abreast of change, researchers need tools that can quickly gauge the health of marine species. With recent advances in Unmanned Aerial Vehicle (UAV) technology, the ability to collect such data has never been greater. However, the ability to analyze this data efficiently is lacking and often creates a daunting backlog. With data analysis limitations in mind, we developed a Machine Learning Algorithm (MLA) that can automate morphometric measurements of large whales. The MLA can be taught to recognize a specific object from a background and then provide information on that object. A base network trained in object detection via ImageNet was modified to recognize southern right whales (*Eubalaena australis*) and provide morphometric information on the body shape of an individual whale. The MLA, named 'CetaCon' is able to measure a whale along its central axis from rostrum to fluke notch and width at every pixel along the body axis. With morphometric data on a multitude of individual whales, CetaCon is able to output a population distribution of body shape, with the added ability to compare individual whales to this distribution to determine how they vary from the mean. Distributions from disparate populations can also be compared in order to monitor whale health across temporal and spatial lenses. CetaCon will provide a standard tool with which researchers can easily analyze large amounts of morphometric data in a relatively fast and easy manner. It will not only facilitate the development and validation of methods for rapid assessment of condition, health and demography for southern right whales, but has the potential for modification for cetacean species around the globe.

The contribution of citizen science to the conservation of Mediterranean monk seal (Monachus monachus) population at Madeira archipelago

Monitoring to assess situations and space-temporary trends is fundamental in biodiversity conservation programs. A particularly powerful tool which plays a fundamental and growing role in the conservation-society-policy relationship is Citizen Science. The society voluntarily participates in conservation projects based on their enthusiasm and concern for environmental problems. In addition to provide important and reliable data, it has the potential to change society's attitudes toward science and the conservation of the planet.

In the case of Mediterranean monk seal conservation at Madeira archipelago, the RED SOS *Lobo Marinho* Network was created under an EU LIFE project, to gather collaboration and data from citizens, willing to provide monk seal observations as well as to warn the competent authority about threats and problematic situations for seals that may need intervention. Collaboration agreements

were established with 22 official institutions, 17 whales watching and diving companies, and 17 private volunteers. A protocol of action, which includes an ethical code of behavior in the presence of seals and a specific RED SOS telephone number, has served to coordinate and homogenize the gathering of information among the participants, including many spontaneous collaborators. Between 2014 and 2018, 686 monk seal sightings have been reported throughout the whole archipelago, 74% from non-official institutions (39% citizens, 18% sports divers and 15% fishermen from coast and fishing sailors, 2% tourists).

Observations reports have contributed with good information about the seals habitat use and with quality images that have been incorporated into the seal identification catalogues. It also provided warnings about seals in difficult situations (mostly animals disturbed by humans or weak) allowing the intervention of authorities in 7 occasions, and allowed the recovery of one carcass for necropsy purposes. RedSOS has proven to be an effective public participation tool for conservation and as an informal educational experience that promotes environmental awareness.

The use of Unmanned Aerial Vehicles (UAVs) to sample small cetaceans blow microbiome.

Unmanned Aerial Systems (UAVs) are increasingly used for studying and monitoring free ranging cetaceans. These charismatic species are considered by many sentinels of ecosystem and environmental health. Our study focused on assessing a standard non-invasive method for sampling and analyzing cetacean blow samples collected using UAVs.

In order to set sampling and analytical methods, a series of blow samples from 6 bottlenose dolphins (*Tursiops truncatus*) kept under human care at Acquario di Genova were collected using 6-well plates, positioned at different heights over the blowhole. The same sampling kit, assembled on a waterproof UAV, was used to sample wild bottlenose dolphins in the Gulf of Ambracia (Greece) and a sperm whale (*Physeter macrocephalus*) in southern Tyrrhenian Sea (Italy). Samples obtained from wild cetaceans, did not provide a biological matrix for genetic and pathological biochemical studies. Nevertheless, we managed to identify a variety of microorganisms (microbiota) presents in the dolphins' upper respiratory tract by using 16S Illumina Amplicon Sequencing. As expected, the water samples contained more bacterial taxa while those from animals were similar in taxa richness. The composition of the bacterial community differed between the Greek water, wild animals and samples from dolphins under human care.

Although the number of samples used for this study was limited, our results are rather encouraging. Using UAVs to collect exhaled air from small cetaceans is a quite challenging process both logistically and technically. Main difficulties are derived from behavioral differences when compared with larger cetaceans; their fast swimming speed and the unpredictable movements together with short-lasting ventilations, lower blows and dynamic social structure forced us to approach them differently that what to do typically when sampling in whales. Our newly developed tool was clearly proficient in achieving its goal, as supported by the evident microbial differences between sea water and blow samples.

Mediterranean monk seals interactions with fisheries at Madeira archipelago

Negative interactions with fisheries has been identified as one of the major threats to Mediterranean monk seal conservation along its distribution range. In Madeira, previous studies showed that most fishermen believe that the species does not cause damage and are not accidentally

entangled in fishing gear. This may be caused by the prohibition of fishing nets in the archipelago, and a low overlapping with seals foraging areas, due to the great dependency of this sector on the exploitation of deep-water species, large pelagic migratory fishes and small pelagic fishes. To evaluate this interaction, a program of observers onboard Madeira fishing vessels was developed between 2016 and 2018 with presence on 200 fishing trips of a duration between several hours and 3 days, in 20 different boats from 9 different fishing harbors, using 8 different fishing gears. No interactions with seals was observed, and only in 2 occasions a seal was observed, both from boats fishing with traps just hundreds of meters from the coast. To determine fishermen's attitude towards the seals, interviews were performed to 98 fishermen of 45 different boats, with 24 questions about fishing gear, target species, evolution of captures, current problems for fisheries, and monk seals. 47% of fishermen never observe seals while fishing, 82% think that seals should be in protected areas without fishing, 52% wouldn't like the monk seal population growing, and 2 out of 3 captains consider that monk seals harm fisheries. In general fishermen are afraid of being blamed as the responsible for the monk seal decline.

Current interaction with fisheries is low and restricted to coastal fisheries, but fishermen still have a reluctant attitude towards them, making information and awareness campaigns necessary.

Residency, local movements and potential isolation of the Madagascar Omura's whale population

Most baleen whales are migratory, with life history patterns and ecological parameters determined by spatiotemporal separation of feeding and breeding. Omura's whales are a species whose range is exclusively tropical/warm temperate, and thus does not engage in long-range latitudinal migration. Here we report multidisciplinary evidence indicating that the population off northwest Madagascar is non-migratory and likely constrained to a restricted, isolated range. Passive acoustic monitoring conducted at four sites across 80km for one year indicated residency of the Omura's whale population in this region; song was present year-round with strong spatial and some temporal heterogeneity. Four satellite-tagged individuals yielded 30 to 58 day-long tracks during November to January, displayed restricted movements along a 405km stretch of continental shelf (mean=283km), and moved multiple times throughout their individual ranges (mean track=2530km). Behavioral switching state-space models indicated highly localized movements (mean b-mode=1.8), involving short periods of transiting between specific areas where the whales displayed localized movements for several days, likely feeding. During directed field surveys, feeding was frequently observed on dense patches of the tropical krill *Pseudeuphausia latifrons*, which appeared episodically following dense blooms of cyanobacteria *Trichodesmium* sp. Photographic re-sights of individuals were evident within and across years, including at least one reproductive female sighted in four of six years from 2012 to 2017, once with a calf, suggesting strong site fidelity. Species distribution models indicated favorable habitat conditions for Omura's whales along the northwest coast of Madagascar, defined primarily by shallow depth and high photosynthetically active radiation, with little other predicted suitable habitat throughout the Southwest Indian Ocean. Combination of these data indicate that this is a resident, non-migratory population whose distribution is likely determined by local, shallow-water ecological processes and patchy, ephemeral prey resources. Furthermore, this population of Omura's whale may be isolated within a fragmented oceanic/global range for the species.

Do male and female sperm whales live separate lives because females outcompete males for the best food?

Sperm whales are characterized by a complex social system, with groups of females forming long-lasting social units, and males becoming increasingly solitary with age. The evolution of this complexity may have been partly driven by the proximate competition between males and females to access the best food resources. Particularly, females appear to be outcompeting males, which might have forced the latter to explore waters at higher latitudes to support their large size. Even though there is evidence of reduced male feeding success when co-occurring with females, no study has explicitly assessed intra-specific differences in diet that could support this hypothesis. In this study, we aim to compare the diet of female and male sperm whales in the waters around the Balearic Islands, a breeding ground for the IUCN 'Endangered' population of Mediterranean sperm whales, where females and males co-occur but segregate at a fine spatial scale. Dietary differences will be assessed through the analysis of N and C stable isotopes in skin samples, and combined with long-term feeding success and habitat use data to assess the degree of sexual segregation. Analyzing sperm whale diet can elucidate critical aspects of their interactions with conspecifics, the environment, and other species therein, as well as provide important information for their conservation.

Our neighbors the inshore dolphins: A citizen science mark-recapture assessment of urban bottlenose dolphins in La Paz Bay, BCS.

By the nature of their near-shore distribution, inshore bottlenose dolphins often suffer from adverse effects derived from anthropogenic disturbances such as maritime traffic, fishery interactions and habitat degradation, which take place in the temporal scale in the short to mid-term. In La Paz Bay, these inshore dolphins are sympatric for over six months with whale sharks aggregating at less than a mile from the shoreline, both species represent a very important resource for the local eco-tourism, a key income-sector for La Paz. Effective management and conservation strategies require information regarding their abundance. This assessment estimates the effective population sizes of bottlenose dolphins in La Paz Bay using photo-identification. This case study aims to contribute to the understanding of the processes that influence habitat use of free-ranging populations of inshore dolphins under high levels of anthropogenic pressures due to their almost urban-occurrence. Using boat excursions focusing in both charismatic species as platform of opportunity, photo-Identification data have been gathered since 2015 and processed to construct a history of encounters. Open population models (CJS) were applied to generate Insights in demography (Φ: apparent survival, p: probability-capture) and population size. The best-fitted CJS model was that considering the effect in all population parameters, average survival estimates (0.92; C.I: 0.29-1) and probability of capture (0.25; C.I: 0.09-0.59) are associated with a population size of 79 individuals (C.I: 70-90). This abundance estimate was similar to previous estimations considering 6 years (1989-1994). The core area of distribution for the species is characterized by important biological productivity and low predation risk, which may promote these demographic pattern. However, what could be the critical calving/foraging habitat for this inshore marine predator is encroached by coastal development. Citizen science approaches presents a cost-effective alternative to increase monitoring. A more in depth assessment of behavior and demography is currently underway.

Toward the evidence of male mating strategies in Indo-Pacific bottlenose dolphin populations along the south-west coastline of Western Australia.

Indo-Pacific bottlenose dolphins (*Tursiops aduncus*) inhabiting the coastal and estuarine waters of Perth, Western Australia, define three socio-geographic resident communities. Their small sizes and individual long-term interactions associated with respective site fidelity would suggest an intra-community complex social structure. This study investigated the presence of male alliances within the Swan Canning Riverpark (SCR) estuarine community, their stability, and access to females. Association indices along with tests for preferred and avoided affiliates were examined using eight years of photo-identification and behavioral data. Two resident adult male alliances (one trio and one pair) were detected from

three parameters: high association indices (SI > 0.79), significant preferred affiliates within alliances, and significant avoidance between alliances (SI < 0.05). Other males were occasionally associated with one of the alliances (SI = 0.37 – 0.21). Males were seen with females in 106 encounters (36%), many of whom (86%) when females were considered to be receptive at that time (i.e., no calf or > 2-year old calf if present). Rare events of what looked like a 'rooster strut' and the annual observation of adult females from the adjacent communities with the SCR male alliances (6% of the encounters) also suggest mating competition, most likely for non-randomly selected females (i.e., eight out of 67 adjacent females including two observed in multiple years). Although both alliances will see a change in the next few years due to loss of affiliates, two resident juveniles showed significant preferred affiliates with a high association index (SI = 0.68) estimated over the last five years, an indication of future alliance formation. However, consistent loss of individuals due to human impacts (i.e., fishing line entanglement) may deflate the benefits for males to form alliances and/or increase the competition level for females if the numbers of SCR resident females decrease.

Sea surface temperature drives narwhals' movements in the Arctic

Arctic cetaceans are expected to face behavioral adaptations in response to increasing temperatures and sea-ice loss due to climate change. The distribution of the narwhal extending from the Canadian Arctic Archipelago (CAA) to Franz Josef Land (Russia) illustrates the use of contrasting environmental conditions, suggesting a certain degree of behavioral plasticity of this cold-tolerant species. However, the way narwhals will cope with a warming Arctic ocean is poorly documented. The objective of this study was to conduct a comparative analysis of narwhal movements tracked at different summering grounds to (1) assess the Sea Surface Temperature (SST) trend at the summering grounds in relation to (2) their temperature tolerance, in order to (3) anticipate their future hotspots. Between 1993 and 2018, a total of 142 narwhals were satellite-tracked on both sides of Greenland (94 west and 48 east) at three main summering grounds: the CAA, Northwest Greenland (NG) and Southeast Greenland (SG). The use of state-of-the-art ocean models run over a long time-series (20 years) showed a sharp SST increase in NG and SG, whereas no change occurred in the CAA. The largest abundance of narwhals is found in CAA (>100.000), but it is unknown whether increasing temperatures have caused narwhals to leave their low abundance (<5.000 individuals) summering grounds in NG and SG. Additionally, the Generalized Additive Models showed a "dome shaped" relationship between whale density and SST, with a temperature optimum 3°C higher in SG (3°C) compared to NG and CAA (0°C). This result suggests that narwhals from SG could be forced to migrate to new habitats due to an imminent global warming scenario.

Do fin whales avoid noisy area? Analyse of trajectories in relation to shipping noise.

Western part of the Mediterranean Sea hosts populations of fin whales. Depending on the seasons, the animals are known to be located in the Pelagos Sanctuary (in the Ligurian Sea), and can migrate around Corsica and Balearic Islands. This area is also frequented by several shipping activities: regular ferry lanes, as well as tanker and super-containers of various sizes. These types of boat are major contributor to low frequency ambient noise in the Mediterranean. Such anthropogenic noise can cause masking of the communications of baleen whales, and may lead to the risk of impacts at the population scale.

In this study, the relation between fin whales migration patterns and shipping noise levels is investigated. Positions of animals are retrieved using tagged data. Received levels are computed using AIS and propagation model.

Results are firstly analyzed in terms of masking. Additional behavioral data from the tags, such as speed and cape, and environmental information, such as chlorophyll concentration, provide

preliminary framework for risk assessment and identify suitable management solution for conservation.

Metapopulation dynamics of coastal dolphins through mark-recapture techniques: A case study from southeast China.

Indo-Pacific humpback dolphins (*Sousa chinensis*) inhabiting the Pearl River Delta (PRD) region, southeast China, are affected by multitude of anthropogenic impacts. Although early research and conservation efforts date back two decades, much of the dolphin population ecology remained poorly understood. We used a multi-year photo-ID dataset collected across the PRD and a suite of modelling techniques to investigate the population socio-demographic structure, connectivity and trend. Manifold quantitative measures indicate that in the PRD, humpback dolphins form a complex metapopulation with socially distinct and spatially discrete subpopulations. Individual site fidelity is weak in the short-term (days/weeks), but moderate-to-strong in the long-term (years). Individual movement across few tens of kilometres is common, across several tens of kilometres infrequent, and across few hundreds of kilometres is unlikely. Although dolphin groups are fluid and inter-individual associations are short-lasting, there is a notable social structure across the region with well-discernible social communities. The spatial ranges of communities are identical to that of subpopulations, and it seems that the ranging/foraging strategies of individuals determine their potential affiliates and hence the broader social dynamics and structure of the PRD metapopulation. Population models indicate that there are ~2000 dolphins in the PRD coastal waters, but their survival rates are well-below the threshold of long-term population persistence. The metapopulation connectivity, albeit low-level, prevents demographic independence of the subpopulations and has an overall stabilising effect on population viability. Even so, however, the metapopulation is declining ~3% annually, more rapidly than previously thought, which corresponds to the IUCN's Critically Endangered status. Local extirpation of any of the subpopulations within PRD, which seems likely according to current population trajectory, may have dire consequences as it will likely trigger major population fragmentation. Consequently, a better understanding of metapopulation dynamics of the PRD dolphins is crucial to any future conservation actions.

More than snacks: An analysis of drone observed blue whale surface lunge feeding linked with prey data.

To understand how predators optimize foraging strategies, extensive knowledge of predator behavior and prey distribution is needed. Blue whale foraging behavior is primarily driven by krill patch density, but studies have not fully considered surface feeding as a substantial ecological component or significant foraging strategy. Neglect of surface feeding behavior stems from a paradigm that krill density is greater at depth. Yet, we use 90.6 h of echosounder data collected on a blue whale foraging ground in New Zealand to demonstrate that krill density was greater toward the surface (< 20 m). Foraging blue whales (n=15 of 32 sightings) had short dive times (2.59 ± 0.28 min) and used habitat with relatively shallow, dense krill aggregations. These results indicate that blue whales in this region may exploit shallow krill aggregations to minimize energetic costs and oxygen consumption during diving. Additionally, we used an unmanned aerial system to captured unique video of a blue whale's surface feeding behavior on well-illuminated krill patches. Kinematic analysis of the video illustrates the whale's use of vision to target the patches and make foraging decisions, with subsequent biomechanical coordination to maximize prey engulfment. At strike, the whale's mouth begins to open while at maximum speed (3.33 m/s), and reaches its widest gape angle of 33° 1.5 s after strike when maximum upward head pitch (15°) and maximum deceleration (3.7 m s^{-2}) also occur. Surface krill in the target patch (45 m^2) begin to respond 0.8 s pre-strike when the whale is 2 m away, and moving 3 m/s. Understanding how blue whales optimize foraging effort presents logistical challenges, which may cause incomplete sampling and biased ecological knowledge. We conclude that

surface foraging could be an important strategy for blue whales, and integration of UAS with tag-based studies may expand our understanding of their foraging ecology.

Preliminary results of total mercury concentrations along leopard seal whiskers

With increasing changes to the climate and increasing human presence in Antarctica, efficient tools are required to monitor the health of Antarctic ecosystems. Leopard seals (*Hydrurga leptonyx*) are important top level consumers of diverse prey in the Antarctic Peninsula, with a documented top-down effect on other Antarctic fur seals. With lifetime Antarctic residences, these apex predators should be an ideal sentinel species for tracking the health of the Antarctic Peninsula ecosystem. However, leopard seal diet and contaminant loads have been sparsely studied. In this study, we analyzed leopard seal vibrissae for total mercury (THg) using laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS). Due to a lack of suitable microanalytical standards, results are expressed as ratios of counts of Hg relative to S, the latter of which has been shown to have relatively stable concentrations in other natural keratin- and cuticle-like materials (e.g., hair). Initial results from two adult female whiskers show that Hg/S intensity ratios range between 0.007 and 0.080, with respective means of 0.03 and 0.01. These respective 5-8 year time series suggest that THg concentrations may fluctuate by over an order of magnitude during portions of leopard seal lives. Although preliminary, these data support the prospect of using whisker-based time series to track contaminant loads and diet changes over multi-year intervals. Future analysis will integrate new keratin microanalytical standards for quantifying "true" THg concentrations, in addition to stable C and N isotope analysis to see how seasonal changes in isotope ratios relate to the LA-ICP-MS Hg time series.

How do dolphins communicate their emotions? Potential role of behavioral laterality.

Charles, Aviva; Delfour, Fabienne[1]; Mercera, Birgitta[2]

Corresponding Author: aviva.charles@outlook.fr

Behavioral laterality, i.e how specific behaviors are realized using either the left or right side of the body predominantly, reflects the difference between the left and the right hemisphere. In vertebrates' brain, respectively the left hemisphere controls routine tasks, and the right hemisphere emergency responses to unexpected stimuli and expression of intense, negatively connoted emotions as fear. According to this theory, social behaviors should be lateralized. Within their fusion-fission society, dolphins should preferentially use their right pectoral fin/eye to perform and maintain social contacts.

We investigated behavioral laterality in 8 bottlenose dolphins (*Tursiops truncatus*), 2 males and 6 females, during their social interactions. Dolphins were observed twice a day for 20 minutes long each time (n= 66). We recorded the number of times dolphins used their right vs left pectoral and investigated visual laterality by recording the duration each dolphin swam on a conspecific's left or right side.

Results at group level didn't show a significant right pectoral bias during pectoral contact. However, at an individual level, females appeared to be more lateralized than males. One female used significantly more often her left than right pectoral fin and two other females swam respectively more on their partner's right and left side.

Even if laterality at group level didn't emerge, our results show an inter-individual variability. This suggests that individual characteristics as the age, sex or affective state potentially influence visual and motor laterality in cetaceans. One supposed function of pectoral rubbing is to provide informations. Moreover, in our study this behavior frequently occurred after aggressive behaviors in order to gain appeasement. Consequently, we suggest that the preferred use of one pectoral fin depends on social contexts and gives precise information on individual's arousal level. Further studies are required to understand how cetaceans express and communicate their emotions.

30 years of Southern right whale monitoring shows that Australia's major calving ground has reached capacity

Seasonal trends in the distribution and abundance of southern right whales (SRW) *Eubalaena australis,* were assessed in Australia's largest calving aggregation ground at the Head of the Great Australian Bight, in the Commonwealth Marine Reserve, South Australia. Annual cliff-based surveys were undertaken between June and October from 1992 to 2016. SRW were primarily distributed within a 15 km by 2 km area within the 10 m depth contour (with 95% of whale sightings made within a 10 km^2 area). The distribution of SRW at Head of Bight varied within an individual season but was consistent among the years. The composition of SRW sightings was 70% female-calf pairs and 30% unaccompanied whales. Peak abundance occurred between mid-July and end-August for female-calf pairs and unaccompanied whales (juveniles or adults not accompanied by a calf), earlier than previously reported. A mean of 16% (range=8-28%, SD= 6.5, 95% CI=0.15) of calving females were present at the site in mid-June and a mean of 37% (range=13-61%, SD= 15.8, 95% CI=0.37) remained at the site at the end of September. Based on nearest neighbour distances of 150 m the area occupied by 95% of SRW at Head of Bight reach carrying capacity at 68 female and calf pairs. Results suggest that the primary aggregation area at Head of Bight has reached saturation capacity and that habitat expansion can be expected as the population increases. This study provides information on SRW seasonal trends in distribution and abundance, timing of arrival and departure from the site and peak abundance periods relevant to application to conservation and marine park management. As management requirements increase with a growing population, there is a need to complete an Australia wide assessment of SRW connectivity and habitat expansion.

Man, you smell! A behavioral and chemical assessment of olfactory discrimination in Australian sea lion males.

A breeding colony of otariids (fur seals and sea lions) can be described by the loud background noise and also by its strong smell. During the breeding season, most otariid adult males develop a strong, highly characteristic musky smell, that the human nose can detect from a long distance. Behavioral observations of Australian sea lions suggest that breeding males are able to detect the presence of other breeding males by raising their rostrum and sniffing the air. To assess if Australian sea lion males can achieve olfactory discrimination during the breeding season, we tested in the field 10 adult males and 6 subadult males with two different scent stimuli: the scent of an adult non-mate guarding male from the colony and a control natural scent (seaweeds). In addition, in 2015 and 2016, we collected general body scents from both adult and subadult males within and without the breeding season in two different colonies for chemical analysis using Gaz Chromatography-Mass Spectrometry (GC-MS). This was to assess differences in body odour production and to identify the chemical compounds involved in this process. We found that males' responses were significantly stronger to male scent than to seaweed scent. Scent samples collected during and outside the breeding season differed significantly in the composition of chemical compounds, and we also found a significant difference in chemical profiles of males from the two distinct breeding colonies. The cause of these differences in males' chemical profiles and the chemical composition of male scents are discussed.

Habitat suitability as a tool to detect spatial and temporal distribution changes of marine mammals

Modeling distribution change as a consequence of climate change requires confidence in model predictions under novel conditions. However,

models often fail if a proper baseline for comparison is not previously defined. A habitat suitability model for short-beaked common dolphin (*Delphinus delphis*) was developed from dedicated sighting survey data collected by NOAA- NEFSC and SEFSC from 2010 to 2017 in the western North Atlantic. The objectives of this study were: 1) identify the main environmental covariates related to the abundance and distribution, based on generalized additive models to establish their habitat suitability, and 2) identify changes in habitat suitability in response to changes in the environmental covariates that could affect the species distribution. The most parsimonious model included SST, distance to the Gulf Stream north wall, distance to shore, bottom temperature, distance to the 1000m isobaths and latitude, explaining 35.3% of the deviance. For validation, the common dolphin model was applied to the summer 2004 environmental covariates and predicted abundance and habitat suitability of the species. The habitat model estimated abundance was not statistically different than the abundance previously reported for 2004 when corrected for availability bias. In addition, the habitat suitability map matched the common dolphin sightings recorded for the season and year. During the study period clear seasonal changes and interannual variability were detected, especially in the northern range of the species distribution within the study area. The effect of SST on common dolphin habitat suitability is discussed in terms of the mechanisms limiting the species distribution that might differ among geographic regions, or at different times.

Tired eyes no more: Automated image recognition of humpback whale fluke identification surpasses human manual matching.

Cheeseman, Ted[1]; Southerland, Ken[2]; OPark, Jinmo; Clapham, Phil[3]

We developed and implemented automated image recognition for humpback whale (*Megaptera novaeangliae*) fluke identification that has achieved matching results exceeding what the human eye is capable of. The algorithm was developed through a *Kaggle.com* competition, generating submissions from 2,131 teams matching 5,000 test fluke images to 20,000 identified reference fluke images. The matching accuracy of the top 181 submitting teams was >0.90, while that of the top five winning algorithms was 0.967 to 0.973. We refactored and implemented the most deployable of the winning algorithms into the citizen science and research collaboration platform *Happywhale.com*. Happywhale has built a database of over 25,000 humpback individuals with at least one fluke ID image per individual through collaborating research groups and citizen science contributions; prior to implementation of this algorithm, matching was undertaken through a combination of previous versions of image recognition algorithms, research collaboration and manual matching. Application of the new algorithm to our known whales found 8.6% (2178 of 25195 individuals) as internal duplicates. Found matches included numerous examples of calf to adult matches with greater changes in fluke pattern than human eyes could reasonably detect. The algorithm performed extremely well with poor-quality images and images with minimally featured all-white and all-black flukes, finding many matches in catalogs that have been manually reviewed for decades. 3% of proposed matches could neither be rejected nor confirmed, and many matches could be confirmed as correct only after further image processing and extended review, demonstrating that automated image recognition has surpassed functional manual human image matching. This new algorithm largely eliminates the need for manual matching; it now forms the basis of two broad collaborative studies of humpback whale migratory patterns and population dynamics across the North Pacific and South Pacific, studies on a scale that would be intractable without effective automated image recognition.

Non-song calls produced by a female humpback whale (Megaptera novaeangliae) in Hawaii

Recently there has been increased interest in non-song vocalizations produced by humpback whales in the quest to understand humpback whale behavior and communication. However, these sounds are still relatively poorly studied in many group types, locations, and from the different sexes. Here we present the first known calls from a juvenile female humpback whale and contrast these with calls from adult dyad groups as well as calls in mother-calf groups recorded in waters off Maui during the breeding season. An Acousonde suction cup acoustic recording and data logging tag, sampling acoustics at 10 kHz and other sensors at 5 to 800 Hz, was deployed on the juvenile female as well as whales in the others group types. Three dyad groups were tagged in March 2016 for a total of approximately 12 hours, and 3 calves and 7 mothers were tagged March 2014-2016 for 44

hours. All were focal followed to record behaviors from the surface in conjunction with acoustic recordings. The juvenile female was tagged March, 17 2015. During the approximately 2.5 hours the tag recorded, the female did not approach any other whales closer than approximately 100 m. Consequently, all calls are believed to be produced by the female. From the acoustic data, 129 calls were recorded. The calls were primarily short (ca. < 0.1 sec) and resembled previously recorded non-song calls from mother-calf groups. Calls tended to be grouped together in bouts separated by periods of silence, like other non-song calls. However, calls were produced at a relatively high rate at almost 52 calls per hour, more frequent than mother-calf and dyad groups. Lone female encounters are rare in the breeding areas and this recording provided a unique opportunity to learn about the vocal development of female humpback whales.

Occurrence and feeding activities of Edeni's whale, Balaenoptera edeni, in the northern Beibu Gulf, China

Chen, Mo[1]; Huang, Shianglin; Wu, Haiping; Zhigang, Mei[2]; Wang, Ding[3]

Stranding records of Eden's whales range from the Yangtze River Estuary to the northern Beibu Gulf, including the Taiwanese coast, but information about the distribution, habitat use and population status of the Eden's whales in Chinese waters is limited, and there have been no live observations, particularly in inshore waters along the Chinese coast. According to the Eden's whale occurrence and feeding sites identifying that based on citizen science information from collaborative fishermen, LEK baselines from questionnaire interviews and records from opportunistic surveys, it provides preliminary knowledge of the Eden's whale in the waters around Weizhou and Xieyang Islands before conducting the systematically-designed field surveys. Eden's whale activities including the occurrence and trap-feeding have been recorded by local fishermen since 2016 and from the field trips by the Beibu Gulf marine mammals joint research group which was established in 2016 conducted in May 2017 and April 2018. Questionnaire results also indicated apparent seasonal activities of Eden's whale in the study region. In March and April, trap-feeding activities become the highest. Eden's whales primarily feed on schooling fishes, likely pelagic-neritic anchovy, shad, and sardine. Eden's whale occurrence in the waters between Weizhou and Xieyang Island may associate with annually periodic activities of their preys. This possibility needs further investigation.

Studying call types and sub-call types of Killer Whales in complex and non-stationary acoustic environment using Deep Learning: A data-driven approach.

Variations of bioacoustic signals pose challenges to categorize calls into classes, subunits, and call series in animal communication research, especially for large datasets. Deep learning methods, together with increasing usage of passive acoustic monitoring, stimulate growing interest in automatic detection and classification. This pilot study demonstrates how to use deep learning to access a large amount of vocalizations of killer whales (*Orcinus orca*) and how to use unsupervised clustering to detect different types of calls and sub-call types.

A deep learning-based segmentation tool with 95% accuracy, was previously trained on noise and vocalizations of Northern Resident Killer Whales (NRKW). A Convolutional Autoencoder, a deep neural network architecture, was pretrained to learn features that best represent NRKW discrete calls, whistles, echolocation clicks, and noises. It is achieved by mapping a given input x to output/reconstruction r via hidden representation h. The call type classifier, using the encoder part of the Convolutional Autoencoder for weight initialization, achieved 96% accuracy in a previous study.

In this study, vocalizations of A30 and A34, two NRKW matrilines, were extracted from 36 hours of archived recordings. Spectral clustering was used to cluster segmented vocalizations from A30 and A34 separately based on autoencoder features. Gap statistic was used to estimate optimal number of clusters. Each cluster was visually (on spectrograms) and aurally examined. Four A30

clusters and two A34 clusters with high homogeneity were matched to discrete call types according to Ford call catalog. By further clustering these clusters, subcall types were identified, which were not referenced in the call catalog. This pilot study shows a promising possibility of using data-driven methods to access large amounts of vocalizations, and to identify subtle structural differences between similar appearing signals. This enables to study variations of vocalizations without or with limited prior assumptions and improves the efficiency of annotation work.

The lack of species baseline knowledge is often the principal barrier to conservation, especially if the species of concern are under a wide range of human pressures that are difficult to control or regulate. While the Western Mediterranean Sea has attracted a relatively high level of research, baseline information remains low in the Eastern Mediterranean. This project aims to fill the knowledge gaps on sperm whales *(Physeter macrocephalus)*, Cuvier's beaked whales *(Ziphius cavirostris)* and delphinidae in Turkish Mediterranean waters. The surveys have been conducted over four seasons between April 2018 and April 2019, with 32 days (420 hours) of acoustic and visual effort, covering 3732 km from the Eastern Hellenic Trench to the Anamur. While bottlenose dolphins *(Tursiops truncatus)* and delphinidae species (38 groups) were detected in 21 and 38 encounters, Cuvier's beaked whales and sperm whales were recorded in 2 and 11 encounters, respectively. Bottlenose dolphins and delphinidae species were detected from coastal waters to 3,500m depth. Dolphins detected acoustically in each season with increased activity at night, their visual recordings were highest during spring and summer. Acoustic analysis shows a prevalence of 33 kHz click frequency. Acoustic detections of beaked whales were in 1000m and 3500m contours of the eastern Hellenic Trench in spring and summer 2018. Sperm whale sightings were concentrated on the 1000m contour, but ranged from 500m to 3000m depths, between the Eastern Hellenic Trench to Kekova. The sightings were highest in summer followed by spring and a single acoustic recording in autumn. Photo-identification data of sperm whales revealed a presence of five male and one possible female with a juvenile. The current research is identifying potentially important marine mammal area(s) and underlines the importance of local research effort for collecting the necessary data in the Eastern Mediterranean.

Whisker stable isotope values indicate long-term foraging strategies for female New Zealand sea lions

Chilvers, B. Louise

docdolphinette@hotmail.com

Determining the foraging strategies for top marine predators is fundamental to

understanding their role in the marine ecosystem and essential to gain insight into how species

and populations may respond to environmental variability and human impacts. The long-term foraging

strategies of individuals can be studied using stable isotope analysis of whiskers, which

archive keratinous tissue. Here, stable isotope analysis (δ13C and δ15N) along the length of

whiskers from female New Zealand (NZ) sea lions Phocarctos hookeri was used to investigate

individuals' long-term foraging strategies. Previous telemetry studies showed that individual

female NZ sea lions have one of 2 distinct foraging strategies that are habitual within and between

years. Furthermore, past stable isotope research showed that these 2 distinct foraging strategies,

i.e. benthic (foraging on the sea floor) or mesopelagic (foraging at various depths in the water column),

can be identified through δ13C and δ15N stable isotope values from blood and whiskers. In

the present study, chronological serial stable isotope sampling of female NZ sea lion whiskers confirmed

long-term consistency of individual foraging strategies. Thirty-one of 35 individuals

showed constant benthic (n = 13) or mesopelagic (n = 18) isotopic values along the length of their

whiskers. The remaining 4 individuals showed mesopelagic foraging strategies but with slight

oscillations. Serial stable isotope analysis of whiskers is a powerful tool for investigating the ecological

niche of top marine predators throughout their adult life. This tool can be used within the

Auckland Islands' NZ sea lion population to determine the proportion of the female population

that are exposed to detrimental interactions with fisheries.

Can beluga exposure to shipping noise be reduced despite a traffic increase? An individual-based model to inform a noise abatement process in the St. Lawrence estuary and the Saguenay River.

In the context of the Quebec Maritime Strategy, several port-industrial complexes could be developed nearby or within the critical summer habitat of the endangered St. Lawrence Estuary (SLE) beluga population. In the absence of efficient noise abatement measures, the traffic increase associated with the planned development projects would increase belugas' cumulative exposure to shipping noise. A chronic exposure to noise is a recognized stressor, that might play a role in the current decline of the population. Any increase of anthropogenic pressure could lower even more their chance of recovery. In this context, the Government of Quebec funded a research program led by Université du Québec en Outaouais to assess the potential impacts of port-industrial development projects and explore and recommend noise reduction options in collaboration with multiple stakeholders.

This interdisciplinary research program first focuses on improving a prototype of an individual-based simulation model for beluga and vessel movements coupled with models of underwater sound sources and propagation. This simulation model will be used to assess and compare realistic scenarios of navigation noise abatement co-developed by a multi-stakeholder working group. The research program is tied in with other scientific efforts including some conducted under the Canadian Ocean Protection Plan. The research program will also propose an economic framework of the noise abatement options based on their costs and benefits. This study will provide stakeholders, including the Government and the maritime industry, with tools for decision-making and ways of reducing shipping acoustic footprint.

First, we will present the global approach to 1) cumulative noise impact assessment of navigation on SLE beluga and 2) noise abatement options co-development and recommendation process. We will then describe the main modules of the simulation model with a focus on describing the vessel and whale movement sub-models, and acoustic model. The simulation plan will finally be discussed.

True's beaked whale: A cryptic species revealed.

Beaked whales are among the least understood families of cetaceans, with many species known only from stranded specimens or a few live sightings. True's beaked whale (*Mesoplodon mirus*) was described in 1913 based on a stranding in North Carolina, but until recently, live animals were only rarely identified. In 2017, we initiated a study of the ecology of deep-diving cetaceans in the shelf break region of Georges Bank in the western North Atlantic, initially focusing on True's beaked whales. This multidisciplinary study integrates visual and passive acoustic monitoring, genetic sampling, and the collection of dive data via a digital acoustic recording tag (DTAG). Between 2017 and 2018, two large vessel surveys covered over 5900km. Small boat work was conducted around beaked whales on 8 days for collection of photo-IDs, biopsy samples, seawater for environmental (e)DNA and deployment of DTAGs. True's beaked whales were sighted over 250 times, comprised of approximately 80 groups. Focal follow data were collected from 10 groups, providing description of surface and dive intervals over periods of up to 9hr. Over 350 acoustic events from the towed hydrophone array were classified as likely True's beaked whale. Species identity was confirmed by biopsy samples and eDNA barcoding, allowing confident descriptions of echolocation click characteristics and external appearance. A DTAG was deployed for 12hr on one individual in a group of five, documenting 9 foraging dives with a mean maximum depth of 1037m (sd 89.6m) and a mean duration of 32.7min (sd 4.2min). Seafloor depth in the area of foraging was over 2000m, indicating exploitation of mesopelagic prey. Cuvier's beaked whales were frequently sighted and acoustically detected in proximity to True's. Results of this study will provide much needed data for identifying True's beaked whale in the field, as well as describe the ecology of this cryptic, understudied species.

Distribution and occurrence of large whales in New York Bight prior to 2017: Establishing baselines and informing management.

Corresponding Author: echou@wcs.org

The New York Bight is one of the busiest waterways in the world, where industries such as shipping, tourism, fishing and renewable energy development coincide with a diversity of marine wildlife. Large whales have been sighted with increasing frequency in recent years, yet detailed information on species distribution, required for effective management and planning, remains scarce. With growing conservation concerns, a synthesis of large whale sightings data from 1998 to 2017, including published and unpublished data, was conducted. MaxEnt species distribution models were constructed for two commonly sighted species: fin and humpback whales. A total of 221 fin and 225 humpback whale sightings were used in the analysis. Bathymetry, distance to shore, slope of the seafloor, sea surface temperature, chlorophyll-a concentration and zooplankton biomass were included as covariates. Zooplankton data, a proxy for foraging potential, were only available for waters within the 200m isobath, thus two models were run for each species: the first included all covariates for waters less than 200m; the second included all covariates except the zooplankton data for the entire study extent. Areas with high probability of presence were largely coastal in both fin whale models, with low probability of presence past 200m. Humpback whale models identified high probability of presence near New York Harbor and areas along the 200m isobath. Distance to shore and

chlorophyll-a concentration contributed most to fin and humpback whale models, respectively. Inclusion of zooplankton data appeared to influence the probable distribution of both species as a result of patches of relatively high zooplankton biomass. Results also highlighted areas of anthropogenic overlap with whale occurrence, including potential offshore wind energy areas. These results provide valuable baselines to inform future research and monitoring efforts, and the development of best management mitigation practices that may minimize impacts to whales in the New York Bight.

Estimating body mass of free-living whales using non-invasive aerial photogrammetry and 3D volumetrics.

Corresponding Author: f.christiansen@live.se

Body mass is a key life history trait in animals, determining metabolic rates, food requirements and fasting endurance. Despite being the largest animals on the planet, no method currently exists to estimate body mass of free-living whales. We provide a non-invasive method to accurately estimate body mass of right whales (*Eubalaena sp.*) while accounting for both their structural size (body length) and relative body condition (body width). First, aerial photogrammetry from unmanned aerial vehicles was used to measure the body length, width (lateral distance) and height (dorso-ventral distance) of free-living southern right whales (*E. australis*; 48 calves, 7 juveniles and 31 lactating females) in Península Valdés, Argentina. From these data, body volume was estimated by modelling the whales as a series of infinitely small ellipses. Compared to a circular cross-sectional model, our elliptical model improved volume estimates by 23.6% (mean=6.1%, SD=5.3). The body girth of the whales was next calculated at three measurement sites (across the pectoral fin, the umbilicus and the anus) and a linear model was developed to predict body volume from the body girth and length data. This model was then used to estimate the body volume of eight lethally caught North Pacific right whales (*E. japonica*), for which body mass was measured. Using the predicted volume and known mass of the lethally caught whales, we then calculated a volume-to-mass conversion factor of 755kg m^{-3} (SD=50). This conversion factor was consequently used to predict the body mass of the free-living whales from Argentina. Our body mass model predictions were accurate to within 5.7% (mean=1.6%, SD=0.01) of estimated mass, which is six times higher than a simple body length-to-mass model. Our modelling approach opens up new avenues to incorporate allometric relationships of body mass into studies of large whale bioenergetics and ecophysiology.

Genetic structure as revealed by mtDNA and Microsatellites in Northern Fur Seals, Callorhinus ursinus

Corresponding Author: coolaoi95@gmail.com

The Northern Fur Seal is a widely distributed philopatric species that breeds on a limited number of islands across the North Pacific Ocean. Recently, the number of individuals on breeding islands in Alaska has been decreasing, but in Russia it has been increasing. Furthermore, on the coast of Hokkaido Japan, reports of fishery damage from this species are increasing. For management and conservation of this species, it is necessary to clarify whether population structure exists. Due to differences in population dynamics among breeding islands, and because many individuals are philopatric (Baker et al. 1995), the species can be classified as two subpopulations as Russian and Alaska. However, previous studies were unable to find population structure in the northern fur seal (Dickerson et al. 2010). The aim of this study is to clarify the presence or absence of population structure using new polymorphic makers. We investigate the genetic variation of northern fur seal among breeding islands, using 432 individuals from nine islands (each n=48). To test for genetic variability and population differentiation among islands, 13 microsatellite loci, 295 bp from the mtDNA control region and 1198 bp from the mtDNA cyt-b region were used. In mtDNA, consensus sequences from all samples were aligned in MEGA7. Population structure among population groupings was performed in Arlequin3.5 and PopART1.7 was used to create network diagram. In

microsatellite loci, polymorphism was detected with GENEPOP and Arlequin3.5 was used to compute unbiased estimates of F_{ST}. The most likely number of populations (K) was estimated using STRUCTURE2.3.4 and DAPC analysis. In total, we identified 220 different haplotypes in the control region and 173 different haplotypes in the cyt-b region. In 13 microsatellite loci, F_{ST} suggested population structure between some Russian and Alaskan populations. STRUCTURE analysis estimated that K=1, but the DAPC analysis estimated that K=2.

AgentSeal: Movement of harbour seals: an individual-based modelling framework as a reliable management tool to study multiple stressors.

Chudzinska, Magda[1]; McConnell, Bernie[2]; Smout, Sophie[3]

Marine environments are threatened by human exploitation, degradation, construction and operation of offshore structures. Such environmental changes can strongly influence behaviour and performance of individuals e.g. foraging, breeding success. Design of a reliable tool which can predict long-term consequences of a combination of stressors on animal movement and population dynamics is important, especially to allow regulators, developers and NGOs to make 'what if' scenario predictions.

We present results of an individual-based model (IBM) for harbour seals, a species showing recent declines in parts of the UK. The IBM simulates movements of harbour seals according to realistic decision rules. Model outputs include the predicted spatio-temporal distribution of the animals and their energetic status and can be used to predict simultaneous and cumulative effects of different stressors at individual and population level. This is the first seal IBM which includes dynamic processes such as changes in food availability and bioenergetic needs of animals.

The model structure and parameterisation is based on observations and data collected over 20 years by SMRU including telemetry data from 300 animals, annual survey counts, bio-energetics and physiology, and behavioural observations. Results from the first phase of modelling represent seals along East Scotland, simulated in 15 min time steps over 1 month of foraging.

This model successfully reproduces bioenergetics, movement at various scales: fine- (step length and turning angle) and large-scale (trip duration and extent, spatial distribution); and daily activity budget. It also reveals that mechanisms related to prey digestion determine energetic and activity budget of seals and that underlying prey abundance and distribution is a crucial element of the model.

Further phases of modelling will extend these investigations to take account of annual movement including breeding, moulting and migration; simulation of the effect of multiple stressors on movement and population dynamics of seals.

Extreme synchrony in diving behavior of Cuvier's beaked whales (Ziphius cavirostris) off Cape Hatteras, North Carolina.

Cuvier's beaked whales are sensitive to certain anthropogenic noises, but we understand very little about how sociality mediates their behavioral responses to disturbance. Studies of the social behavior of this species are challenging because of their pelagic distribution and the limited time they are available to observe at the surface. Only adult males have erupted teeth and high levels of scarring suggest that males compete agonistically for access to females. We predicted that associations among adult males would be unstable over time and tested this prediction by evaluating the diving behavior of pairs of animals instrumented in the same group with satellite-linked depth-recording tags off Cape Hatteras, USA. We used diving records and a null model to determine if dyads tagged together dive more synchronously than expected by chance. We found that adult male-male dyads (n = 4) showed extended periods of diving synchrony, with 77-89% of the beginnings and ends of each long dive (>33 min; usually >800 meters) occurring within 60 seconds of each other. This synchrony persisted

from 6 to 17 days. All dyads that included an adult male with a different age sex class individual (n = 4) dove synchronously for less than a day. Higher resolution data on one male dyad showed synchrony in both short and long dives, and visual observations over multiple days suggested that the two males remained together in the same group. We explored several explanations for these surprising results, including cooperative foraging, predator defense, extended competitive bouts, and the existence of male-male alliances. We argue that male-male alliances are the most likely explanation for these observations and describe further work we are engaged in to characterize the longer-term fission-fusion dynamics of groups and to determine the duration of these putative alliances.

Site fidelity of Delphinus delphis by photo-identification technique in Samos Island (Eastern Mediterranean Sea)

Although several local populations were observed within the Mediterranean Sea, the short-beaked common dolphin (*Delphinus delphis*) is ranked as Endangered by IUCN due to its sharp decline during the last decades. Conservation actions to fulfil targets under the range of several international agreements and limit potential threats on this species require robust information on its site fidelity, residency patterns and habitat use. Particularly, identifying critical habitats for *D. delphis* seems to be the first step towards the establishment of an effective conservation strategy within the Eastern Mediterranean Sea. Therefore, a monitoring study on *D. delphis* based on photo-identification data was carried out in Samos Island, providing a knowledge contribution for the Eastern Aegean Sea.

Systematic cetacean surveys and sightings data were collected from February 2016 to July 2018. Individual photo-identification was performed based on a combination of long-term natural marks and dorsal fin pigmentation patterns. The site fidelity rate and the long-term residency pattern were estimated for the photo-identified individuals.

Through the study period, an effort of 164 surveys with 8200 km covered were applied, obtaining 86 sightings of *D. delphis*. Photo-identification data were collected in 38 sightings, providing 73 individuals distinctly identified. The occurrence of re-sighted individuals was up to 6 times as well as of multi-year resident dolphins, providing the evidence that *D. delphis* showed varied degrees of site fidelity in the study area. Results suggest the southern waters of Samos Island as a crucial habitat for the continuous presence of the species. However, a long-term research with wider survey coverage have a critical importance in the identification of a larger *D. delphis* population which will help to understand the currently unknown migration patterns and habitat use of the species within the Eastern Mediterranean Sea.

Declining winter sea ice is associated with a northward shift of bowhead whale winter range.

Since the winter of 2016/17, unprecedented declines in the extent of winter sea ice have occurred in the Bering Sea. These declines resulted in the primary wintering area of Bering-Chukchi-Beaufort (BCB) bowhead whales (*Balaena mysticetus*) becoming ice-free. As a result, it was

unknown if whales would use their traditional wintering area or shift their distribution northwards to continue to winter under sea ice. Data from satellite transmitters were used to compare the winter (January-March) distribution and dive behavior before the decline in Bering Sea ice (n=28 whales, 2009-2016) and after (n=4 whales, 2018; n=4 whales, 2019). During 2009-2016, whales primarily wintered south of St. Lawrence Island (~62.5° North latitude). In both 2018 and 2019, whales remained north of the southern ice margin, shifting northward ~540 km (into the Chukchi Sea) in 2018 and ~220 km in 2019 when ice extent was greater. The proportion of square- and U-shaped dives, thought to be associated with feeding, did not change with the shift in winter distribution (~90% of all dives). The average percentage of time whales spent at or near the seafloor, however, was less during the winters of 2018 (21%) and 2019 (16%) than during 2008-2016 (30%). These data suggest whales were feeding in the northern wintering areas, but targeting different depths. Bowhead whales wintering north of the ice margin may relate to killer whale avoidance and be less linked to their preference to associate with ice. Bowhead whales associate with ice-free waters in summer, however, killer whales are rarely observed in the BCB bowhead summer range. We are analyzing data from BCB bowhead whales harvested by Alaska Natives to determine if changes in winter distribution and foraging behavior have altered body condition.

Estimating age at weaning for Pacific walruses using trace elements in teeth.

In mammals, the age at which a mother weans her young is directly related to the amount of energy she invests in that offspring. Thus, weaning age can be indicative of the health and nutritional status of the mother, the availability of resources in the environment, and sex-related differences in maternal investment. Recently, a technique has emerged to estimate weaning age using strontium (Sr) and barium (Ba) concentrations in teeth. Though successfully applied to a number of terrestrial mammals, this method has not been used for marine mammals. The aims of this study were to examine Sr and Ba concentrations in Pacific walrus (n = 118) tooth cementum to determine whether a weaning signal exists and, if yes, to estimate weaning age for female (n = 92) and male (n = 26) walruses. For most individuals, the weaning signal was recorded as a steep decline in Sr (from ~400 to ~250 ppm) and Ba (from ~12 to ~2 ppm); however, this signal was detectable in more teeth for Sr (~93%) than Ba (~80%). Estimates from both elements typically agreed closely, with a mean difference of 0.1 years (Sr estimate – Ba estimate) for males and females. The median estimated age at weaning was three years for both sexes, with ~37% of walruses weaning by age two, ~81% by age three, and ~97% by age four. These estimates compare reasonably well with the relatively sparse literature values, though they suggest that the average weaning age may be slightly later than previously believed. Estimated weaning age did not vary with year of birth (1914 – 2002), indicating that environmental conditions, food availability, and population density are not important drivers of weaning age in walruses. These results demonstrate the potential value of this approach for studying lactation duration and weaning in marine mammals.

Seafloor geomorphic data predictors or bathymetric proxies? An alternative approach into modelling distribution of cetaceans.

Seafloor geomorphic features, such as submarine canyons, continental shelves, continental slopes or seamounts, have been rarely attempted in modelling as explanatory variables, and when they have been used, usually focus on specific geomorphic features. Despite some attempts to provide more defined identification methods of geomorphic features in research, the prevalence of such identification remains arbitrary. Currently, a global seafloor geomorphic features dataset is accessible, with an objective identification and full representation for each seafloor geomorphic feature. The sperm whale (*Physeter macrocephalus*) and the striped dolphin (*Stenella coeruleoalba)* are two common species in the Mediterranean Sea, with different foraging strategies and relationships with seafloor features. Therefore, these species can provide an understanding of how the use of seafloor geomorphic features into modelling are related with two distinct cetacean-habitat relationships. A standardized ensemble species distribution model (SDM) framework was selected to model the performance of models based on common bathymetric parameters with models based on a distance metric of seafloor geomorphic features,

combined with occurrence data of these two cetacean species. The models shows significant high and low preference for certain seafloor geomorphic regions, or their surroundings. Additionally, our study shows that according to species and modelling technique the model's performance can be improved with the consideration of geomorphic data in comparison with the use of common bathymetric proxies. To our knowledge, this study was the first attempt to use these data as explanatory variables into habitat modelling. We argue that the use of these geomorphic features data as explanatory variables in modelling is providing enhanced insights on the relationship of cetacean species with seafloor regions, and has high potential to improve modelling performance as compared to models commonly limited to the use of bathymetric proxy parameters only.

The latest findings on cetacean welfare in captivity (and how it links to wild research and conservation)

Clegg, Isabella
Animal Welfare Expertise, Winchester, Hampshire, United Kingdom
Corresponding Author: izziclegg@hotmail.co.uk

Animal welfare can be assessed scientifically has recently made the transition from the farm industry to zoos and aquariums. For the past several decades the public display of captive cetaceans has led to controversy due to concerns over the animals' well-being, but which up until recently had not been studied obejctively. In the last few years such research has exponentially increased around the world, mostly on bottlenose dolphins (*Tursiops truncatus*), and this presentation reviews and collates the first animal-based indicators for cetacean welfare in general. Cognitive bias testing has proved a valuable tool, showing that affiliative behaviour (synchronous swimming) is linked to positive welfare states. A certain level of anticipatory behaviour (i.e. preparing for a predictable event) is likely to reflect positive states, but at excessive and sustained levels could indicate poor welfare. Lower frequencies and durations of play suggest negative states in cetaceans, since such parameters decrease following environmental or social stressors. Strong support is given for other potential indicators such as cortisol measurement, Body Condition Scoring (BCS), qualitative ratings of behaviour, and general health parameters. But is any of this relevant to wild cetacean research and conservation? Although perhaps not obvious at first, there are several crossovers between welfare science and conservation biology that have recently been higlighted in the literature, since both focus on the animal's holistic response to environment. Researchers are now suggesting that sometimes an 'individual animal' approach is more effective than population-level conservation, since changes in the environment will affect individuals differently. Furthermore, the rapid and irrevocable decline of some cetacean populations is leading to consideration of *ex situ* conservation options (e.g. VaquitaCPR). Increased collaboration between wild and captive cetacean researchers, and integration of welfare principles into conservation strategy, may significantly enhance our collective understanding of the impacts of environmental change on these animals.

Development of a novel drone-based method to survey marine megafauna at local spatial scales. Lessons learnt from a dugong drone survey in the Pilbara, Western Australia.

Unlike manned aircraft, drones provide the opportunity to conduct safe, rapid and cheap local-scale aerial surveys of marine megafauna. Nonetheless, surveying at the local-scale using drones and aerial imagery requires us to re-think aerial survey concepts to develop methods adapted to this new technology. In this study, we revisited the fundamental steps of aerial survey methods from design and data collection through to analysis, with the aim of assessing the distribution and habitat use of dugongs in local remote waters of the Pilbara, Australia. We used two types of aircrafts: a vertical-take-off-landing fixed-wing (hereafter fixed-wing) and an off-the-shelf multirotor drone (hereafter multirotor). The surveys were conducted from a live-aboard boat over four field trips. The fixed-wing was flown outside standard operating conditions (i.e. beyond visual line of sight and up to 800ft above ground level) following a traditional line transect design with the aim of surveying a 100km^2 area. The multirotor was flown in a grid sampling design compliant with Australian standard operating conditions (i.e. within visual line of sight and not beyond 400ft above ground level) to survey a 35km^2 area. Overall, we conducted over 390 flights (130 hours), collecting over 89000 images, 191 of which contained dugongs. Limitations in the systems (e.g. manufacturing system failure, wind limits for safe operations) led us to refine our survey protocols to

ensure that they were robust. We developed user-friendly software and protocols to manually review the images, map the image footprints and animal sightings in GIS, and model the dugong distribution and relative density in near real-time during the fieldtrip. This new method can be adapted to any species of marine megafauna and become a very powerful cost-effective tool in the context of local-scale studies such as environmental impact assessment projects and to help the conservation and management of endangered species.

Spatial, temporal, and individual-level variation in northern Gulf of Mexico common bottlenose dolphin (Tursiops truncatus) diet

Ecological factors that change over spatial and temporal scales may drive dietary variation of generalist foragers at both population and individual levels. Using stable isotopes from skin samples, we examined the diets of common bottlenose dolphins*(Tursiops truncatus)*captured in 2018 at two field sites in the northern Gulf of Mexico: Mobile Bay, Alabama (MB) and Barataria Bay, Louisiana (BB). We examined in detail temporal (2011 – 2018) and individual-level dietary variation in Mobile Bay using isotopes from liver, muscle, and skin. To provide further insight into individual-level variation in isotopic signatures, we also satellite-tracked 18 tagged dolphins in MB in 2018. In 2018, dolphins from both field sites fed primarily on fish (MB 74%; BB 91%), with smaller amounts of decapods (MB 18%; BB 7%) and, in MB only, cephalopods (9%). In 2011, dolphins in MB fed primarily on cephalopods (liver 67%, muscle 48%, and skin 55%), particularly in weeks prior to sampling. Fish were the dominant prey group in all other years, while cephalopods likely comprised < 20% of dolphin diets in those years. The difference in diets between 2011 and other years suggests potential interannual variation in the availability of prey groups, particularly squid. We found considerable among-individual variation in carbon isotope values despite diet similarity, suggesting different foraging habitats rather than prey groups. Data from the satellite-tracked dolphins confirm that among-individual variation in diet maybe related to fine-scale movement patterns in MB dolphins. By comparing long-term stable isotope data from common bottlenose dolphins, and incorporating movement data, we found that dolphins are capable of considerable dietary flexibility while maintaining relatively small ranges.

Diving behavior of humpback whales (Megaptera novaeangliae) in the western South Atlantic Ocean

Humpback whale (*Megaptera novaeangliae*) diving behavior are relatively well studied in feeding areas (FAs), but information from breeding (BAs) and migratory (MAs) habitats is not as well known. Here we describe the diving behavior of 19 females with calves and 9 males tagged with archival satellite tags deployed in wintering grounds of the coast of Brazil prior to the whale's migration to their feeding destinations. Tag data (mean duration=43 days, range=3-127) yielded a total of 74,059 dives, which were typically shallow (<180m, 98.7%). The distribution among areas was: FA (25.3%); BA (34.3%), and MA (40.4%), with males showing higher frequency of shallow dives than females only in FA. Proportion of deep dives (>180m) was: BAs (2.1%); FAs (32.3%), and MAs (65.5%), with similar frequency between females and males in BAs, higher frequency of females in MAs and higher frequency of males in FAs. Overall, dive depth in the BA averaged 28.3m (range = 1.5-236m) while mean duration was 4.07min (range = 0.1-26min). Females performed relatively shallower and shorter dives (27.1m and 3.78min, respectively) than males (29.23m and 4.72min). In MAs, mean depth and duration were 40.6m (1.5-

464m) and 3.92min (0.1-30.6min), with no obvious difference between females and males in depth (40.1m vs 41.2m) but slightly longer durations for males (4.38min vs 3.60min). In the FAs, mean dive depth and duration were 42m (10-320m) and 2.89min (0.26-30.2min) with females slightly shallow and shorter dives observed for females (37.14m and 2.74min) when compared to males (43.03m and 2.92min). Dive shape frequency was 7.6% for V-shape (mean depth = 41m), 41.6% for square-shape (mean depth = 33m) and 50.8% for U-shape (mean depth= 44.4m). There is evidence that foraging dives occurred during the migration suggesting that animals may be feeding more often than previously thought during this phase of their life cycle.

Ships do not comply with voluntary whale protection measures in Northeast USA waters

Ship strikes are a major source of mortality for whales worldwide. Slowing ships to ten knots or less can reduce the likelihood of strikes that result in whale fatality. But getting ships to slow down requires overcoming challenges in both communicating conservation measures and convincing ship operators to reduce speed. On the east coast of the USA, ships are required to slow down in seasonal protection zones for endangered North Atlantic right whales (*Eubalaena glacialis*). When aggregations of right whales occur outside of seasonal protection zones, temporary zones are established and ships are asked to voluntarily avoid the area or reduce speed. In November 2018, aerial surveys found an aggregation of right whales in close proximity to one of the New York shipping lanes and outside of any seasonal protection zone. A temporary Dynamic Management Area (DMA) was established and the request that ships reduce speed was broadcast on marine radio as part of a standard US Coast Guard Notice to Mariners. The aggregation persisted into April 2019 as did the broadcasts. In March, the Coast Guard conducted a 'pulse' operation in which ships >300gt approaching the DMA faster than ten knots were contacted directly and asked to voluntarily slow down to ten knots or less when transiting the DMA. We used Automatic Identification System (AIS) data to measure ships' average speed through the DMA for two weeks prior to the operation, for the week-long pulse operation, and for two weeks following it. The distance-weighted average ship speed for these three periods was 12.5, 13.4, and 13.9 knots, respectively. The lack of detectable change in ships' speed despite direct communication to operators demonstrates that conservation measures without consequence were not effective in this case study.

The Pelagos effect: Changes in cetacean distribution over 15 years along a Fix Linear Transect in the Pelagos Sanctuary.

The Pelagos Sanctuary has been established in north Western Mediterranean Sea in 2004, considering the higher abundance of cetaceans, and especially fin whales (*Balaenoptera physalus*) and striped dolphins (*Stenella coeruleoalba*), in the area. In order to investigate changes over time in cetacean distribution and assess possible positive effect of the creation of the sanctuary, we compared cetacean relative abundance along a fixed transect over 15 years. Pre-Sanctuary assessment was based on Laran and Drouolt-Dulau (2007) based on the 2001-2003 years, while for post-Sanctuary analysis we used data collected from 2016-2019 along the same fixed transect. These data were collected within the FLT MED MonNet project. The most frequently encountered species were the fin whale representing 49% of all sightings with 210 individuals, then the striped dolphin with 42% and 1576 individuals. The relative abundance of striped dolphins increases constantly from June to August 2016 -2019, ($3.1x10^{-1}$ ind.km^{-1}), contrary to what observed in pre-Sanctuary assessment, when two peaks, in May and September where observed (>1.3×10^{-2} ind.km^{-1}). For winter, we observed a peak in November ($3.2x10^{-1}$ ind.km^{-1}) with a minimum value in January, while a consistent minimum value (<0.6×10^{-2} ind.km^{-1}) was obtained from December to April in 2001-2003. Concerning fin whales, while summer relative abundance is similar in the two considered periods, both showing a peak in August with 5.6×10^{-2} ind.km^{-1} and $4.56x10^{-2}$

ind.km^{-1} respectively for pre and post Sanctuary, strong differences occur for winter. While relative abundance was almost zero from November to January 2001-2003, we observed constant presence of the species with an intense peak in January with 5.69x10^{-2} ind.km^{-1}. In general, higher abundance of striped dolphins have been observed post-Sanctuary as well as an higher presence of fin whales in the area during winter time. Changes in environmental parameters (sea surface temperature and chlorophyll) were also investigated.

X Marks the spot: Suspected broadhead arrow injuries in two bottlenose dolphins (Tursiops truncatus) along the Alabama Coast.

The northern Gulf of Mexico is a hotspot for negative human interaction with wild bottlenose dolphins. Mortalities include fisheries interactions and intentional harm such as gunshots, arrows, boat strikes, and blunt force trauma. Since 2016, distinctive X-shaped marks of unknown origin have been documented on at least two stranded dolphins in Alabama. To determine if the origin of these X-shaped lesions were fisheries interactions or intentional harm, forensic analysis was conducted on various impression patterns of nets and weapons that could make similar markings. Clay casts and carcass reenactment was performed to test whether the lesions could be linked to a specific weapon, comparisons were made to photos of known fisheries interactions and intentional harm cases, and histopathological evaluation was performed on the lesions. While X-shaped lesions on carcasses are typically linked to net interactions or scavenging, the depth and location of lesions on the carcasses in these cases were notably different. These lesions were determined to be a pattern injury from a common source. Bruising and the presence of neutrophils at wound sites indicated these injuries were inflicted prior to death, although not the primary cause of death. The size and shape of lesions matched the structure of a 4-point broadhead arrow typically used for small game hunting or bow-fishing. This work highlights the need for detailed evaluation of atypical lesions and subtle signs of intentional harm. Results suggest that intentional harm with broadhead arrows is at least a regional concern where broadhead arrows are commonly used in small game hunting. Detailed evaluation of external lesions on cetaceans is necessary for reliable detection and diagnosis of human interactions and sharing data across stranding networks will help track local and regional trends of intentional harm to help guide management and enforcement in areas of need.

The unexpected benefits of ferries: Lessons in humility and patience from Oman and Congo.

Bottlenose dolphins (*Tursiops truncatus*) are globally distributed in temperate and tropical climates and along most continental coastlines. Some populations or "stocks" display high site fidelity to small regions while others migrate seasonally, often composed of resident and transient animals. Their occurrence across the eastern coast of the United States extends from Florida to as north as New Jersey, yet there is limited knowledge about their inshore distribution in the New York Bight. We examined the distribution and occurrence of bottlenose dolphins in the coastal regions of the Western New York Bight. Sighting and photo-identification data were gathered opportunistically aboard a seasonal whale-watching vessel and analyzed to evaluate their distribution including group size and distance to shore. From April to December 2011–2018, there were 320 sightings of bottlenose dolphins. We detected an increase in the numbers of occurrences (87.16%) over 8 years. Large groups of 25-100

animals were regularly observed nearshore in close proximity to the shoreline (49.26%). The persistent seasonal occurrence of dolphins in the Western New York Bight represents the northern extent of their migratory range. Our findings provide important baseline data documenting the presence of this species in the New York Bight and illustrate the need for continued monitoring efforts in this area of substantial industrial development.

Estimating exposure to ship noise of the Southern Resident killer whale population in the Salish Sea, Canada

The endangered Southern Resident Killer Whales (SRKW) of the Salish Sea, western Canada, display behavioral reactions to vessel noise, alter their vocalizations to overcome increased noise levels and are affected by masking when in proximity to vessels. As vessel traffic is expected to double by 2030, these effects could prevent the recovery of SRKW, currently down to 75 individuals. Within the scope of the Noise Exposure to the Marine Environment from Ships (NEMES) project, our study assessed noise exposure for SRKW and developed a set of geovisualization tools to support vessel noise management. We combined information on the distribution of SRKW (kernel density estimation) with the output of a cumulative noise model describing sound levels generated by commercial vessels. Cumulative distribution functions were used to evaluate SRKW's noise exposure levels and median cumulative noise values were used to identify main noise contributors within the study area. Ferries, tugboats, vehicle carriers, recreational vessels, containers, and bulkers showed high levels of exposure for SRKW. Building on these results, we developed a suite of three geovisualization tools developed as add-ons to the ArcGIS Pro platform that focused on mapping exposure hotspots, computing probabilistic levels of exposure, and identifying alternative shipping routes that would minimize exposure for cetacean species. Using the Salish Sea as a case-study, the tools were applied to test two alternative management options to reduce noise exposure for SRKW: re-routing and lateral displacement. Management actions aiming at reducing SRKW noise exposure levels during the summer should prioritize the main contributors to vessel noise in the Salish Sea and take into consideration the spatial distribution of their levels of exposure. By enabling marine managers and planners to explore and analyze acoustic and biological data, the framework and tools developed in this study facilitate the adoption and implementation of adaptive noise management strategies.

Odontoceti's humerus: A novel study on its morphometry and bone density using helical CT.

Cetaceans are Mammals that have evolved through a series of morphophysiological adjustments of the various biological systems that allow them to live under water. One of them, the bone tissue is not fully understood and it is related both with the musculoskeletal and haematopoietic systems.

From 2016 to date, humeri of 90 specimens belonging to 11 different species were collected from stranded animals in Canary Islands (Spain). Samples were analysed by means of helical computed tomography (CT), a technique particularly effective in the study of bone tissues, allowing measurements of bone densities. These have been measured from specific cross sections of the distal epiphysis, the diaphysis and the proximal epiphysis (separating the tubercle from the head of the humerus). Bone densities of the cortical and trabecular bone have been measured separately. Collected data led to trend plots focusing on the changes of the values along bones cross sections.

Comparing these data, bone densities gradients showed a similar behaviour in individuals of the same species according to growth of each animal. Moreover it was interesting to discover that animals with similar diving habits have similar plots, thus differentiating between shallow and deep divers: deep divers have lower bone densities

in the range of 200-800 Hounsfield while shallow divers's range between 400-1600.

The objectives of this project are the anatomical description together with the morphometric and bone density studies of the Cetaceans' humerus, to obtain reference values that could help in a classification of the degree of growth of the animals, based on their skeletal development. Moreover, these data could be used to support diagnoses of pathologies related to the bone tissue.

Circum-polar analysis of Southern Ocean humpback whales

The Southern Ocean offers some of the most remote, logistically challenging research environments on Earth, yet these waters are the feeding grounds for circum-polar populations of humpback whales (*Megaptera novaeangliae*). The more accessible Antarctic Peninsula region is the best studied habitat, but is not reflective of most of the open waters. Over the past decade, increasingly sophisticated satellite tags have been deployed on humpback whales revealing new migration paths and feeding grounds. We have compiled satellite tag data from humpback whales throughout all of the Southern Hemisphere oceans representing the different breeding grounds and/or migratory corridors. We focused on the Austral summer feeding grounds in the Southern Ocean and used state space models and environmental variables such as distance from ice edge, lagged productivity, sea surface temperature to infer behavioural states such as foraging or resting, and travelling. Humpback whales are not uniformly predictable in time or space throughout the Southern Ocean. Often considered 'ice-edge' whales, the proximity to ice-edge varied from tens to several hundreds of kilometres with lag effects of ice-concentration a strong indicator of productivity driving whale feeding areas. Near-land areas of higher productivity e.g., west Antarctic Peninsula, Balleny Islands, South Georgia and the South Sandwich Islands were important to whales, but many whales occupied discontinuous patches of open ocean waters associated with krill productivity. Our circum-polar analysis of humpback whale habitat use and movement patterns will inform the development of Important Marine Mammal Areas (IUCN). With heterogeneous changes in ice dynamics in Antarctica, this work will provide predictive habitat modelling enabling a better understanding of humpback whales' future in the Southern Ocean.

The acoustic repertoire of free-ranging bottlenose dolphins (Tursiops truncatus) in south Abaco, Bahamas.

Quantifying and characterizing vocalizations emitted by a species is a necessary first step in understanding signal function and assessing intraspecific variability within and across geographic areas. Bottlenose dolphins (*Tursiops truncatus*) produce a wide variety of sounds used for communication among conspecifics and for interacting with their environment. In this study, recordings of a resident population of free-ranging common bottlenose dolphins made on a moored *Loggerhead* DSG-ST acoustic recording device and a 10 m hydrophone array during nearshore boat-based surveys in south Abaco,

Bahamas from 2008-2018 were analyzed. Results demonstrated that the dolphins inhabiting this region emit a variety of signal types consisting of: whistles, signature whistles, burst pulse (BP) sounds, low frequency narrow-band (LFN) sounds, and brays. Whistles had a great frequency range, between 1.31-30.38 kHz, and the mean acoustic parameters fell in range with those from other studies. In total, 11 well-defined, stereotyped signature whistle contours were identified. LFN sounds occurred infrequently and had low peak frequencies (mean = 0.52 kHz ± 0.28), short durations (mean = 0.09 s ± 0.07) and were either produced in trains or as components of bray calls. The identified BP sounds had a mean (±SD) inter-pulse interval of 2.44 ms (±1.00) with durations mostly under 0.25 s. We also report on emissions akin to moans and a potential novel signal type. This study provides baseline data for a relatively undisturbed population of bottlenose dolphins and contributes to the knowledge of the acoustic repertoire of this species.

A comparison of the external pigmentation patterns of two Cuvier's beaked whale populations as evidence towards combining photo identification data for improvements in future demographic analyses.

Population demographics, the number of individuals within a population of know age and sex, is an important aspect of a species' biology. A model has previously been used to reliably sex Cuvier's beaked whales using external pigmentation patterns and scarring density thresholds. However, this methodology was only applied to and tested on a population from the Mediterranean Sea. To test if this methodology was robust in a different geographic population it was applied to 49 animals of known sex from the Southern California Anti-Submarine Warfare Range. A binomial GLM was fitted using the dorsal fin zone scarring density of 47 adult animals (22 females and 25 males) from the Mediterranean. A density threshold of 0.072 was calculated, with adult male classification being above this threshold. This threshold, when applied to the Californian population, correctly predicted the sex of 46 animals (94%). Furthermore, when the same model was fitted to the Californian population it correctly predicted the sex of 43 Mediterranean animals (91%). It was found that the scarring density between the between the two populations was not significantly different for males ($F(1,51)= 0.502$, $p=0.48$) or females ($F(1,51)=0.000$,$p = 0.99$). This study has shown that the modelling methods are robust across different populations. In addition, the similarity found in the external characteristics of these two populations suggests the potential for using combined photographic datasets from different populations. This would dramatically increase the amount of data available, allowing for further and more complex investigations into the demographics of this species. For instance scarring gain rate, a possible proxy for age, could be calculated from photographic identification recaptures. Currently only six adult male recaptures have been analysed from the Californian population but a scar density gain rate of 0.014 per year was found.

Feeling out your Food: A histological analysis of the vibrissal system in pinnipeds.

Cooper, Cameron; Liwanag, Heather
California Polytechnic State University, San Luis Obispo, California
Corresponding Author: Ccoope05@calpoly.edu

The vibrissal (whisker) system is present in nearly all mammals and is especially important in deep-diving mammals. Pinnipeds have specialized whiskers that are richly endowed with mechanoreceptors and are highly innervated, indicating that they are sensitive sensory structures. Despite the biological importance of the vibrissal system, we have little comparative data across pinniped species. In pinnipeds studied thus far, each vibrissal unit consists of a follicle sinus complex characterized by a three-part blood sinus system: the upper cavernous sinus (UCS), ring sinus (RS), and lower cavernous sinus (LCS). The UCS is unique to pinnipeds and lacks innervation. Based on this lack of innervation, we hypothesize that the UCS plays a thermoregulatory role, insulating temperature-dependent mechanoreceptors. The objectives of this study are (1) to measure and compare the relative lengths of the three sinuses (UCS, RS, and LCS) across pinniped species and (2) to examine the UCS as a thermoregulatory structure. To do this, we are measuring and comparing the relative lengths of the UCS in deep-diving polar Weddell seals (Leptonychotes weddellii), deep-diving temperate northern elephant seals (Mirounga angustirostris, NES), and shallow-diving temperate harbor seals (Phoca vitulina). Skin tissue samples from the vibrissal pads were collected from Weddell seals (n=6), NES (n=4), and harbor seals (n= 2) that died

in the wild or during rehabilitation efforts. Individual vibrissal follicles were removed and histologically processed using standard methodology. We expect that the species faced with the coldest environment at depth will have the longest UCS. This represents the first study to characterize the microstructures of the vibrissal system in Weddell seals and the first study to investigate the UCS as a thermoregulatory structure. Temperature regulation of the mechanoreceptors on the vibrissae directly impacts foraging ability. Therefore, maintaining the functionality of this system under cold conditions is imperative for foraging success.

Fifteen years of data reveals insights into some of the most internationally recognised orca (Orcinus orca) in the world.

Copello, Juan[1]; Cazenave, Jorge[1]; Visser, Ingrid[2]

Corresponding Author: ingrid@orca.org.nz

Since 2004, we have documented the orca (*Orcinus orca*) who intentionally strand on the beaches of Punta Norte, Peninsula Valdes, Argentina. This zone (a maximum of 14 km in length), is delimited by South American sealion (*Otaria flavescens*) colony locations. Arguably, these orca are the most internationally recognised population world-wide, due to their foraging behaviour. Our database of 15 years of research illustrates that the population is extremely small (fewer than 30 individuals). There are three stable groups based on matrilineal frameworks, however there is also an element of fission-fusion structure as there are individuals who roam between the groups and others who appear for limited times within only a season or two.

Foraging, when the orca are at Punta Norte, includes pinnipeds, cetaceans and birds. When foraging is focused on sealions, we have documented up to 70 attacks in a single day (in 2018, when 15 orca were in the group). Success rates of captures (compared to attacks) during any one season, ranged from 38% to 68% and was influenced by the age classes hunting.

Although orca have been documented in all months of the year at Punta Norte, during the sealion pup hunting season (February-May), in the eight years between 2011-2018, orca were typically present on 42.5% of the days, with the longest duration between sightings being 36 days in 2018. Between 2004-2015 in any one season, this unique population of orca typically had five to seven individuals who intentionally stranded to hunt. Then, in 2016, when younger orca began hunting, the number increased to 10. As this foraging strategy is high-risk, training is a prevalent part of their behavioural repertoire, starting from a very young age. Given the small number of animals, this population is fragile and vulnerable.

A new forensic approach on cetaceans to assess drowning diagnosis and to contribute to the assessment of bycatch-linked death: The diatom test.

By-catch is considered one of the major anthropogenic threats for cetaceans worldwide. Estimates of mortality caused by fishing activities is necessary to understand if it's a real conservation menace and if mitigation actions are required. By-catch diagnosis is currently based on gross findings, which are often non-specific and generally impaired by postmortem autolytic changes.These factors limit diagnosis to fresh or moderately decomposed stranded animals. Additional forensic approaches are needed to support by-catch diagnosis in all carcasses decomposition condition.

The research of diatoms algae used in human forensic medicine to support drowning has been investigated also in marine vertebrates: in preliminary studies, bone marrow has been considered the most suitable tissue in cetaceans due to low probability of contamination during the diatom extraction protocol. This forensic technique has been further investigated on 4 bottlenose dolphins (*Tursiups truncatus*) stranded along the north-western Adriatic sea coastline between 2017 and 2018. The decomposition code according to Geraci and Loundsboury (2005) was estimated being between 3 and 4. 2 of them were deemed to be died after interaction with fishery, according to necropsy results. The humeri were sampled for the research of diatoms in bone marrow, according to Rubini and colleagues protocol (2018).

In each animal, from 2 to 14 diatoms were found with no significative differences between the suspected by-caught ones and the others.

Despite the limited number, these results stress a relevant question related to the mechanism of death during by-catch, since it's not yet clear if cetaceans died for drowning or asphyxia, respectively allowing or not the passage of diatoms in the bloodstream. These doubts request further studies increasing the sample size, to improve this technique despite it is routinely used in forensic medicine in terrestrial mammals.

A call for more comparative studies in cetacean conservation biology.

Some baleen whale populations have recovered remarkably well, others have not. Some odontocete populations are thriving, while others are in dire straits. Climatic and other anthropogenic variation, overlying more 'natural' stressors, in multiple comparable systems offer opportunities to make inference on processes driving resultant integrated differences. However, study sites – ocean basins for migratory whales, bays or estuaries with their individual populations of dolphins – all have their own unique features. It's unlikely that we will ever have a clean, split-plot design, from which we can make inference on processes driving cetaceans' conservation status. This does not mean that we must be condemned to inference from anecdote. To steal from Tolstoy – are all happy cetacean populations alike, and must each unhappy population be unhappy in its own way? Or are there sufficient commonalities in processes driving conservation issues that we can start to see a bigger picture? We now have cheap tools - photogrammetry; remote sample collections for physiological and microbiome assessments; health assessments – to help diagnose the causes of abundance changes. We demonstrated this recently, for some of the species on which we have been working, notably endangered North Atlantic right whales and Southern Resident killer whales. However, we can take these tools further, constructing studies that use a comparative approach using multiple populations across study sites - from ocean basins to bays - in order to strengthen our capacity to make inference on processes driving conservation status. We will demonstrate this using some of our recent work as exemplars. We need to remember that exploring new ways to make inference only becomes possible when we choose to look for these new ways. The field of nonlethal and noninvasive cetacean research is mature enough now for us to conduct these studies. Let's do so.

Co-management of marine mammals in Alaska: A case study-based review.

Cornish, Vicki[1]; Malek, Jennafer[2]

Co-management of subsistence use of Alaska marine mammals is a key provision of the Marine Mammal Protection Act (MMPA). Under authority of Section 119 of the MMPA, US Fish and Wildlife Service and National Marine Fisheries Service can enter into agreements with Alaska Native organizations (ANOs) to cooperatively manage the use of marine mammals by Alaska Natives for subsistence and cultural purposes. Some of the cooperative agreements have been more effective than others, and there is general agreement that co-management partnerships can be improved. The goal of this review was to strengthen co-management relationships to improve the conservation of marine mammals in a region where they are of critical ecological, social, and economic importance. The objectives of the review were to: (1) develop a "working" definition of co-management for the purpose of the review, (2) interview co-management partners, marine mammal hunters, and resource users regarding their perspectives on co-management, and (3) develop recommendations to help increase the effectiveness of co-management relationships. With the help of a Steering Committee comprised of Alaska Natives with co-management experiences and federal resource managers, we selected three case study agreements: Aleut Marine Mammal Commission, Aleut Community of St Paul Island, and Eskimo Walrus Commission. We conducted interviews with federal agency staff and ANO members and also held focus group interviews in seven coastal communities. Findings fell into seven overarching categories: key elements of co-management; partner roles and expectations; communication; organizational structure and accountability; leadership training and transitioning; agency practices and decision-making processes; and challenges of subsistence hunting and the future of co-management. Based on our findings, we developed recommendations and suggested action items with the intent of strengthening co-management and enhancing conservation of Alaska marine mammals used for subsistence and cultural purposes.

Predicting cetacean distribution in the eastern north Atlantic (Iberian Peninsula and African coasts and Macaronesia) to support marine management

Using six years of cetacean occurrence data collected along cargo ship routes between Iberian Peninsula and NW Africa coasts and the Macaronesian islands, we developed ecological niche models (ENMs) to predict the distribution of the eight most sighted taxa of cetaceans in the area (seven species and one genus), representative of all cetacean major groups (small delphinoids, toothed and baleen whales). Two different modelling approaches were used: presence/pseudo-absence with GAMs, including sightings collected during on effort sampling; and presence only with MAXENT, including all sightings. Variables used for model fitting included topographic (depth, slope, distance to coast, distance to seamounts), oceanographic (chlorophyll, temperature and sea level anomalies), detectability (sea-state, wind-state and visibility), geographic (latitude), and seasonal (day of the year) features.

The best model for the most frequently sighted species, *Delphinus delphis*, explained around 20% of deviance by GAM. Predictions pointed for a more northern and coastal distribution with occurrence peaks in continental (Portugal and NW Africa) and island (excluding Cape Verde) shores. MAXENT predicted distribution varied among the modelled species, illustrating narrow or broad-range (e.g., *Ziphius cavirostris* VS *Stenella frontalis*), coastal or oceanic (e.g., *Tursiops truncatus* VS *Globicephala* sp.), and northern or southern species (e.g., *Delphinus delphis* VS *Physeter macrocephalus*). Both modelling techniques were consistent and complementary, allowing an in-depth analysis on the ecological significance of each predictor and on the spatial distribution of species across the study area.

Our results are an important contribution to knowledge of cetacean distribution at basin-scale as baseline data for the European conservation agenda, especially in less-surveyed areas in open-ocean. Our models allow the definition of priority areas, monitoring plans, and conservation measures within the EEZs, which is essential to comply with the Marine Strategy Framework Directive requirements.

Exceptional survey and acoustic recording of the wild bottlenose dolphin (Tursiops Truncatus) during bycatch event in the Adriatic Sea

Changes in marine mammal vocal structures have been investigating for decades to assess whether they correlate with stress levels or stress indicators. Because of their acoustic plasticity, the interpretation of acoustic signals of dolphins has been studied most extensively. This preliminary study describes the changes in acoustic parameters detected in whistles spectral contours in a bycatch event that involved three individuals during a midwater trawling survey using passive acoustic monitoring (PAM). The results indicate a total

number of 76 upsweep whistles, 23 during the catch event and 53 during non-catch events, that were analyzed and compared. Statistical analysis highlighted significant differences among upsweep parameters. Specifically, Dr was significantly higher ($p<0.001$) and fMax, fC, and BW were significantly lower ($p<0.001$) in the upsweeps of the catch event (Mann–Whitney U-test; $p<0.001$). Furthermore, our data show that vocal production during the catch event was characterized by a combination of two signals, an ascending whistle (upsweep) and a distinctive pulsed signal that the we denominated "low-frequency burst clouds" in the frequency band ranged from 4.5 to 7 kHz). This capture event reveals a novel aspect of T. truncatus acoustic communication, it confirms their acoustic plasticity and suggests that states of discomfort are conveyed through their language.

D-PorCCA, a new tool to study the behaviour of harbour porpoises

Cosentino, Mel[1]; Schwarzbach, Patrick[2]; Tougaard, Jakob[3]; Nairn, David; Guarato, Francesco[4]; Jackson, Joseph[5]; Windmill, James[5]

The behaviour of harbour porpoises can be deduced from the variation pattern of their vocalisations. They produce only narrow-band high-frequency (NBHF) clicks, emitted in so-called click trains. Therefore, available acoustic recordings can be used to increase our understanding of their behaviour. Behavioural studies, however, are time consuming and require an accurate, automated classifier and a click train identifier. Here, we present D-PorCCA, a graphical user interface to study recordings from harbour porpoises in the wild. D-PorCCA is an independent tool developed in Matlab and includes an impulsive-sound detector and a new high-accuracy porpoise click classifier (PorCC). PorCC classifies each signal as either: noise (N), low-quality (LQ), or high-quality (HQ) porpoise click. The user can decide on the echolocation events they want to visualise, specifying the length of the click train (including both HQ and LQ clicks) and the minimum separation time between echolocation events. These events are plotted as time vs amplitude, vs inter-click interval, and vs centroid frequency (or direction of arrival, if available). Additionally, the waveform, power spectrum, and spectrogram of each click within the echolocation event is available. Click trains of interest can be easily selected by the user and extracted for further analysis. These events are then automatically cleaned of echoes and other noise sources, after which the pattern of the click train is automatically investigated to determine whether there is one or more animals vocalising simultaneously (i.e., overlapping click trains), as well as which behaviour the animal was potentially engaged in (e.g., feeding). D-PorCCA is a user-friendly tool with potential for behavioural studies of wild harbour porpoises as well as other NBHF species, as it focuses on clicks trains, and can be used to fill knowledge gaps of these elusive species. Moreover, it has potential for application in large monitoring project, such as SAMBAH.

Movement patterns, diving behavior and physiology of the leopard seal in the Antarctic peninsula.

The Antarctic Peninsula is one of the most rapidly changing habitats in the world. To better understand the ability of the leopard seal, an apex predator in the Antarctic ecosystem, to cope with a changing environment, we examined the foraging behavior and habitat utilization of leopard seals using satellite telemetry. We deployed 12 satellite-linked tracking devices on 3 adult males, 8 adult females, and one juvenile female leopard seal on Cape Shirreff Livingston Island, Antarctica during April-May 2018. The animals ranged from 147 to 540 kg with a mean mass of 389 ± 95 kg. Three of the twelve leopard seals remained within the South Shetland Islands, while two female seals transited well to the northeast, with one stopping at South Georgia Island. On average leopard seals made short shallow dives with a mean depth of 28 ± 7 sd

meters and a duration of 3.8 ± 0.5 sd min. However, they occasionally made deep dives, with the single deepest dive being to 428 m and lasting 10.1 minutes. Their physiological parameters were consistent with a shallow aerobic diver, with a blood volume of 134 ± 5.2 sd ml/kg. Their hematocrit ranged from 44 – 56 with a mean of 51 ± 4 sd. We determined myoglobin concentrations in the locomotor muscles 6 of the animals and those ranged between 44.9 ± 1.4 se mg/gr for *Longissimus dorsi* and 32.9 ± 0.8 se for pectoralis muscle. The second season of fieldwork is underway during May 2019 and the results of these studies will be analyzed and presented. The diving and movement date are providing insight into the habitat requirements of this Antarctic top predator. Information on their habitat requirements can be used to predict how their habitat might shift as the climate changes.

Seal parapoxvirus in north American pinnipeds: A molecular and phylogenetic analysis.

Parapoxviruses cause nodular lesions in the skin and mucosal membranes of pinnipeds and infections by these viruses have been documented in marine mammals admitted to rehabilitation facilities worldwide. Seal parapoxvirus is currently categorized as a tentative species of the *Parapoxvirus* genus.

Between 2009 and 2018, tissue samples and ocular swabs were tested from 11 pinnipeds with parapoxvirus infection with origin in rehabilitation facilities on the east and west coasts of the United States of America, representing 4 species (grey seal, harbor seal, California sea lion and northern elephant seal). Our aims were to obtain additional sequences of the parapoxviruses from the clinical samples, targeting the genes *B2L*, GM-CSF/IL-2 inhibition factor (*GIF*) and *vIL-10*, to further resolve the evolutionary relationship with other members of the genus. We also compared the sequences between different pinniped species and locations.

The sequence analysis showed that the parapoxvirus sequences from the seal samples differed significantly from parapoxviruses found in terrestrial hosts and that the pinniped parapoxviruses formed a separate cluster within the genus. Five distinct parapoxvirus variants were detected. Parapoxviruses from harbor seals from the Atlantic and Pacific coast clustered separately, indicating different virus variants in the two subspecies, likely reflecting geographical distance and co-evolution of the virus with the host. One variant of parapoxvirus was found in both a California sea lion and a northern elephant seal housed in the same facility, suggesting transmission occurred between species that belong to different families.

Results of this study support the classification of seal parapoxvirus as a separate species within the genus *Parapoxvirus* and give further insight into the phylogenetic relationships between the different circulating seal parapoxvirus strains.

The gross morphology of the internal tracheobronchial venous plexus of cetaceans

Costidis, Alex
Virginia Aquarium and Marine Science Center
Corresponding Author:
acostidi@virginiaaquarium.com

An extensive internal tracheobronchial venous plexus (ITVP) has been described in bottlenose dolphins, striped dolphins, pygmy sperm whales, and Baird's beaked whale (Costidis & Rommel, 2012; Cozzi *et al*, 2005; Davenport *et al*, 2013; Fanning and Harrison, 1974; Ninomiya *et al*, 2005). Descriptions have mainly involved histological characterizations, so little is known about anatomical connections, extent or function(s) of the plexus. Contrast enhanced computed tomographic (CT) angiography and gross dissection were used to investigate the anatomic connections and extent of the ITVP, and to locate a main vein for targetted catheterization. The primary venous connection was found to be at the birfurcation of the right accessory bronchus. This bronchial vein connects to the intrathoracic caudal vena cava. Large numbers of the plexus veins converge in a fluvial pattern toward this bronchial veins, suggesting this vein is a major emmissary. Numerous smaller ancillary venous emissaries are present throughout the laryngeal and tracheobronchial regions and with the bronchial

vein connect the ITVP to systemic venous circulation. Connectionsto pulmonary venous circulation like those suggested by Ninomiya *et al* (2005) have not yet been found. Threshold and manual segmentation of CT data from perfused pulmonatry trees were used to calculate luminal volume occupied by the engorged ITVP. Preliminary estimates of plexus volume were 38% and 36% of luminal volume in a common bottlenose dolphin (*Tursiops truncatus*) and common dolphin (*Delphinus delphis*), respectively. Such large luminal volume occupancy could have significant effects on the physics of dive-related trachobronchial collapse, by altering the amount of dead space as well as tracheobronchial compliance. Reduced dead space will result in delayed alveolar collapse during a dive, and increased diving-related nitrogen absorption. Similarly, alterations in tracheobronchial compliance will also affect the depth of alveolar collapse. Together, these findings may provide insights for modeling pulmonary shunt and diving gas kinetics.

Aerial surveys for protected marine species around Norfolk Canyon, Virginia, USA

Cotter, Mark[1]; Coates, Shannon[2]; Pusser, Todd; Bell, Joel[3]

As part of a larger multidisciplinary monitoring program supporting Atlantic Fleet Training and Testing (AFTT) activities, the U.S. Navy funded line-transect aerial surveys to collect baseline information on marine mammal occurrence, distribution, composition, and basic behavior within the Virginia Capes (VACAPES) range complex in the mid-Atlantic off Virginia Beach, Virginia. The primary survey area included the waters between 80 and 160 km offshore of Virginia Beach, encompassing an area of approximately 9,200 square kilometers. From April 2018 to May 2019, a total of over 13,000 kilometers of trackline was covered over 23 survey days. Sixteen cetacean species were identified, including protected species such as North Atlantic right (NARW), blue, fin, sei, and sperm whales. Also recorded were True's and Sowerby's beaked whales, which have been rarely encountered in this region previously. Other notable observations include two sightings of eight individual feeding NARW, which were in close proximity to several other foraging humpback, fin, sei, and minke whales. Additionally, a rarely encountered lone adult blue whale was seen over the continental shelf feeding amongst fin whales. In addition to cetaceans, turtles, fish, sharks, and rays were also opportunistically recorded and identified to species when possible. We have documented two species of large pelagic rays (Chilean and giant devil rays) that have likely been misidentified as a general "manta ray" during past survey efforts along the U.S. Atlantic coast. This region is a high-use area for commercial shipping and military activities, and this study is a valuable component of continued monitoring efforts to document the occurrence of protected marine species over a longer temporal span in a seasonally dynamic environment.

Offshore wind and marine mammals in the US: Integrating legal compliance and ecological needs for practicable policy development.

Offshore wind development in the U.S. is rapidly advancing, with multiple recent lease sales on the east coast and areas under consideration on the west coast. As projects progress, agencies such as the Bureau of Ocean Energy Management and National Oceanic and Atmospheric Administration are preparing and adapting policies that may affect offshore wind projects to ensure impacts to marine mammals are within legal limitations as prescribed in the Marine Mammal Protection Act. Key challenges with policy development are related to project scaling and applied worst-case-scenarios and modeling assumptions. To adapt policies, we suggest (1) improved regulatory alignment among agencies for decision-making early in project evaluation; (2) engagement with key stakeholders such as developers and the conservation community; and (3) risk management strategies that allow more complex and realistic consideration of marine mammals' roles in ecological systems. With respect to offshore wind, we will (1) provide examples of challenges integrating marine mammal considerations under different laws and disconnections that can arise between policies and ecological goals; (2) make recommendations about application of policies to meet legal and ecological needs; and (3) differentiate between potential policies on the east and west coasts given different technologies and taxa. An example of a disconnection between policies and ecological needs is application of a larger radius to harassment for vibratory technologies because this discourages use despite reduced acute noise production.

Another example is that shutdown mitigations for geophysical surveys often are required to employ larger mitigation radii than the legal criteria would suggest are needed. Further, although laws have different purposes, we recommend early recognition among agencies of acceptable modeling approaches and coordination to ensure appropriate review and consideration of monitoring and mitigation.

Validation of dive foraging indices using archived and transmitted acceleration data: The case of the Weddell seal.

Dive data collected from archival and satellite tags can provide valuable information on foraging activity via the characterisation of movement patterns (e.g. wiggles, hunting time). Besides, head-mounted accelerometers have proven to be effective for detecting prey catch attempt (PrCA) behaviours. However, device retrieval is typically required to access the high-resolution data they record, restricting use to animals returning to predictable locations.

In this study, we present and validate data obtained from newly developed satellite-relay data tags, capable of remotely transmitting summaries of tri-axial accelerometer measurements. We then use these summaries to assess foraging metrics generated from dive data only. Tags were deployed on four female Weddell seals in November 2014 at Dumont d'Urville, and successfully acquired data over ~two months. Retrieved archival data for one individual, and transmitted data for four individuals were used to (1) compare and validate abstracted accelerometer transmissions against outputs from established processing procedures, and (2) assess the validity of previously developed dive foraging indices, calculated solely from time-depth measurements.

We found transmitted estimates of PrCA behaviours were generally comparable to those obtained from archival processing, although a small but consistent over-estimation was noted. Following this, dive foraging segments were identified either from (1) sinuosity in the trajectories of high-resolution depth archives, or (2) vertical speeds between low resolution transmissions of key depth inflection points along a dive profile. In both cases, more than 93% of the estimated PrCA behaviours (from either abstracted transmissions or archival processing) fell into inferred dive foraging segments (*i.e.* « hunting » segments), suggesting the two methods provide a reliable indicator of foraging effort.

The validation of transmitted acceleration data and foraging indices derived from time-depth recordings offers new avenues for the study of foraging activity and dive energetics. This is especially pertinent for species from which tag retrieval is challenging.

Patterns of persistent organic pollutant concentrations in common bottlenose dolphins (Tursiops truncatus) at multiple spatial scales.

Persistent organic pollutant (POP) concentrations increase at high trophic levels through biomagnification. Common bottlenose dolphins (*Tursiops truncatus*) are an upper trophic level species in estuarine and coastal ecosystems; thus, they accumulate high concentrations of these persistent, lipophilic contaminants. Dolphins near Brunswick, Georgia (USA) have some of the highest recorded blubber concentrations of polychlorinated biphenyls (PCB) in marine mammals studied to date. The Sapelo Island National Estuarine Research Reserve was thought to be a relatively pristine comparison site for the Brunswick study, but dolphins studied from this site also have high concentrations of POPs. Contaminant concentrations from blubber biopsies of dolphins in waterways near Savannah, Georgia (USA) were compared with other dolphins in the southeastern U.S. Male common bottlenose dolphins (n=20) were biopsied in Savannah in spring 2017; additional biopsies were collected in spring 2019 (n=51; sex to be determined). The male dolphins sampled in 2017 had significantly

lower mean concentrations of all contaminants except for dieldrin when compared to concentrations in males in the Brunswick and Sapelo locations. In addition, male dolphins in Savannah had the lowest mean concentrations of PCBs (31.1 μg/g) compared to males at 14 other locations in the southeastern U.S. These values were significantly lower than the values in animals from Brunswick and Sapelo, Georgia, indicating that Savannah could serve as a comparison site to further investigate health effects of POPs in common bottlenose dolphins from the southeastern U.S. Contaminants data were coupled with sighting histories of individuals with ≥10 sightings from 2009-2017 and mapped in ArcMap 10.4 (22.3 ± 12.1 sightings); there were no clear geographic patterns in historical sighting record versus contaminant concentrations near Savannah, Georgia. However, including additional males sampled in 2019 may indicate fine-scale spatial patterns in habitat use and contaminant levels similar to the broad-scale spatial patterns found between field sites.

A different kind of wax museum: Forecasting population trajectories of baleen whales using reproductive parameters from earplugs.

It is logistically difficult to obtain reliable estimates of baleen whale growth rates when sampling populations of low densities and/or in complex habitats. Here we evaluate baleen whale population dynamics by analyzing progesterone, the pregnancy hormone, in baleen whale waxy earplugs (N = 11, total lamina = 835, age range = 13 – 63 years). To identify pregnancies, we calculated percent change in progesterone from the previous lamina, ranked these points, conducted a sensitivity analysis, then assigned the top 30% of points as pregnancies. From these pregnancies, we estimated age at first pregnancy, pregnancy intervals, and pregnancy rate. Our results matched well with published calving intervals, age at first birth, and birth rate. Alternatively, if we inferred pregnancy using 40-50% progesterone percent change cutoffs we estimated higher pregnancy rates, which suggests some conceptions do not necessarily result in birth or the calf does not survive long afterward. Next, we compared multiple individuals for age-specific fecundity (aligned by age). Our results demonstrated, for the first time, age-specific fecundity in fin whales (n = 3, total lamina = 117), as well as reproductive senescence beginning at 25 years and theoretically reaching zero fecundity at 75 years. Finally, we modelled the maximum rate of increase (ROI) of a population of fin whales using a ROI model which includes age-specific fecundity and reproductive senescence. Compared to the standard ROI model, our results suggest a 22.8% reduction in future population size when projecting the ROI from each model forward to the year 2050. Using a model that incorporates age-specific fecundity and reproductive senescence is vital to effective management and can be used to assess how exposures to stressors can impact vital rates of baleen whale populations over the long-term. These results represent significant departures in population trends for these long-lived and vulnerable species.

Song production by the eastern North Pacific right whale, Eubalaena japonica.

Song has not been documented in any right whale species. Here, we present evidence of song production by the eastern North Pacific right whale (NPRW, *Eubalaena japonica*), in the southeastern Bering Sea. Songs were localized to calling NPRW in real-time using directional sonobuoys; singers whose sex could be determined were all males. These sonobuoy data and autonomous recorder data from 17 year-long deployments were analyzed to document and characterize song types. Four unique song types were documented over eight years (2009-2017) at five distinct locations. Each song type consists of a hierarchical structure of 1-3 different repeating phrases comprised predominantly of gunshot calls; three of the four song types contained additional sound types (downsweep, moan, low-frequency pulsive call).

Songs were detected every year from July through early January; all four song types remained consistent over eight years. Two different songs often occurred simultaneously, produced by different animals; the same song was never detected simultaneously at the same location. However, the detection of the same song on the same day and time at two locations 310 km apart indicates multiple animals can produce the same song. These findings provide support that male NPRW produce song; it remains unknown if females also sing. We hypothesize that these patterns may be a reproductive display similar to song in other mysticetes. Although song has not been documented in congeneric right whale species, songs presented here fit the classification of song attributed to other cetacean species. Possible functions of these songs and their management implications will be discussed.

Oceanographic characteristics associated with movements and high-use areas of spotted seals (Phoca largha) in the Chukchi and Bering seas.

Spotted seals (*Phoca largha*) are pelagic foragers that use seasonal pack ice for pupping, nursing, and resting when ice is present (December–June) and coastal haulout sites for resting during the open-water season (July–November). Decreases in the extent and duration of ice cover associated with climate change have eased access to the Arctic for development and shipping, prioritizing the identification of areas important to seals. We worked with Alaska Native hunters to deploy satellite-linked tags on 24 spotted seals (including 20 CTD tags) in nearshore areas of the Beaufort and Bering seas during 2016–2018 to study movements and identify high-use areas. Individual seals were tracked for 137–638 days. Seals tagged in the Beaufort Sea moved into the Chukchi Sea and made recurrent east-west movements, spending 1–27 days foraging near Herald Shoal, primarily in warm Alaskan Coastal Water, and 0.1–5.7 days resting on coastal islands. Seals tagged in the Bering Sea also made recurrent east-west movements, spending 1–25 days foraging in the central Bering Sea, primarily between St. Lawrence Island and St. Matthew Island in Alaskan Coastal Water and Bering Shelf Water, and 0.03–6.2 days resting on coastal islands. In December, seals in the Chukchi Sea moved south, ahead of the advancing pack ice, into the Bering Sea. By mid-January, all seals regardless of their tagging location foraged along the pack ice edge in the central Bering Sea. CTD data will be used to identify oceanographic characteristics of the high-use foraging areas. Tagging seals in both the Beaufort and Bering seas allowed us to identify spotted seal movements and high-use areas throughout the continental shelf. Further studies that include additional tagging locations will likely identify other important foraging and resting areas.

Lessons learned from decades of swimming with dolphins: A New Zealand case study.

Over recent years, cetacean watching has experienced extensive global growth in size and scope. Patron interest in close interactions has prompted industry expansion to include cetacean swimming. This activity persists, despite numerous studies detecting alterations (*i.e.,* avoidance, increased activity, behavioural budget) with potential cumulative effects identified. New Zealand is a global leader in industry development, specifically amongst swim-with-dolphin operations. As such, this case study was designed to investigate swim-with-dolphin tourism management by examining 1) long-term swim-with-dolphin trends and 2) the engagement of *Nationally Endangered* bottlenose dolphins in swim-with-dolphin encounters, modelled via several proxies. Two datasets, spanning nearly two decades, from Queen Charlotte Sound, New Zealand (QCS), were analysed. A total of 5,295 tourism logbook records from January 1995–November 2011 were collated and 145 bottlenose dolphin swim encounters were assessed aboard a tour vessel from November 2011–April 2014. Logbook records indicated regional expansion of swim-with-dolphin tourism, consistent with global trends. Observed swim encounters included up to five attempts (duration mean=4.2 min, SE=0.15, n=493), primarily when dolphins were travelling (43.2%, n= 60). Most vessel approaches were invasive (*i.e.,* "J" or in-path; 74.5%, n=347), with calves/neonates present during 77.9% (n=113) of swim encounters. Proxies for dolphin engagement

were analysed via linear or generalized linear models. Proxies included 1) dolphin reactions (primarily neutral; 82.9%, n=387); influenced by swimmer orientation, initial dolphin behaviour and dolphin group size and 2) distance operators travelled to track dolphins during swim encounters (mean=11.7 km, SE=0.46, n=140); influenced by location in QCS, initial dolphin behaviour and dolphin group size. Findings suggest animal habituation, operator pursuit of interaction and ultimately, lack of dolphin engagement; outcomes that may equate to negative consequences for this population. Moreover, this research highlights inconsistencies within NZ Marine Mammals Protection Regulations (1992) that require attention. The study concludes with valuable recommendations for tourism management.

Investigating epigenetic manifestations of stress in southern resident killer whales

Most studies testing for genetic impacts on individual fitness and population viability are based on patterns of DNA sequence variation, such as homozygosity and/or the presence of specific alleles. However, theory and research show that the largest impacts are likely due to changes in gene expression, rather than sequence variation itself. In the Northeast Pacific Ocean, Southern Resident killer whales are critically endangered and only 75 individuals remain. Despite conservation efforts, they face continued anthropogenic stressors such as noise/disturbance from vessels and nutritional limitations. Increased stress can lead to a number of negative fitness consequences, such as higher rates of disease and increased signs of ageing. These long-lasting effects are largely due to epigenetic changes in DNA methylation patterns. We investigated epigenetic manifestations of stress in Southern Resident killer whales compared to the closely related, less disturbed and more robust population of Northern Residents. We used bisulfite amplicon sequencing to compare patterns of DNA methylation in three genes involved in stress response (BDNF, CRH and NR3C1) and two control genes (GAPDH and ACTB) between these two populations. Comparison of methylation patterns between these populations in stress response genes, relative to the control genes, identify the degree to which anthropogenic stressors are manifesting themselves genetically in the Southern Resident killer whales. With these data we have also estimated the effect of these epigenetic changes at a population level, and thus provide a direct mechanistic link between anthropogenic stress and fitness outcomes via the key intermediate link of epigenetic changes.

In plane sight: A capture-recapture study of North Atlantic right whales in the southern Gulf of St. Lawrence from an aerial platform.

The decline and observed occupancy shifts of the North Atlantic right whale (*Eubalaena glacialis*) beginning in 2010 have prompted dedicated survey effort in new areas. Historically, right whales have been sighted in the southern Gulf of St. Lawrence (Gulf) and this area has been hypothesized as suitable habitat, but one previously lacking substantial survey effort. Capture-recapture aerial surveys were focused around the Orpheline Trough and Shediac Valley regions in the southern Gulf between June and August. A total of 153 unique individuals were identified (2015: $n = 35$; 2017: $n = 105$; 2018: $n = 131$) over 45 survey days (2015: $n = 4$; 2017: $n = 15$; 2018: $n = 26$), and the demographic breakdown of these individuals was similar to that of the entire population. Of the individuals identified, 87% were captured on more than one survey day, and 73% of the animals captured in 2018 had been captured in previous seasons. Best fit Jolly-Seber models were used to estimate abundance within 2017 and 2018 resulting in approximately 6 (SE 5) and 1 (SE 1) whale(s) going undetected, respectively. These results suggest almost all animals present were captured using this survey methodology, and there is a high rate of inter-annual return within these individuals. After an unprecedented 12 right whale mortalities

were documented in the Gulf in 2017, zero calves were observed in the following calving season, and of the seven females that calved in the 2018/2019 calving season, four had been sighted in the Gulf in the preceding summers. The recovery of this endangered species relies on the ability of adult females to thrive and reproduce, and with approximately one third of the population observed in the southern Gulf, these analyses demonstrate the importance of this feeding area for right whales.

What do whales look like from space?

Satellites orbiting 600km away from Earth could potentially provide new and invaluable information for whale conservation. They can access places, rarely surveyed by boats or planes, due to the inaccessibility of such areas. Some satellites can now provide images with a very high resolution (under 50cm), allowing for the detection of large-sized whales. We have been testing the feasibility of using satellite imagery as a reliable method to study whales. We used the WorldView-3 satellite, which offers the highest commercially available spatial resolution of 31cm. We showed that four whale species could be detected, including fin whales (*Balaenoptera physalus*), southern right whales (*Eubalaena glacialis*), grey whales (*Eschrichtius robustus*), and humpback whales (*Megaptera novaeangliae*). The 31cm resolution allowed us to detect whale-defining features, such as flippers and flukes. Using these results, we are now focusing on automating the detection of fin whales in the Ligurian Sea and understanding how deep below the sea surface we can detect whales.

Is relocation of cetaceans from certified zoos and aquaria to marine sanctuaries an option?

Culik, Boris
F³: Forschung . Fakten . Fantasie, Heikendorf, Germany
Corresponding Author: bculik@fh3.de

Animal rights organisations demand relocation of marine mammals from certified parks to sea-side enclosures. Is that advisable? By comparison to their natural habitat, aquaria are small and shallow, but the same is true for any type of sea-side sanctuary. What issues are at stake?

To ensure optimal care, veterinarians, trainers and technical personnel control a variety of indispensable activity, health, water and food parameters. Under optimal conditions, marine mammals form tight bonds and interact with their trainers and are frequently rewarded. Similar high levels of professional care and interaction would be indispensable in any facility.

Many existing collections are captive-bred hybrids. They do not match genetic, social, acoustic or behavioural characteristics or bacterial fingerprint of wild populations. Unplanned release from enclosures, by Illegal activities, natural disasters or mechanical failures cannot be ruled out. However, their introduction into the wild would put these animals as well as local environments and populations at risk and is prohibited by international legislation.

Dolphinids reach old ages, orcas living longer than 50 years and caring for them constitutes a long lasting financial and ethical commitment. Several governments and institutions have decided to end captive breeding and fade out collections. However, a loss of facilities and expertise will affect the possibilities to save critically endangered species.

Sanctuary projects seem to struggle with legal, professional, and economic aspects and the duration of the commitment they can guarantee. I propose to turn the focus of the debate on commercial capture operations, the welfare of cetaceans in sub-optimal facilities including sea pens and to cooperate with certified aquaria in enforcing best practice and the rescue of endangered species.

Broad-scale acoustic monitoring for cetaceans and underwater noise in relation to offshore wind farm construction in Scotland.

Culloch, Ross[1]; Davies, Ian[1]; Edwards, Ewan[1]; Chevallard, Pablo; Merchant, Nathan[2]; van Geel, Nienke[3]; Brookes, Kate[1]

Marine construction projects, such as offshore wind farms and port developments often use techniques that produce significant levels of noise underwater, which could have effects on marine wildlife. Marine Scotland is the government body responsible for regulating these activities in

Scottish waters and for ensuring that wildlife populations are protected in line with legislation.

Large scale offshore wind farm construction started off the Scottish east coast in 2017, using piled foundations. To monitor for potential broad-scale changes in the distribution of protected cetacean species during construction activities, Marine Scotland deployed an array of 30 click detectors and 10 broadband acoustic recorders across the Scottish east coast each summer since 2013. Here we present baseline distributions for dolphins and harbour porpoises, along with ambient noise levels recorded concurrently.

Dolphin detections across the monitored area are highly variable, with some locations that are clearly favoured. Harbour porpoise are ubiquitous and in more than 60% of locations are detected on 100% of monitored days. This is likely to mean that there is more power to detect changes in porpoise distribution in relation to offshore wind farm pile driving than for dolphins.

U.S. import rule on bycatch: An NGO perspective.

The United States – the world's largest importer of seafood – issued a new regulation that will ban seafood imports from nations whose fisheries kill marine mammals in excess of the United States' own strong bycatch standards. The U.S. has already begun implementing the rule, which will be fully effective in 2022 and may affect over 120 nations around the world. Exporting nations have already begun tracking, assessing, and limiting their bycatch in response to the rule, in order to maintain access to the lucrative U.S. market.

The presentation will provide an NGO perspective on the U.S. imports rule, including its standards and implementation, and discuss where the rule may be most effective and its potential limitations. We will provide case studies evaluating the rule's impact thus far, including the U.S. decision to ban certain Mexican imports due to bycatch of critically endangered vaquita. We will conclude by identifying how researchers, conservationists, and NGOs around the world can contribute to the process by providing critical data and information.

The impact of dredging activity on harbour porpoise, Phocoena phocoena, behaviour in Dublin Bay.

As part of Dublin Ports 6-year Alexandra Basin Redevelopment Project parts of Dublin Port and it's navigational channel are being deepened to -10m Chart Datum to accomodate larger cargo ships and cruise liners. This dredged material is dumped within a designated spoil zone approximately 15km from Dublin Port and which is located within a Special Area of Conservation (SAC) for harbour porpoises (*Phocoena phocoena*). Specialist underwater acoustic data collection equipment called C-PODs have been deployed in this spoil zone from December 2016 until present. This equipment collects digital information on detected cetacean click trains. The objectives of this study are to use this data to determine the level of foraging activity within this dump zone using a click train parameter called inter-click interval, and to compare foraging activity from before, during and after dredging activity has occurred. This will allow the aim of the research to be addressed: whether dumping activty from dredging work impacts harbour porpoise behaviour, specifically foraging behaviour.

Scoring of the severity of sperm whale behavioral responses to pulsed and continuous active sonar signals

This study investigates how naval sonar affects sperm whales' behavior. In previous work, we showed that controlled exposure experiments (CEEs) of 1-2 kHz pulsed active sonar (PAS) induced costly behavioral responses in whales (e.g. cessation of feeding), similar to anti-predator responses. Since then, new continuous active sonar (CAS) systems are being developed to improve target detection. This raises new concerns about how CAS might affect whales' behavior. To address this question, we conducted CEEs of 1-2 kHz CAS and PAS on sperm whales in Northern Norway, and compared behavioral changes displayed during both sonar types and a no-sonar control. We inspected the behavioral data recorded by acoustic and movement recording tags (Dtag) and visual observations of the tagged whales, and we used a severity scale, revised from Southall et al. (2007) ranging from 0 to 9, to assign severity scores to behavioral changes during exposure sessions. A blind procedure was applied to ensure that any unconscious biases of the scoring panels did not result in differences between exposure types. The results show that sperm whales hardly responded to the no-sonar control. Most severe responses (severity≥4, with potential to impact vital rates) were scored during both PAS and CAS exposures and included cessation of feeding, horizontal avoidance responses and changes in social sound production and dive behaviors. They started at received SPLs (sound pressure levels) and SELs (sounds exposure levels) of respectively 119-160 dB re 1 µPa and 137-177 dB re 1 μPa^2s during CAS, and 138-175 dB re 1 µPa and 143-181 152 dB re 1 μPa^2s during PAS. Highest scores (severity=6) were associated to cessation of feeding or avoidance responses scored during PAS exposures. Less severe responses (severity<4) concerned mostly changes in vocal and dive behaviors during CAS, whereas during PAS they could also involve changes in group distribution.

A comparison of three analytical techniques for population monitoring of coastal odontocetes.

Determining the appropriate method of population monitoring to inform conservation measures depends upon management objectives, species ecology, available resources, and geographic location. Here, we evaluate the relative effectiveness of three abundance estimation techniques: mark-recapture, line-transect distance sampling, and density surface modeling using data collected on odontocetes in Maui Nui, Hawaii. From 2013-2018, 317 systematic boat-based surveys were conducted to estimate the abundance and distribution of island-associated stocks of bottlenose dolphins (*Tursiops truncatus)*, spinner dolphins (*Stenella longirostris longirostris)*, pantropical spotted dolphins (*Stenella attenuate)*, and false killer whales (*Pseudorca crassidens)*. Standard photo-identification and distance sampling techniques were used and resulted in 247 encounters and 569 marked individuals. Abundance estimates were calculated using open populations models (mark-recapture), a Horvitz-Thompson estimator (distance sampling), and Generalized Additive Models (density surface models). The efficacy of each technique was evaluated using power analysis to determine the probability of detecting a decline of 50% over a 15-year period, at which point a stock could be classified as "depleted". Estimates for each species varied but were most consistent across techniques for bottlenose dolphins ($Abundance_{SD}$ = 17.24). Best models, based on published abundance estimates and model fit, produced estimates of 90 bottlenose dolphins (95% CI = 47-133, distance sampling), 406 spinner dolphins (95% CI = 266-547, mark-recapture), 336 spotted dolphins (95% CI = 246-427, mark-recapture), and 53 false killer whales (95% CI = 17-88, mark-recapture). Mark-recapture estimates were consistently more effective across all species with an average probability of 96.5% in detecting a decline of 50% over a 15-year period. This study highlights the importance of establishing population monitoring goals to guide data collection and analysis and presents a framework for future monitoring of small stocks of odontocetes, such as those resident to the Hawaiian Islands.

MiCO: An online system to explore important use areas and migratory connectivity for marine species.

Areas of the ocean used by highly migratory marine species for life-cycle activities and the connectivity among these important areas have been described within hundreds of peer-reviewed publications. Currently, no centralized system exists to access actionable knowledge about global migratory connectivity across marine mammals, seabirds, sea turtles, and fish, hindering the ability of decision making policy fora to quickly leverage this information. MiCO (Migratory Connectivity in the Ocean) is a publicly accessible system for policy makers, managers, researchers, and conservation groups to explore important areas of use (nodes) and the corridors connecting them. Various system entry points allow users to explore by species, country, or data contributor; filter results by attributes or regions of interest; intersect areas with management boundaries; view an interactive abstract network diagram; and download summary reports or ESRI shapefiles. Georeferenced nodes and corridors are generated from contributed telemetry data. A state-space model is fit to estimate true locations and temporally normalize the data, then each track is segmented into migrating and non-migrating portions. Kernel density estimates are derived for each segment, and the 90% UD polygon is used to represent the node or corridor. Initial results from 47 humpback whales tagged in the Antarctic Peninsula reveal a migratory corridor connecting a foraging node in Antarctic waters with a breeding node in Colombian and Ecuadorian waters, with whales passing through national waters of Argentina, Peru, Chile and areas beyond national jurisdiction. MiCO is a developing prototype that will eventually house multiple data types demonstrating connectivity, including telemetry, genetic, mark and recapture, passive acoustic and stable isotope data. Understanding the spatio-temporal and abstracted movements of highly migratory species is vital to the ongoing efforts to conserve species, manage human activities, and to inform future research efforts both within exclusive economic zones and in areas beyond national jurisdictions.

Bayesian mark-recapture assessment of Cuvier's beaked whales on a navy sonar range

Beaked whales are sensitive to mid-frequency active sonar (MFAS), with responses to exposure ranging from behavioral and likely physiological changes to mass stranding events. Assessment of population-level impacts of MFAS on beaked whales is challenging due to the elusive nature of these prodigious divers. An eleven-year photo-identification study of Cuvier's beaked whales (*Ziphius cavirostris*) in the San Nicolas Basin west of San Clemente Island, California revealed widespread, high interannual site fidelity, despite frequent sonar use on a coincident Navy training range. Sighting probability for *Z. cavirostris* was enhanced by leveraging automated acoustic detections from the Navy's acoustic array, which monitored the basin synoptically for beaked whales. We used Bayesian mark-recapture models to assess the annual apparent survival, abundance, and annual rate of change in abundance of *Z. cavirostris* using the San Nicolas Basin. We used simulation to assess our power to detect a change in abundance over the current time series and under several scenarios of increased sample size. We found high apparent annual survival and no evidence of a declining trend in the small local population of *Z. cavirostris*, but the uncertainty of our estimates and the results of our design analysis underscored the need to continue monitoring and to gather complementary information on the movement ecology and reproductive rates of *Z. cavirostris* in the San Nicolas Basin to better assess their status and trajectory.

Gulf of Mexico Dolphin Identification System (GoMDIS) – A collaborative program to better define bottlenose dolphin (Tursiops truncatus) movements.

The 2010 *Deepwater Horizon* oil spill and Unusual Mortality Events in the northern Gulf of Mexico demonstrated the need for an improved understanding of bottlenose dolphin (*Tursiops truncatus*) movement and ranging patterns in this area. No mechanism existed for detecting and monitoring changes in distribution in response to these events, or for readily identifying the origins of stranded dolphins. To address these issues, a collaboration was formed in 2012 involving federal and state agencies, non-profits, and academia working on photo-identification projects, as well as stranding programs and international partners. The Gulf of Mexico Dolphin Identification System (GoMDIS) provides a venue to archive dolphin identification data from collaborating research groups Gulf-wide, including Cuba and Mexico. The objectives are: 1) maintain a collaborative compilation of dolphin identification data, 2) build and maintain a repository for identification images and 3) facilitate data sharing among colleagues to examine dolphin movements throughout the Gulf. The Chicago Zoological Society's Sarasota Dolphin Research Program (SDRP) curates GoMDIS. Data are provided by our contributors and stored both offline on our secure server at SDRP, and on Duke University's OBIS-SEAMAP that provides an online workspace for collaborators to go through animal matching workflow. GoMDIS is constantly updating, currently including 32 catalogs, 19,456 animals and 33,621 images, yielding 1,248 matches between projects (current and archived) to date. We expect GoMDIS to grow and evolve as a long-term conservation tool and resource for management. We also envision extending our study region to the wider Caribbean for better understanding of ranging patterns and shifts. To ensure continuing success, it will be necessary to 1) find funding for operations, 2) incorporate new research and stranding programs, 3) receive and process catalogs with an improved data processing framework, and 4) maintain communication between the curator and collaborators.

High genetic diversity of Southwestern Atlantic sei whales (Balaenoptera borealis) and evidence of strong genetic differentiation with North Atlantic Ocean

Like other rorqual whales, sei whales (*Balaenoptera borealis*) were commercially hunted almost to depletion in the 20th century. The species is one of the least studied whales, and the impacts of whaling on genetic diversity and population structure for sei whales from Southwestern Atlantic Ocean (SWA) are still unknown. We present the first analysis of genetic diversity, based on mtDNA control region sequences and microsatellite genotypes, for SWA sei whales and evaluate the consequences of commercial whaling on the genetic variability of this population. Also, to investigate the phylogenetic relationship between these whales and North Atlantic (NA) sei whales, we compared our mtDNA haplotypes to sequences previously reported (7 haplotypes representing 84 individuals) on GenBank. Biopsy samples (n=20) were collected in the South and Southeast regions of Brazil between 2016 and 2018, during the Cetacean Monitoring Project in Santos Basin (PMC-BS/PETROBRAS). The SWA population showed a high genetic diversity for both mtDNA ($h=0.953$, $\pi=0.8\%$) and microsatellite ($A=10.33$, $H_O=0.760$) markers, which are much higher than that of NA sei whales ($h=0.520$, $\pi=0.2\%$; $A=6.18$, $H_O=0.650$). Additionally, no genetic bottleneck was detected. We found strong and significant mtDNA genetic differentiation ($FST=0.816$, $p=0.000$) between SWA and NA sei whales. However, although the genealogy estimated from the mtDNA sequences showed a clear division of the haplotypes into a SWA and a NA clade, one haplotype (Hap_6) detected in a single sample from the Azores was included in the SWA clade. Our results show that SWA sei whales have retained high levels of genetic diversity after whaling. Preliminary results also indicate differentiation between SWA and NA populations, but the position of one NA haplotype in the SWA clade suggests a recent migration of the maternal lineage. These findings are important for understanding the population structure, migratory connections and isolation of sei whales in the Atlantic Ocean.

Humans and whales under the weather: Using generalized additive models to predict visitors of the largest marine and whale museum of Germany.

Public outreach is one of the most important components of conservation science. Often social media campaigns are believed to be successful, museums are believed to be places that cannot achieve these large audiences. The German Oceanographic Museum is the most visited natural history museum of Germany. Since the opening of the Ozeaneum in 2008 over 10 Mio people have visited our exhibitions. We work along the principle "Sensitize– make problems visible - show solutions. With annual campaigns we are calling for "No Plastic Ocean" and "No Noisy Seas". With these campaigns we are raising awareness. While it is clear that those campaigns reach the interested public, they are targeting a much broader audience than social media campaigns. We achieve awareness in newspapers, magazines, radio and television and implement the topics into our advertising. After being honored as "European Museum of the Year 2010" and reaching more than 1 Mio visitors per year, especially the Ozeaneum, no longer "new", was losing visitors. In 2013 strict restrictions of the funding bodies even called for a "resurgence plan". 2013 was however also a perfect weather year, when visitors did not want to leave the cozy beaches of Mecklenburg-Vorpommern. We therefore used generalized additive models of our visitors to detect the causes of decline and also see whether a future drop in attendance rates is probable. The analysis showed, that 2013 was not the worst year since the opening of the Ozeaneum and that other effects like public holidays with high temperatures, cloud-cover, rain and snow are having a huge effect on the attendance rates. The models constructed are highly reliable (R^2-adj of 52 %) and provide a basis for ongoing discussions about the future of natural history museums under the weather.

Persistent organic pollutants in blubber of Sei whales (Balaenoptera borealis) from South Atlantic.

da Silva, Josilene; Taniguchi, Satie; Caruso Bícego, Marcia; Andre Lourenço, Rafael
Oceanographic Institute of the University of São Paulo, São Paulo, Brazil
Corresponding Author: josilenehsilva@gmail.com

Persistent organic pollutants (POP) such as polychlorinated biphenyls (PCB), polybrominated diphenyl ethers (PBDE), and chlorinated pesticides are highly lipophilic compounds that can be found in several organisms, such as the marine mammals as Sei whales (*Balaenoptera borealis*) that are largely open ocean whales. Sei whale is found in all oceans, but usually live in temperate waters. It is believed that this species migrate considerable distances between higher latitude in summer to lower latitude in winter. In the southern hemisphere, the occurrence of this species was recorded in waters off Brazil, Chile, Peru, South Africa and South Georgia. A total of seven samples were obtained from unrestrained living Sei whales using biopsy darts in Santos Basin, Brazil, for analysis of POP. The concentration of POP in the blubber samples were relatively low and presented, in ng g^{-1} wet weight (ww), maximum concentration of 32.0 for PCB, 3.77 for hexachlorobenzene, 1.35 for p,p'-DDE, 1.14 for Dieldrin and 0.26 for PBDE. The present study showed lower levels of POP in Sei whales found in South Atlantic compared to those reported in the Northern Hemisphere. It may be related to their low level in the trophic web and can also be associated to a lower degree of POP contamination in that area. This study has contributed to mitigate the lack of scientific data about POP contamination in this species not only in South Atlantic but also in Southern Hemisphere.

Aggression towards neonates and possible infanticide in the Boto, or Amazon river dolphin (Inia geoffrensis).

Observations of attacks by adult male Amazon river dolphins, or botos (*Inia geoffrensis*), together with post-mortem examinations of carcasses from within and near the Mamirauá Reserve, Brazil, suggest that some proportion of calves suffer direct aggression from adult males, with some perhaps dying as a result. No cases of female attacks on calves and infanticide have been witnessed. The benefits to males of attacking and killing calves are currently unknown for botos. As some attacks do not result in the death of the calf, mortality, if it occurs, may be an inadvertent consequence of the behavior rather than the motive for it. Our observations suggest that males who commit infanticide are unlikely to gain direct fitness benefits in terms of accelerated return of females to reproductive condition. By contrast, our observations suggest that male aggression against calves may represent a form of socio-sexual or group display. Strikingly, and unlike most documented examples in other species, infanticide-like behavior in botos is most of the time seen to be a group phenomenon. Even if unintended, the death

of calves from male aggression may have significant negative population-level impacts, given how in this species females produce only single calves at intervals of several years.

Analysis of manatee ear bone chemistry as a tool to track West Indian manatee migrations in the northcentral Gulf of Mexico.

DaCosta, Kayla[1]; Carmichael, Ruth H.[2]

Corresponding Author: kdacosta@disl.org

Migration, habitat use, and diet of West Indian manatees in the northcentral Gulf of Mexico (nGOM) are minimally studied and critical for determining population connectivity and conservation needs. Chemical analysis of inert tissues with annual growth (i.e. ear bones, otoliths, baleen, hair) provide information about migration pathways, habitat use, and diet during an individual's lifetime. These analyses can build on other studies (e.g.; satellite/GPS tags, photo identification, opportunistic sighting) without requiring capture or sighting. We examined variations in trace element ratios (e.g. Sr:Ca, Ba:Ca, Zn:Ca) and stable isotope signatures ($d^{13}C$ & $d^{15}N$) among growth layers within and among individuals to better understand variations that may correspond with seasonal migrations or ontogenetic changes in habitat and/or diet. Manatee ear bones were collected from necropsied animals along the nGOM coast from Mississippi to the western Florida panhandle and the western Florida peninsula to evaluate regional differences between these groups. Preliminary results indicate that Zn:Ca ratios increased within individuals through time, while some individuals had Sr:Ca and Ba:Ca ratios that followed annual patterns in variation of saltwater versus freshwater influence through time. Changes in Sr:Ca ratios and isotope signatures occur around 1-2 years, indicating a potential diet shift as individuals transition from a milk- to forage-based diet. Regional differences exist in some elements (Sr:Ca, Mg:Ca, $d^{13}C$), with trace element ratios higher and $d^{13}C$ values lower in animals in the nGOM than peninsular Florida. Use of these techniques will provide a novel method for reconstructing past migration, habitat use, and diet which will aid in understanding current and historical habitat use by West Indian manatees in the nGOM.

Influence of human population size, proximity and development on the presence of antimicrobial resistance genes within the intestines of pinnipeds

Microbial marine pollution has been proven by the presence of bacterial pathogens of human and cattle origin within the intestines of pre-weaned grey seal pups born on the Isle of May (IoM), Scotland, UK suggesting significant land-sea-land transfer. The proximity to large human and cattle populations, even in highly developed countries with modern sewage treatment facilities, was considered to be the main risk factor. Antimicrobial resistance (AMR) is of critical concern and considered to be driven by over/inappropriate use of antimicrobial therapy against human and veterinary bacterial pathogens. We investigated the resistome, the presence of antibiotic resistance genes in both pathogenic and non-pathogenic bacteria, by rectal swabbing various species of pinnipeds in; 1) close proximity to (IoM) and 2) distant from (Monach Isles, Scotland) a large human population in a highly developed country, 3) close proximity to a limited but increasing human population (Caamaño Island, Galápagos, Ecuador) and 4) an oceanic island remote from human habitation (Gough Island, Tristan de Cunha, UK). DNA was extracted from rectal swabs and the resistome, including respective relative abundance, was analysed using high throughput WaferGen SmartChip qPCR technology. A total of 40 AMR genes (AMG) were detected that encoded resistance to several antibiotics including sulphonamide, tetracycline, β-lactam, amphenicol and efflux-pumps. Samples from the IoM, Galapagos, Gough and Monach islands had 21, 37, 4 and 1 AMG, respectively, but the greatest relative abundance, ≥10 fold, was on the IoM.

To our knowledge, this is the first study reporting the resistome in pinnipeds in areas of contrasting human populations using a culture-independent method. Understanding the possible source of ARG will allow us to evaluate their occurrence and spread within coastal and global ecosystems.

This is not the drone you are looking for…. The challenges of adopting new UAS technologies in marine science.

Dale, Julian[1]; Bierlich, K.C.[2]; Johnston, David[3]

Rapid growth in affordable unoccupied aircraft systems (UAS) has resulted in widespread uptake of these high-resolution data samplers by the marine science and conservation community. UAS provide alternative approaches for marine mammal data collection, but present challenges in terms of safe operation and baseline limitations of data quality. Here we address two specific challenges faced by new UAS operators: 1) expectations of data quality dictated by platform and sensor choice and, 2) the logistics of sustained safe operations. Understanding data errors and accuracy of UAS photogrammetric measurements is critical. In terms of data quality, we compare photogrammetric accuracy across 6 UAS aircraft by taking 10 images at 10m increments from 20m to 120m altitude using a floating scale bar for calibration. We conducted this procedure for ten combinations of aircraft, camera, and altimeters. All data were analysed by two independent observers and comparisons reveal that consumer off-the-shelf (COTS) UAS returned up to 12% error (+/- 3.07) in photogrammetric measurements compared to 0.5% (+/- 0.30) error for custom sensor packages. Unlike occupied aviation, UAS has limited data available for users regarding points of failures and life expectancy. This reduces capacity for planning, maintenance, and budgeting for the safe and useful life of these systems, which in turn increases risk of aircraft failure, decreases pilot and animal safety, and hampers successful data collection. We detail enterprise-scale maintenance and monitoring workflows for UAS, providing evidence of failures experienced for both custom and COTS platforms. These workflows clearly indicate how consistent collection and assessment of technical flight data can guide operators towards best practices and to help them understand the boundaries of this technology as they are explored.

Porpoise Listening Station – Long-term monitoring of harbour porpoise in relation to noise and artificial reef structure.

Loud vessel noise been found to affect foraging of tagged harbor porpoises but little is known about effects of vessel traffic on their long-term behavior. In spring 2017, a live research and public outreach porpoise monitoring system was deployed at 10 meters depth on the seabed next to an artificial reef in a high porpoise density area in Little Belt, Denmark. The study area lies between two bridges and frequently used by recreational vessels and commercial shipping. The high porpoise density and the complex mixture of anthropogenic underwater noise makes the area ideal for investigating whether porpoise presence is affected by vessel traffic as measured by echo sounders throughout the year. The permanent live hydrophone system includes two underwater cameras, one above water and an AIS logger, and has collected data since March 2017 using Pamguard. The results demonstrate that porpoises are present in the area year-round and displays a strong diel trend with almost four times more echolocation activity during night (78% of all positive porpoise minutes across years). There is a seasonal variation in porpoise detections with higher activity in April-May and November-December. Background noise levels increase during the day, with 91% of the total echo sounder detections occurring in daylight hours. The observed behavioral pattern could be due to the elevated vessel noise at day and/or prey availability during night. However, in June-August there are more daylight porpoise detections and peak of echo sounder detections from vessels, indicating that porpoises do not necessarily avoid the area during elevated vessel activity. Studies on artificial reefs have shown strong attractions to higher food availability during dark hours. We therefore hypothesize that a strong motivation to feed on the reef predominantly during night is due to prey

availability more than an effect of avoidance to vessel noise.

Another brick in the wall: Assessing population structure of Bryde's whales (Balaenoptera brydei) through a multi-method approach.

Studies with Bryde's whales have suggested population structuring in certain regions. In Brazil, information about the species is scarce, and systematic and broader studies are needed to understand many aspects of its ecology. Thus, we seek to determine the population structure of Bryde's whales in the South and Southeast Brazilian coast, an area with increasing oil and gas exploration. We investigated if there is spatial-temporal structuring driven by coastal and oceanic habitats through multiple and complementary sources of information (habitat use modeling, photo-identification, satellite telemetry, and population genetics). Data collection began in 2015 and was performed regularly by the Cetacean Monitoring Project in Santos Basin (PMC-BS/PETROBRAS) through Line Transect and Telemetry cruises. We recorded 73 groups: 45 groups in coastal waters (<200m), being three groups with calves; and 28 groups in deeper waters (≥200m), being one with calf. The best-fitting model (GLMM) indicated that distribution is influenced by depth, salinity, and minimum surface temperature. We had five resightings of an individual in the same coastal region between 2016 and 2017. One individual was tagged in winter and sent location data for 28 days. This whale remained on the coast for 12 days and then moved to offshore (up to 600m deep), where the signal ended. Extremely low levels of mitochondrial and nuclear genetic diversity were found (n=13), with no differentiation between coastal and offshore whales. Our results point to the existence of a panmictic population, that remain in Santos Basin along the year and uses the region for both feeding and breeding purposes, performing shifts between coastal and continental shelf break habitats. There is also fidelity to some sites. The physio-oceanographic characteristics that drive its distribution are consistent with upwelling events in the region and the shifts between habitats probably reflect changes in productivity and, consequently, in its prey availability.

Causes of death of common dolphins along the Irish coastline 2017-2019

Strandings of common dolphins (*Delphinus delphis*) have increased year on year along the Irish coast since 2013, especially over the winter period (December to February); an increase out of proportion with other species. Between 2006 and 2010 the Irish Whale and Dolphin Group received 134 records for this species; an average of 27 animals per year. However, in the years 2013 to 2018, this number rose to an average of 84 per year. The cause for the increased stranding rates is unclear, though several cases of suspected fisheries interactions were identified based on post-mortem examinations of animals necropsied during the peak stranding period in 2013. Since June 2017, a cetacean post-mortem scheme funded by the European Maritime and Fisheries Fund and the Irish government has aimed to investigate causes of death in common dolphins, striped dolphins (*Stenella coeruleoalba*) and harbour porpoises (*Phocoena phocoena*). Here, we present the findings for common dolphins. Between June 2017 and April 2019, a total of 72 common dolphins were recovered and necropsied by the Regional Veterinary Laboratory, with oversight by the UK's Cetacean Strandings Investigation Programme (CSIP) at the Institute of Zoology. Necropsies were undertaken in accordance with CSIP's guidelines. Of the 36 common dolphins necropsied between June 2017 and March 2018 for which results are currently available, causes of death were attributed to infectious disease (36%), starvation/hypothermia (22%), live stranding (17%), gas embolism (3%), suspected bycatch (8%), other (8%), or were not established (6%). Preliminary results suggest that

interactions with fisheries were not a significant source of mortality in the observed stranded animals, with incidences of infectious diseases and starvation higher than reported elsewhere.

Long-term bonds: Associations among Atlantic spotted dolphins (Stenella frontalis) off Bimini, the Bahamas.

Social systems are characterized by the associations and interactions between individuals. For highly social groups such as delphinids, understanding the demographics and long-term association patterns of a population is the first step in interpreting its overall social structure and specific relationships between individuals. This study is the first to investigate the social patterns of a population of Atlantic spotted dolphins (*Stenella frontalis*) off Bimini, The Bahamas, during a 14-year period (2003-2016). We generated association indices and conducted cluster, network, and temporal analyses using SOCPROG 2.8. Dolphins in this group display long-term, year-round residency around Bimini, as well as long-term preferences in association with a combination of rapid disassociation, constant companions, and casual acquaintances. We found no evidence of distinct social clusters within the study group; however, we discovered at least one subgroup with higher association than the rest of the population. This group was composed of male spotted dolphins, which overall tended to associate together more than females and chose companions with similar levels of association to themselves. Despite strong relationships between males, we found no evidence for the existence of alliances or coalitions. Bimini spotted dolphins do not experience the same social forces thought to drive such supportive relationships in other study groups; they do not experience aggressive interactions with sympatric bottlenose dolphins (*Tursiops truncatus*), nor are males limited in their access to females. After defining the close associations between pairs of dolphins, we discuss alternative reasons for close partnerships aside from those seen in other delphinid populations. This study provides a baseline understanding of the social structure of this population that will allow us to investigate the variable relationships between individuals, in addition to exploring the effects of demographic changes within the resident population.

Advances on the ecology, behavior and conservation of franciscanas in northern São Paulo, Brazil, through aerial surveys.

The franciscana (*Pontoporia blainvillei*) is the most threatened small cetacean in southwestern Atlantic because of the high range-wide bycatch mortality. Since franciscanas are rarely sighted in the wild, knowledge on its social ecology and behavior is scanty. Franciscanas in northern São Paulo, southeastern Brazil, comprise one population known as Franciscana Management Area (FMA) 2a. Here we contribute to the knowledge of some ecological and behavioral aspects of the franciscana in the wild and present abundance estimates for this population. Aerial surveys (twin-engine airplane and helicopter) were carried out from November to January (2010; 2017-2018). Group size ranged from 1 to 6 animals (median=3). Nevertheless, large concentrations of several groups have been recorded, totalizing aggregations of 20-50 franciscanas. The great majority of the mother-calf groups (93%) had 1-3 more accompanying individuals. There is a clear preference for the mother to be in the first position (79%) in these groups, but no lateralization in the position of the calf in relation to the mother (p=0.93) was detected, regardless of the accompanying dolphins. For the first time, franciscana mating behavior was photographically documented, with the male on the bottom position. Feeding behavior was observed, including foraging sprints and rotations. In two occasions, a calf in close association with one adult was recorded to swim away and initiate an association with another adult, suggesting the existence of some degree of extra-maternal care in franciscanas. Contrary to other areas, franciscanas in FMA 2a inhabit very clear waters sometimes associated to rocky shores, from the coastline to the 35m isobath. Abundance in FMA 2a was estimated at 2,040 animals in 2010 (CV=0.42, 95%CI=926-4,495). Although mean annual (2015-2018) stranding mortality in this area is 65 animals (sd=7,8), the lack of bycatch estimates still

precludes a better understanding of the fishery impact on the FMA 2a population.

Convergence and divergence of songs suggests ongoing, but annually variable, mixing of humpback whale populations throughout the North Pacific

All humpback whale (*Megaptera novaeangliae*) males in a population sing fundamentally the same version of a complex, progressively changing, series of sounds at any one time – the song. The purpose of this study was to describe the relationship of humpback whale populations across the North Pacific based on song composition. Songs were collected from Philippines, Japan, Hawaii and Mexico in 2011, 2012 and 2013. The presence and proportion of 11 phrase types were compared within and between populations to investigate song similarity and change. Results included: shared song phrases across the North Pacific; variable, temporary, regional song differences; varying rate of song change; and distance a factor, but not predictor in degree of similarity. Shared phrases indicate ongoing mixing of populations throughout the North Pacific. Year to year differences in degree of similarity suggest variability in these interactions. Songs appear to diverge as populations split up and converge when they amalgamate. Song studies complicate current US management policy designating four distinct populations in the North Pacific. North and South Pacific humpback whale population structure may be comparable, although song dynamics may be different. The fluidity of song composition suggests it provides acoustic definition or identity to changing associations of whales.

Inner ear morphology of early (toothed) baleen whales (Cetacea: Aetiocetidae) and implications for the origins of infrasonic hearing in baleen whales.

Understanding the evolution of hearing in cetaceans is crucial to discovering the origins of underwater hearing modalities, and may also help the conservation of extant taxa in the context of an increasingly (and anthropogenically) 'noisy' ocean. While much recent work has centered on modern baleen whales and recent fossils, aetiocetids (Cetacea: Aetiocetidae) – the toothed baleen whale group most closely related to whales possessing baleen – have not yet been examined. Aetiocetids are an essential group to study for understanding the ecologies and origins of modern baleen whale hearing because of this close relationship to modern baleen whales and transitional position representing changes in feeding strategies from using teeth in raptorial feeding to filter feeding with baleen. Here, we perform an in-depth analysis of the bony labyrinth, which can provide data on both ecology and hearing abilities, of an aetiocetid-like taxon. We use microcomputed tomography (microCT) to image and examine two petrosals belonging to adult and juvenile specimens (CCNHM 5402 and 4202) from the Pysht Formation (30.5–26.5 Ma) of Washington, USA. The cochleae are tightly coiled towards the apex, and overall resemble a mixture of features similar to other mysticetes and some odontocetes. Morphological measurements were added to an extensive dataset of cetaceans and other artiodactyls to determine whether this species had similar hearing abilities to modern mysticetes. The semicircular canals and vestibule are also measured and described in detail as they relate to other aspects of ecology; notably, they are relatively smaller than some other mysticetes compared to the cochlea size. Nondestructive microCT scanning approaches provide unique opportunities to better understand the evolution and ecology of aetiocetids, which occupy a crucial position in the evolutionary and ecological history of mysticetes.

From necropsy to 3D reconstruction: How 3D models can help to attract youth into STEM.

We noticed most of the students had difficulties to imagine the detailed whole organisms and to understand the anatomy on the basis of dissections,

cross sections or book pictures. New and updated teaching techniques would be then required to help the understanding and so to make sciences more appealing to students. It appears 3D modelling is a powerful teaching tool because establishments of models allow highlighting the most important parts of the organisms and scenarios can help to draw attention on the relationships between anatomical parts. A µCT scan, also known as computed tomography scan, makes use of computer-processed combinations of many X-ray measurements taken from different angles to produce cross-sectional images (virtual "slices") of specific areas of a object, allowing the user to see inside the object without cutting it. Once the slices are acquired, the aim is to re-construct the body by keeping the structures of interests (bones, skins, etc.). At the level of the skeleton for example, different bones can be then coloured to underline the different units that form the skeleton. Thanks to an EU-funded project (Marine Mammals Science Education) and collaboration between professors from universities and teachers from high schools, we use 3D animal models to explain precisely the anatomy of marine mammals to pupils and students. µCT scans were realized on harbour porpoise and a harbour seal at the Faculty of Veterinary Medicine (ULiège) to get a closer look at the animal skeleton to highlight the different adaptations (flippers, nares position, elongated skull, cervical vertebrae, etc.) related to their peculiar way of life. The porpoise and seal skulls are compared with human and dog skulls to highlight the common and different features. These 3D animations are also intended to be used by museums to highlight the complexity of marine science for a large public.

Dolphin specialized behavior is resistant to demographic and environmental changes

Social structure has far-reaching implications for population-level processes, such as the transmission of behavioral specializations among individuals. Social structures and behavioral specializations, however, can be disrupted by changes in population composition and environmental conditions. We examined here how the social structure of a small bottlenose dolphin population (~50 individuals), specialized in foraging with artisanal fishermen in southern Brazil, responded to an abrupt population turnover (30%) and decline in its main prey availability (mullets) in the last 10 years. We found that the population frequency of foraging with fishermen decreased from 0.257±0.197SD in 2007-2009 to 0.144±0.191SD in 2013–2016. The individuals observed in both periods also foraged with fishermen less frequently, indicating that the reduction in the use of the specialized foraging did not result from the population turnover, but instead from reduced mullet availability. Interestingly, the individuals that entered the population in 2013–2016 foraged with fishermen as frequently as the population average, suggesting that they quickly adopted the specialized tactic. The dolphin social structure also changed between these periods. In 2007–2009, dolphins were clustered into social modules (0.240; CI: 0.219–0.237) assorted around the foraging with fishermen (0.457±0.033SE); in 2013–2016 such a social division coupled to the specialized tactic was no longer clear (0.114; CI: 0.118–0.122; 0.195±0.047SE). These results reveal that the social structure is flexible and responds to demographic and resource availability changes. Despite the overall decline in foraging with fishermen, the quick adoption of the tactic by the new dolphins strongly suggests that social learning underlies the transmission of this tactic among unrelated individuals, making horizontal learning key to the resistance of this specialized behavior against the population and social turnover. These findings illustrate the importance of assessing the stability of animal social systems and cultural behaviors in the face of rapid environmental changes.

Toward the identification of important cetacean's areas under threat at a regional scale: The ACCOBAMS Cetacean Critical Habitat's process.

David, Léa[1]; Panigada, Simone[2]; SALIVAS, Maylis[3]

Countries member of ACCOBAMS and its Scientific Committee are engaged, since several years, in identifying Cetacean Critical Habitats (CCHs), which refer to "those parts of a cetacean's range that are essential for day-to-day well-being and survival, as well as for maintaining a healthy population growth rate".

Important Marine Mammal Areas (IMMAs) in the Mediterranean Sea have been identified during a joint workshop organized by the IUCN Marine Mammal Protected Areas Task Force, in collaboration with ACCOBAMS and the Tethys Research Institute (Greece, October 2016). However, in the context of cetacean conservation and management it is essential to incorporate the concept of actual and/or potential human activities and threats at the population level.

The ACCOBAMS Scientific Committee recommended that in providing advice to the Countries under the ongoing ACCOBAMS threat-based management approach, the concepts of both IMMAs and CCH are considered and incorporated. IMMAs provide an initial biocentric process to be followed by that of the CCHs, in which the spatial distribution of threats is identified, quantified and overlapped to IMMAs. Management advice is then based upon an integration of the two approaches and the prioritization of mitigation approaches on a case-specific basis. This will assist in providing the parties with advice on targeted and effective conservation measures, such as those, *inter alia*, related to mitigating ship strikes.

Using both the IMMA and CCH approaches in the ACCOBAMS region will have a significant added value, since these two concepts reinforce and strengthen each other. Indeed, the global scope of IMMAs will help in promoting awareness and visibility at the international level, while CCHs provide a tool to foster the regional commitment and to revise and update the list of areas of special concern for cetaceans in the ACCOBAMS region, as well as supporting the related conservation and management measures.

Foraging habitat associations of North Atlantic right whales (Eubalaena glacialis) measured using ocean gliders

North Atlantic right whales (*Eubalaena glacialis*) migrate seasonally into several temperate North Atlantic habitats to feed on dense aggregations of planktonic copepods. Recently a previously unknown foraging area was discovered within the Gulf of St. Lawrence (GSL), a body of water that lies several hundred kilometers north of the known right whale foraging range. Key feeding habitat characteristics, such as dominant prey species, water mass hydrography and tidal current amplitude, appear strikingly different in the GSL relative to other described habitats. This study is the first description of regional environmental associations of right whales in the newly discovered habitat. Between 2016 and 2018 profiling gliders were equipped with hydrophones and conductivity-temperature-depth sensors and deployed continuously between 2 and 6 months per year to measure physical habitat associations of right whales in the GSL. Binary multivariate regression models were applied to these data to explain right whale acoustic presence-absence as a function of variables describing water mass characteristics. Models containing the main effects of temperature, salinity and stratification were selected over a null model containing only static explanatory variables such as bathymetric depth. This demonstrates that dynamic oceanographic processes are important for explaining regional right whale occurrence. The odds of acoustically detecting a right whale each day were twenty times higher in stratified summer conditions than well-mixed conditions typical of the windy autumn period, suggesting a preference for certain seasonally-varying physical processes that affect prey energy density and availability. After accounting for the seasonal effect, right whales were ten times less likely to be detected in warm, fresh water that signifies the regional coastal current, suggesting that right whales target offshore species of copepods such as *Calanus* spp., as opposed to coastal species, in this habitat. This study identifies key spatiotemporal constraints on right whale occurrence and demonstrates the use of gliders as tools to study whale-habitat associations.

Behavior-based association patterns in common bottlenose dolphins (Tursiops truncatus) in Boca Ciega Bay, Florida

Common bottlenose dolphins (*Tursiops truncatus*) in Boca Ciega Bay, Florida live in a complex, fission-fusion society where group membership and

size change frequently. As dolphins display high behavioral plasticity, changes in behavioral state can potentially influence group size and composition. Individuals may require stronger associations when engaging in cooperative behavior, such as group foraging, than when individuals are competing for access to limited resources. This study examines the association patterns of common bottlenose dolphins in Boca Ciega Bay, Florida, in four different behavioral states (foraging, socializing, travelling, milling).

Photo ID and group behavioral data records were collected during 2011-2015 as part of the ongoing research conducted by the Eckerd College Dolphin Project, and were analyzed using SOCPROG social analysis software. Permutation tests, comparing observed association patterns to random datasets, revealed differences in association patterns between the different behavioral states. Significant preferred associations were revealed in all behavior states except for foraging; which fits with the lack of observations of cooperative foraging in this area. Standardized lagged association rates were determined within each behavioral state to investigate differences in the temporal patterning of associations. Travelling and milling association rates showed preferential associations over time, while socializing and foraging association rates did not. This study provides insight into the role that ecology plays in the evolution of these social structures, especially when compared with similar studies conducted on other populations of common bottlenose dolphins in Cedar Key, Florida and in Shannon Estuary, Ireland, as well as Indo-Pacific bottlenose dolphins (*Tursiops aduncus*) in Shark Bay, Australia.

Bridging the gap between visual and acoustic data for north Atlantic right whales.

North Atlantic right whales (NARWs) are one of the most endangered, but well-studied cetacean populations in the world. Dedicated NARW survey efforts have amounted to long-term visual and acoustic datasets across their western North Atlantic range. Management primarily focuses on visual data to determine NARW habitat, as they provide an estimate of the number of animals present from surface observations in a given location. While NARW visual data is robust, reliable, and dates back to the 1970s, data collection is limited by weather conditions, daylight, and survey range with most effort historically occurring during summer months. Over the last 15+ years, passive acoustic monitoring (PAM) has emerged as a complementary and effective way to determine NARW presence. PAM can provide continuous, year-round coverage of a broad area at comparably low costs, but it cannot be used to determine the number of individuals present, or to identify non-vocalizing animals. Both visual and acoustic data exist spanning the southern NARW calving grounds off Florida, USA to northern feeding grounds off Nova Scotia, Canada. To date, these datasets have been used independently of one another. This study uses an occupancy modeling approach to merge visual and acoustic data together, combining the breadth and limitations of both data sets, to provide better estimates of NARW occupancy throughout their range, across seasons and years. Visual data (1992 to 2016) from Roberts et al. 2016 and acoustic data (2004 to 2018) from Davis et al. 2017, with recent additions to both datasets, were combined into 10km spatial grids and subsequently overlaid into occupancy models using RPresence. These results are a first attempt to fill in information gaps by using both data types together, providing a better understanding of important areas for a critically endangered species, and an alternative method for predicting long-term changes in occupancy.

Stable isotopes of sea lion whiskers reflect impact of ocean warming on diet.

Davis, Madison
San Diego State University, San Jose, CA
Corresponding Author: mcdavis@sdsu.edu

Marine biological processes are dependent on dynamic, seasonal trends in temperature. Observed and projected periods of oceanographic warming have the potential to drastically alter basic oceanographic dynamics. These changes impact upper trophic level predators significantly, making changes in their population parameters during environmental change an indicator of overall ecosystem state or condition. California sea lions are abundant predators that occupy the California Current System and whose weaning and reproduction are significantly impacted by the changes in primary productivity and concurrent shifts in their prey that occur during anomalous temperature events. By monitoring changes in sea lion diet through stable isotopes deposited in inert tissues in their whiskers, I plan to construct a dietary timeline across 30 adult females, providing a continuous dietary analysis across a temporal range of environmental conditions. Retrospective analysis of diet on an individual level can provide

insight into the long-term effects that an increasingly warmer ocean can have on predators and on trophic interactions.

The lesion profile of cetaceans diagnosed with neurobrucellosis in Scottish waters 1991 to March 2019.

Brucella ceti was first reported in the early 1990's and has since become an important pathogen in cetaceans worldwide. Possibly the most important disease manifestation is *B.ceti*-associated meningoencephalitis or neurobrucellosis in cetaceans. In Scotland, *Brucella* sp. have been isolated from eleven species of cetacean and *B.ceti*-associated meningoencephalitis in seven. In this study, we re-examined historical cases for gross and histological evidence of neurobrucellosis and, along with new cases, neurological lesion profiling was performed to determine differences and/or similarities between cases and sequence types. New cases with gross lesions suggestive of neurobrucellosis had their whole spinal cords removed for histological examination. Histological sections of brains from defined areas were blinded, and scored from zero to five; zero being no lesions present and five being severe lymphocyte infiltration and/or perivascular cuffing, lesions typically associated with neurobrucellosis in cetaceans. Analysis showed that lesions in most cetacean species occur in the meninges and increase in severity from rostral (cerebrum) to caudal (medulla) and lesions in the brain parenchyma follow a similar pattern. Lesions in the brain parenchyma were more common in animals with a more severe meningitis. Cases of neurobrucellosis were more common in pelagic delphinids, particularly striped dolphins and Atlantic white-sided dolphins, but absent in other species, such as white beaked dolphins, despite similar numbers being examined and this warrants further investigation. Cases also occurred in Sowerby's beaked whales and a novel case of meningoencephalitis in a single minke whale with dual *Brucella pinnipedialis* and herpesvirus infection. These findings suggest that pelagic delphinids are more susceptible to *B.ceti*-associated meningoencephalitis and this should be a differential diagnosis for any live-stranded cetacean.

Effect of boat activity on the acoustic communication of bottlenose dolphins (Tursiops truncatus) of Dolphin Bay, Bocas Del Toro, Panama

Bottlenose dolphin whistles play an important role in their communication. There are two types of whistles: (1) variant whistles that are used by all dolphins for group cohesion when traveling, foraging and socializing; and (2) signature whistles, which are unique to each individual and are used to maintain contact between specific group members (e.g. mother-calf). Given the role whistles play on dolphin communication and behavior, here I study the impact of boat activity on the emission of whistles types, the context, and the whistle acoustic structure. Recordings were obtained from multiple years using broadband recordings systems deployed from boats and recently deployed autonomous recordings systems at the Bocas del Toro in Panama. Using both active and passive recordings allowed for the behavioral context of some whistles to be known, as well as for 24-hour examination of whistle emission. A total of 1,635 whistles were analyzed with 1,145 being identified as variant and 490 as signature, following the Signature Identification (SIGID). Variant whistles were more common independently of behavior or boat presence. In terms of acoustic structure, the two type of whistles are significantly different from each other, with signature whistles been more complex than variants with longer durations, broader frequency ranges, and more modulation. In the presence of boats, signature whistles showed a narrowing of their frequency range most likely a strategy to avoid potential masking by boat noise. Our study shows that when studying the impact of noise associated to boat traffic on dolphin whistle acoustic structure is important to differentiate between variant and signature whistles.

Nature vs nurture. Echolocation clicks of Sotalia fluviatilis and Sotalia guianensis; Sister species in contrasting environments.

Successful toothed whale orientation, navigation, and foraging is dependent on the key sensory modality of echolocation. Biosonar signal characteristics determine an echolocating animal's sensory volume and have allowed species to adapt to unique foraging niches. Yet, the evolutionary drivers behind odontocete biosonar parameters remain poorly understood. Recent studies have shown that source parameters are related to body size and have also highlighted the possible influence of habitat. However, only a few studies have compared the biosonar characteristics of closely related species in different habitats, raising questions on the extent to which habitat shapes source parameters. Here we use the two *Sotalia* species, *fluviatilis* and *guianensis,* to test the hypothesis that habitats shape biosonar parameters by comparing source parameters among these sister species in different environments. Using the same seven-element vertical hydrophone array, *S. fluviatilis* were recorded in the deep channels and open areas of the Rio Negro in the Amazon River and *S. guianensis* in the entrance to the coastal Guaraíra Lagoon in Tibau do Sul, Brazil. *S. fluviatilis* produced biosonar clicks with a mean source level of 199±4 dB re 1µPa pp, mean centroid frequency of 126±7 kHz with inter click intervals (ICIs) of 52±22 ms. This marks a considerable difference from the low amplitude and short ICI biosonar of the sympatric boto, *Inia geoffrensis geoffrensis,* commonly found in the shallow narrow channels of the river. In contrast, *S. guianensis* used biosonar clicks with 194±7 dB re 1µPa pp, mean centroid frequency of 117±13 kHz and ICIs of 43±26 ms to navigate the shallow and narrow entrance to the lagoon, which is closer to the biosonar characteristics of *Inia g. geoffrensis.* This study affirms the influence of habitat on biosonar source parameters and the dynamic plasticity of delphinid biosonar which has allowed for adaptations to diverse foraging niches.

Changes in bottlenose dolphin immune functions associated with the deepwater horizon oil spill in the northern Gulf of Mexico, a recurrence?

The explosion of the Deepwater Horizon platform in 2010 resulted in an unprecedented release of oil in the Gulf of Mexico. Comprehensive health assessments were conducted on bottlenose dolphins in Barataria Bay, LA (BB), in 2011, 2013, 2014, 2016, 2017 and 2018, to assess potential health effects resulting from exposure to oil. Results were compared to those for Sarasota Bay, FL (SB), dolphins not exposed to oil (sampled in 2011, 2012, 2013, 2014 and 2018). We previously reported significant increases in T lymphocyte proliferation, as well as lower Th1 cytokines IL-2, IL-12 and IFNg, lower Th2 cytokines IL-5 and IL-13 but higher IL-4, and lower Treg cytokine IL-10, in BB 2011 compared to SB, with values returning to "normal" in 2013, 2014 and 2016. These changes in immune functions were generally similar to those in the relatively few studies in other species upon exposure to oil in particular or PAHs in general, and consistent in time and space with exposure to oil from DWH. Interestingly, results from health assessment captures in BB in 2017 and 2018 showed a recurrence of increased T cell proliferation and a cytokine balance tilt towards a Th2, rather than Th1 or Treg response, as was observed in 2011. Further exploration showed that dolphins born after the spill appeared to exacerbate this trend, suggesting the possibility that dolphins born after the spill would suffer the negative health consequences of exposure to oil. These observations could be explained by either transgenerational effects on the developing fetus, continued exposure to oil in BB dolphins, or a combination of both. Our study highlights the need for assessing subtle, sub-clinical aspects of health to understand potential ongoing and future consequences of exposure to oil spills.

Macaronesian Region is an important biodiversity hotspot located in the North Atlantic Ocean, between Europe and Africa, conformed by four archipelagos (Azores, Madeira, Canary Islands and Cabo Verde Islands). Among the species that inhabits this area, cetaceans occupy a remarkable place in terms of abundance and diversity, having confirmed the presence of 32 different species residing or transiting their waters.

Macaronesian Cetacean Health Network (SANICET) was conceived with the objective of carrying out a program of health surveillance of Macaronesian cetacean populations or, in other words, to assess and monitoring those possible risk factors or threats that could affect, directly or indirectly, the conservation of these cetaceans. Diverse scientific groups specialists in cetaceans that usually work in this Region, in different areas of knowledge: animal health, ecology and oceanography, joined efforts to integrate and harmonize procedures and knowledge from a multidisciplinary and interregional point of view, connecting them up into a powerful ICT tool of recent creation, a Collaborative Virtual Community (CVC) which shares data, information and methods, overcoming territorial and border fragmentation in the cetaceans conservation.

This initiative took shape through the MARCET Project (Interreg-MAC 2014-2020), in which the scientific studies proposed are directed towards the management for the preservation of the good environmental status of Macaronesian marine areas, the conservation of their cetacean populations and the promotion of a sustainable ecotourism model, mainly related to Whale Watching activity.

Using citizen science to investigate marine mammal occurrences and respond to strandings in the Negros Occidental Coastal Wetlands Conservation Area, Philippines.

The Negros Occidental Coastal Wetlands Conservation Area is the Philippines' 7th Ramsar Site of Wetlands of International Importance. It consists of 23,000 ha of coastal wetlands which include the municipal waters of 10 cities and municipalities of Negros Occidental and are part of two major marine bodies: the Guimaras Strait and Panay Gulf. Its biodiversity include 72 recorded species of migratory birds and the economically important nylon shell (*Paphia undulate*) and angel wings seashell (*Pholas orientalis*). Despite its economic importance to the fishing community, little attention has been given to large marine

vertebrates such as marine mammals, turtles, and whale sharks. In 2010, interview surveys by Dolar et al. (2011) led to the discovery of the Philippines' second population of Irrawaddy dolphins (*Orcaella brevirostris*) in one of the coastal areas of NOCWCA. Since then, the awareness on marine mammals have led to heightened vigilance on sightings and response to stranding events, especially with the recent establishment of the Negros Occidental Coastal Wetland Area Management Alliance (NOCWAMA), an alliance of environmental managers tasked to foresee the sustainability of the wetlands. The Alliance also recognized the role of the academe in providing scientific data to contribute to management-related decisions. In 2017, a marine mammal and whale shark stranding response and rescue training was conducted to strengthen the NOCWAMA's conservation capabilities and to effectively collect and report data as well. This study utilized fisher interviews to investigate the occurrences of other marine mammals that are often sighted by municipal fishers when going out to sea, or during stranding events. The study resulted in mapping out potential sites for further investigation, including habitats for endangered dugong and Irrawaddy dolphins.

Environmental factors related to group size and habitat use of Guiana dolphins from São Marcos Bay, northeast Brazil

de Moura, Jailson[1]; Pagliani, Bruna[2]; Pivari, Daniela[3]

Environmental changes can affect the social structure and disrupt habitat use of marine mammal species. An impact on the social dynamics of dolphins, including group size structure, may attenuate the feeding success and increasing predation risk, especially considering species exhibiting small home ranges, which impose particular habitat dependency and high vulnerability to environmental changes. In this regard, the Guiana dolphin, *Sotalia guianensis*is a particularly endangered species due to its coastal distribution considerable small home range. The aim of this study was first to conduct a spatial assessment of the dolphin groups sighted during a fieldwork conducted in the São Marcos Bay (SMB; Northeastern Brazil), one of the most import port areas from Brazil, from where about 120 millions tons of diverse mineral are annually transported worldwide. The results show an overlap between the distribution of the dolphin groups and the port activities area, which includes the loading zone at main port area and the navigation channel used by large cargo ships and other vessels. Also, a Generalized Linear Modeling approach (GLM) was conducted in order to identify the best combination of selected variables that best predict the group size of the dolphins. The predictor variables included: salinity, se surface temperature, depth, water transparency, distance from the main port area, and the feeding activity of the groups sighted. The results indicated that larger dolphin groups were found in areas closer to the main port area and were associated to foraging activities. Therefore, the results suggest that this dolphin population might be exposed to threats linked to the port activities, which may include noise pollution, vessel collision and chemical pollution. This study opens a scientific avenue for exploring the effect of potential anthropogenic threats on the Guiana dolphin population at the SMB.

Bycatch, consumption and trade of Burmeister's porpoise (Phocoena spinipinnis) inshore Peruvian southern waters

de Paz Campos, Nelly
ACOREMA; WWF, Lima, Lima, Peru
Corresponding Author: nellydepaz@yahoo.com

It was estimated that in 1990-1993, 15-20,000 dolphins and porpoises were caught in Peruvian artisanal fisheries. In 1996, a national law banned dolphin and porpoise capture and trade. However, a study with onboard observers in the artisanal fishery resulted in very high mortality rates (levels) of four species of small cetaceans, among them, Burmeister's porpoise (*Phocoena spinipinnis*).

Here we presented preliminary results of an ongoing observer program in artisanal gillnet fishery from Tambo de Mora (13° 30' S, 76°11' W) and San Andrés (13° 43' S, 76°13' W), southern Peru. Objectives are: 1) characterize and quantify capture of small cetaceans, 2) sensitize and increase awareness about small cetaceans among fishers and fishing authorities.

On-board observations were registered in surface gillnets and bottom set gillnets. The target species were eagle ray (*Myliobatis peruvianus*), guitarfish (*Rhinobatos planiceps*) and whiptail stingray (*Dasyatis brevis*), among others. Vessels operated from 0.5nm to 5nm and the characteristics of nets were 145m – 182m of length, 9-11 m of height, 12"- 14" of mesh size with 10-15 nets, totalizing 1.85 to 2.22 km of the net. Based on 56 fishing trips during the period of January 2015 to March 2019, the estimated CPUE for Burmeister's porpoise was 0.82 animal/trip^{-1}. Small cetacean

capture composition was 95.8 % porpoises and 4.2 % dusky dolphin and with a 95.75 % recovered dead and 4.3% alive from the nets. Small cetacean meat was used for fisher's consumption or trade; the meat was sold US$0.60 – US$1.5 /kg and is consumed fresh or processed as *muchame*, a dried local dish.

Different approaches were identified for monitoring and reducing cetacean bycatch: 1) socioeconomic and market studies, 2) incorporate devices to avoid incidental captures, 3) sensitize and develop campaigns for reducing demand for small cetacean meat and 4) enforcement of the law.

Movements of common bottlenose dolphins (Tursiops truncatus) within the Pelagos Sanctuary (North-Western Mediterranean Sea).

Common bottlenose dolphin (*Tursiops truncatus*) research and conservation actions were implemented in the Pelagos Sanctuary, the largest marine protected area (87,500 km^2) for Mediterranean marine mammals, within the framework of project "Dolphins Without Borders", Studies were conducted in three areas with a water surface, respectively (west to east), of 11,000, 2,200 and 8,150 km^2, between Nice and Elba Island. During 203 visual surveys, totaling about 8700 km of research effort under positive conditions (sea state < 4 on the Douglas scale), bottlenose dolphins were sighted 101 times. The unified photo-identification catalogue resulted in a total of 185 well-marked individuals.Of these, 53 (28%) matched with at least one of the other two catalogues. Only 2 dolphins (1%), both mother/newborn pairs, sighted between July and September 2018, were included in all the three catalogues. The maximum displacement distance was measured for each dolphin sighted at least twice (n=143): mean and median displacements were respectively 105, and 81 km, with 20% of the dolphins showing a displacement higher than 188 km, while the maximum displacement recorded was 272 km. These movements are longer than those reported in a similar study carried out in the same area, suggesting a possible extension of the dolphins' home range over time. The photo-ID data collected within this project were also matched with those collected along the French Mediterranean coast and Corsica within the GDEGeM project (2014, 381 individuals), resulting in only 4 matches, all involving individuals moving between Liguria and the eastern portion of the French coast. This result seems to confirm that there are quite stable discontinuities in the connectivity of the Pelagos bottlenose dolphin network, in agreement with previous studies.

The unprecedented sensitivity of the external ear canal of odontocetes, evolutionary adaptation, functional morphology, and histopathology

Over the course of evolution, the odontocete hearing apparatus has undergone major adaptations with the development of alternative hearing pathways. As such, the external ear canal lost its function as sound conductor but still constitutes active components such as glands, muscles, an intense vascularization, and sensory nerve formations[1]. Although the function of the ear canal was subject to debate in early cetacean research, it got neglected as focus was put on other structures, and its significance remains a conundrum heretofore. In this study, we analysed the ear canals of various odontocetes (incl. striped dolphin, bottlenose dolphin, common dolphin, harbour porpoise, long-finned pilot whale, and Cuvier´s beaked whale) using macro- and microscopic techniques to study morphology and pathology. Results indicate that the ear canal has acquired an unprecedented sensitivity that could function as an extero- and proprioceptive pressure sensor. We describe mechanoreceptors, identified as simple lamellar corpuscles in all of the odontocetes, while absent in terrestrial mammals, which show

morphological resemblance to the inner core of Pacinian corpuscles as shown by immunohistochemistry, transmission electron microscopy, and immunofluorescence and confocal microscopy. The receptors form part of a complex nervous network that surrounds the ear canal in its superficial half, while it is concentrated into a ´sensory ridge´ in the medial half, associated with cartilage, vascular lacunae, and the tympanic membrane. We provide a preliminary hypothesis that the ear canal has an essential role in the correct functioning of the hearing apparatus. And finally, we describe various pathologies, including purulent otititis externa and granulomatous dermatitis with hyperplastic pigment-laden macrophages, which could negatively affect those functions, and/or could serve as indicators for infectious diseases and other causes of death. These results provide essential information for a better understanding of the sensory system of cetaceans, functional morphology of the hearing apparatus, and associated pathologies.

Feeding of humpback whales (Megaptera novaeangliae) in Nicaragua, Central American Breeding ground.

We report evidence of feeding by humpback whales in the Central American subpopulation of this species along the Pacific coast of Nicaragua during their winter breeding seasons in 2017 and 2018. Boat-based surveys were conducted to collect data on whales as part of ongoing studies at two field sites: Northern and Southern Nicaragua. We documented 18 events with either direct or indirect evidence of whale feeding activity, exclusively in Southern Nicaragua. Lunge feeding was observed on 6 occasions and in 12 sightings there was indirect evidence of feeding including the erratic surface movements, the presence of feces, and close associations with feeding aggregations of seabirds and dolphins. Photo-identification analysis revealed that at least one whale was documented feeding in both years, indicating some whales may regularly feed in this location to account for the energetic demands of migration. These findings provide important insights into the importance of Nicaragua for migrating humpback whales.

Numerical modeling tools investigating marine mammal lung and melon response to underwater explosion impulse

Marine mammals could be exposed to underwater explosions (UNDEX) in various settings, including coastal construction, underwater demolition, and military operations. Primary blast injury (PBI), the gross blast-related trauma or traces of injury in air-filled tissues or tissues adjacent to air-filled regions (e.g. lungs, GI tract), has been documented in a number of marine mammal species after blast exposure. The melon, an important component of echolocation, if damaged, may compromise an animal's ability to navigate, communicate, hunt, and ultimately survive. Little is known about marine mammal susceptibility to PBI, and even less about potential UNDEX damage to the melon. As a result, traditional analysis relies on methods developed almost 40 years ago using terrestrial mammals as surrogates for marine mammals in experimental protocols, ignoring species-specific physiological adaptations to the marine environment. Currently available numerical modeling tools (finite element modeling and computational fluid dynamics) could better inform zones of influence estimates for UNDEX by simulating the response of morphologically accurate proxies with material properties representative of marine mammal tissues. We developed a computational model of a surrogate air-filled spherical membrane structure subjected to directional shock loading to represent the full complexity of *in vivo* marine mammal lung and melon response to UNDEX. This approach incrementally improves the assumptions used by the US Navy, which employs a surrogate of a one-dimensional spherical air bubble of equivalent lung volume for a given marine mammal species, with the bubble oscillating in response to an initial velocity and omnidirectional pressure loading. For the melon, we are developing similar surrogate models to determine potential damage to melons at UNDEX impulse/peak pressures below what would cause severe lung hemorrhage (e.g., death). Verification and validation testing were conducted for the various surrogate models investigating marine mammal lung and melon dynamics.

Oh what a tangled web we weave- bycatch in UK stranded cetaceans

The collaborative Cetacean Strandings Investigation Programme (CSIP) has been funded by UK government since 1990, to provide a systematic and coordinated approach to the surveillance of UK stranded cetaceans and to investigate causes of mortality. In the 29-year period between 1990 and 2018, the CSIP received reports of 15814 cetaceans, of which 13956 were dead strandings, 1155 live strandings and 703 found dead at sea. The CSIP investigated 4039 cetaceans through systematic necropsy during this period. Of these, 764 were diagnosed as having died due to incidental entanglement in fishing gear as non-target species (bycatch), making this the primary direct anthropogenic driver of mortality in UK stranded cetaceans. Bycatch or entanglement was diagnosed as a cause of death in 14 of the 19 cetacean species examined in the UK. Bycatch was most frequently diagnosed in harbour porpoises (*Phocoena phocoena*, n=374, or ~15% of examined cases) and short-beaked common dolphins (*Delphinus delphis*, n=329, or ~42% of examined cases). Frequently observed external pathologies included epidermal netmarks or ropemarks, penetrating wounds to the body wall, excised fins or flukes or other evidence of trauma consistent with fisheries interaction. Bycaught animals were generally in good nutritional condition, had evidence of recent ingestion of prey and other significant factors were eliminated. Southwest England appeared to be a bycatch hotspot in the UK, with 436 diagnosed cases. Bycatch was also strongly seasonal, with 418 cases recorded stranded during the quarter January-March. Bycatch has been a consistent finding every year since the inception of the CSIP in 1990. The welfare implications of bycatch at an individual level are clear from this study. Bycatch can also represent a significant conservation pressure, particularly in small, fragmented or isolated populations. More efficient integration of regional and global efforts is needed to improve mitigation of this significant cetacean threat.

Dietary and isotopic niche overlap between three Arctic phocids in Hudson Bay, Canada.

The sub-Arctic marine environment of Hudson Bay is home to three species of phocid seals: ringed (*Pusa hispida*), bearded (*Erignathus barbatus*), and harbour (*Phoca vitulina*). As climate warming leads to changes in prey distribution, these three species may experience greater dietary niche overlap and resource competition.We investigated spatiotemporal shifts in seal dietary niche overlap and composition to test the hypothesis that these seal species occupy similar ecological niches, particularly ringed and harbour seals. We used stable isotopes and lipid biomarkers from tissues sampled in the fall by Inuit hunters from 2003–2017 in Arviat (west) and Sanikiluaq (east), Nunavut. Long-term analysis of Arviat isotopic niche size using muscle tissue indicated ringed seals (n=537) overlapped with harbour (n=22) and bearded seals (n=43) by 41% and 36%, respectively. However, shorter-term analysis using liver tissue indicated increased overlap to 63% between ringed and harbour seals, and a decrease to 33% between ringed and bearded seals. In Sanikiluaq, ringed seals (n=543) overlapped with bearded seals (n=37) by 47%. Bayesian mixing model diet estimates were similar for ringed and harbour seals, revealing that sand lance and capelin fish were the primary prey, whereas bearded seals consumed primarily sculpin fish and benthic invertebrates. Highly branched isoprenoid index (H-print) from seal liver was used to distinguish pelagic and sympagic carbon sources. Ringed seal H-print was 62%, indicating a pelagic-sourced carbon diet, compared to harbour seal H-Print, 31%, a more sympagic-sourced carbon diet. However, ringed and harbour seals had low absolute concentrations of IP_{25} (18.1 and 10.1 ng/g respectively), suggesting considerable contributions of freshwater sourced carbon in their diets. While dietary and isotopic niche overlap appeared to be

high, lipid biomarkers revealed specific prey differences suggesting niche partitioning. Our observations provide an improved understanding of how these three phocid species are utilizing resources, which provide insight into the structure and function of this sub-Arctic marine system.

Precision-cut adipose tissue slices: A novel approach to study adipose function under multiple stressors in marine mammals.

Marine mammals are increasingly exposed to multiple anthropogenic stressors (pollution, decrease of food quantity/quality, disturbances linked to sonar, oil drilling, boat traffic and coastal development), which are likely to exert an effect on adipose tissue development and function. The disruption of this essential endocrine organ can have deleterious consequences on the organism health and survival. We have developed and validated a novel approach of precision-cut adipose tissue slices from northern elephant seal (NES – *Mirounga angustirostris*) to determine *in vitro* the impact of multiple stressors on adipose function. Blubber biopsies were taken on free-ranging NES from the colony of Año Nuevo (California). We distinguished two layers in the blubber (outer and inner) and two periods of fasting (early and late). Blubber biopsies were cut into 1mm thick slices that were kept in culture media at 37°C. Slices weight was 4.75 ± 1.49 mg and followed a normal distribution. Slices viability was good during at least 3 days of culture. Slices response to metabolic stimuli was assessed by triggering lipolysis with isoproterenol, either at day 0 or at day 2 of culture. Tissue slices in the lipolytic condition released significantly more glycerol than tissue slices in the non-lipolytic condition, even when the stimulus was induced after 2 days of culture. The concentration of glucose in the culture medium did not affect the efficiency of lipolysis and the response to lipolytic stimulus did not vary between outer and inner blubber. The release of glycerol from inner blubber was higher at early as compared to late fast. In conclusion, this model is ready to be used to study the impact of pollutants and other stressors on adipose tissue biology. For that purpose, we are currently exposing the precision-cut slices to compounds mimicking a physiological hormone stress-response and/or an exposure to environmental pollutants.

Camera-trap surveillance of the endangered Mediterranean monk seal in the Gökçeada Island, Northern Aegean Sea, Turkey

Gökçeada Island is one of the important Mediterranean monk seal (*Monachus monachus*) habitats in Turkey and existence of the monk seals has long been well known on the island. There are only six different caves or haul-out sites on the northwestern coast which are convenient for monk seals. This is the first study aims to obtain data on individual identification and number of seals, yearly distribution and frequency of habitat usage and environmental parameters affecting monk seal presence. The preliminary findings of four months of monitoring period between 21 June to 21 October 2017 of two caves and one haul-out site were analysed. Out of 123 monitoring days seals were photographed on 40 days in haul-out site, 23 and 31 days in caves, respectively. Clear diel pattern was observed for the haul-out site rather than the caves. Totally five individuals (adult male and female, two young and one newborn) were detected. In one sighting, five seals were photographed together in a cave. A newborn pup and nursing behaviour/lactation was observed in the first week of October 2017. The longest duration without leaving cave recorded as 43 hour. Monitoring study still in progress together with collecting environmental and anthropogenic parameters (fishing, tourism, sea state etc.) to understand the current situation of these seals using the island, consequently to elaborate better conservation strategies for the survival of this species in the region.

A focal animal 6-points Likert scale to rate intra-unit interactions in sperm whales

(Physeter macrocephalus) off Mauritius Island.
Sarano, François; Sarano, Véronique; Adam, Olivier[1]; Girardet, Justine; Vitry, Hugues; Preud'homme, Axel; Heuzey, René; Glotin, Hervé; Jung, Jean-Luc[2]; Delfour, Fabienne[3]

Female sperm whales (*Physeter macrocephalus*) and their offspring live in stable and matrilineal social groups called units, characterized by stable long-term social relationships. Most females stay in their natal unit while juvenile males disperse before maturity and aggregate with other young males in bachelor schools. In 2011, a project was launched under the Authority of Marine Megafauna Conservation Organization to study sperm whales off Mauritius Island. To date, ninety eight sperm whales are identified using their markings, scars and color patterns: 17 large males, 65 adult females and 16 juveniles belonging to at least 5 units. In order to understand the intra-units' social dynamic and to rate the different types of interactions, we created a social scale following a focal animal 6-point Likert scale that ranges from 1 (the weakest) to 6 (the strongest): 1) individuals seen the same day but hours and miles apart, 2) individuals seen at the same time but >100m apart, 3) > 2 individuals without physical contacts but in visual range (< 20m), 4) socialization: > 2 individual with physical contacts, 5) dyadic interaction and 6) nursing. We added sub-criteria to enrich this scale: for instance 3 and 4 are respectively subdivided into 3a) sleeping and 3b) swimming; 4a) juveniles with adults and 4b) juveniles together or with a nursing female. Five comprised dyadic interactions with (5a, b, c) and without (5d, e) physical contacts, and 6 comprised 6a maternal nursing and 6b allonursing. Aerial observations and underwater videos were carried out from February to May from 2013 to 2017, and from February to August in 2018 for a total 250 hours of audio-video data. After presenting and explaining in details the scale, its sub-criteria and the obtained matrix, we discuss the benefits and pitfalls of using a Likert scale when interested in wild marine

Precocious echolocation ontogeny and click development in the harbour porpoise (Phocoena phocoena).
Delgado-García, Lara[1]; Wahlberg, Magnus[2]
(1) University of Southern Denmark, Barcelona, Spain
(2) Marine Biological Research Centre, University of Southern Denmark, Kerteminde, Denmark
Corresponding Author: lara.del.gar@gmail.com

Despite echolocation being a highly specialized key sense for odontocetes, fundamental for their survival, little is known about sound production and echolocation ontogeny. To investigate this, we studied 3 harbour porpoise calves born in captivity from birth until up to an age of 9 months. Hydrophone array and synchronized video recordings were used to perform acoustic localization of each click, to determine source parameters of the calves' sound emissions. Immediately after birth, all calves emitted high frequency clicks suitable for echolocation. On-axis calf clicks resembled the adult signals but had a broader high-frequency content with higher mean centroid frequency (145KHz) than adults (125kHz), and a simultaneous low-frequency component at 2.3kHz stronger than in adults. Two days postnatal, the calf regulated the intensity of its calls, decreasing click intensity when approaching a target, equally to echolocating adults. Two days post-natal the calf maintained the intervals between clicks above the two-way travel time, as adults do. Four days post-natal, the calf controlled the click emissions rate, decreasing the inter-click interval when approaching the target, indistinguishably from adults. This show that active echolocation and the inferred processing of the echoes is developed within four days post-birth, which makes harbour porpoises the fastest developing echolocator studied so far. Changes in the high frequency content of the calf clicks were observed throughout nine months. This can be explained by the size increase of the sound-producing organs. The long-term changes in the click parameters (duration, frequency centroid and bandwidth) allows for acoustically ageing of individuals, which were different from adults up to 9 months old, close to the weaning time of porpoises. This hints at the possibility of using the click parameters to detect the presence of lactating calves in the wild, allowing specific conservation measures for porpoises during this vulnerable period of their lives.

Vantage points survey of the Black Sea harbour porpoise (Phocoena phocoena ssp. Relicta) in Bulgaria.

During 2015, the Black Sea Harbour Porpoise at vantage point survey located in 6 regions along the Black Sea coast of Bulgaria (Agalina, Durankulak, Emine, Kamchia, Nessebar and Sinemorets) have been made. For each area, the survey lasted 20 days. The real data have been collected during 06. 2015-07.2015 period. As a result, it was found that the species is distributed throughout the all coastal aquatory. The species is observed singly or in groups of 1 to 7 individuals, on average - 3.05 individuals in a group, most often 1 individual. The largest number of individuals were registered in July - 111 from Cape Emine. This determines this area as the most important for the coastal waters for the species. From the total of all 6 points, the species have been registered in 146 observations with a total of 289 individuals, of which 146 individuals in June and 143 individuals in July. In the period August 2016 - August 2017, year-round field observations were carried out from a vantage point in Varna Bay. This Survey covers 66 field days and 330 hours. The observations of the species were 80 and registered individuals - 119. All registrations were in the northern part of the bay, no more than 364m from the coast. The registrations of the species fall into a one-UTM square - NH78, 74. The detailed analysis of the favorable period of observation (April-July) shows that in Varna Bay the highest number of individuals was observed in July 2017. - 32 individuals. In the months of May, June and August of 2017, high rates were also recorded: 23, 26 and 23 individuals, respectively. This indicates that the favorable observation period also includes August.

Improving behavioral studies of wild cetaceans with an Android device

Delrocq, Laurent; Gannier, Adrien
GREC, Antibes, France
Corresponding Author: l.delrocq@laposte.net

Once a contact with wild cetaceans is obtained under good weather conditions, field behavioral studies are particularly difficult to carry out due to the highly dynamic nature of variables. Even in a simple case, such as a single sperm whale surfacing and blowing before its next dive, variables seen as secondary may be missed if data recording is conducted on a paper form. In a complex case, such as long lasting focal follow of a dolphin school, large amounts of data are lost due to our limited capacity to collect information flows on variables such as school structure variations, sub-group movements and surface behaviors, responses to approaching vessels, etc.

GREC developed and tested an Android software, named PADOC (Plateforme d'Acquisition de Données d'Observations Cétologiques) to overcome data collection limitations in field behavioral studies.

PADOC was developed to run on virtually any Android device. It uses GPS and compass sensors if available. It is designed to be easily handed over to part-time researchers.

PADOC allows to record different data types such as group structure, cetacean movements and positions (speed, course), and surface events (jumps, blows, social behavior, etc.). Time and position are automatically recorded with any entered data, and a CSV file is generated so that the data can be easily processed later.

During 2018, behavioral data was collected with PADOC in simple and complex situations: for example, during a 6.5 hour sighting of two sperm whales, each animal's surfacing and fluking times, blowing rates, were collected together with their respective positions and movements.On another occasion, PADOC enabled to store 336 events during a 2.1 hour sighting of a bottlenose dolphin school, including 55 surface events and 9 interactions with recreational boats.

Following initial field tests, PADOC is now ready to be released to field researchers for wider experimental use.

A dramatic decrease of Risso's dolphin presence off French Riviera

Delrocq, Sylvie; Gannier, Alexandre
GREC, Antibes, France
Corresponding Author: s.delrocq@laposte.net

Over the three last decades, regular small boat surveys held year round off Antibes, French Riviera, enabled to monitor the presence of the Risso's dolphin (Grampus griseus). A total of 37 sightings were obtained from 1989 to 2010 in a study area between Cap Camarat and Cap Ferrat, to 20 miles offshore. Total effective effort amounted to 27580 km. Risso's dolphin were observed during all seasons, being more frequent in winter and spring once effort was accounted for. Sightings were located from shelf to deep slope waters

(>2000m depth), with a trend to be farther offshore during winter. Mean school sizes were stable over the period (9.16, SD=7.13). We estimated average sighting rates (ASR) for three consecutive 10-year periods: 1989-1998, 1999-2008 and 2009-2018. Sample unit was one year. ASR was 0.226 ind./100km (SD=0.185) for 1989-1998, 0.114 (SD=0.112) for 1999-2008, and 0.015 (SD=0.045) for 2009-2018. Not a single sighting was obtained after 2010. Even if yearly sighting rates were irregular, with high values of 0.615 ind./100km in 1996 or 0.428 in 1993, the decreasing trend is further materialized by the frequency of '0 sighting' years: one for 1989-1998 and 9 for 2009-2018. Recent literature includes large scale aerial survey reports showing several Risso's dolphin sightings well in the oceanic domain, in winter and summer. Our own survey data showed Grampus can still be observed over slope waters in various regions. To explain the dramatic presence drop, one hypothesis would be that western Ligurian waters are now less suitable for Risso's dolphin feeding. However, the species diet is diverse, consisting in various species of benthic or pelagic squid. Another hypothesis would be that the sperm whale, also a squid-eater, takes a larger share of the prey biomass, which is possible since this species is now more frequent compared to 20-30 years ago.

Perinate bottlenose dolphin mortality following the Northern Gulf of Mexico unusual mortality event

Deming, Alissa[1]; Carmichael, Ruth H.[2]

Corresponding Author: alissademing@gmail.com

During the Deepwater Horizon oil spill Unusual Mortality Event (UME; 2010-2014) high numbers of perinate (premature, stillborn, neonate) dolphins were found dead along the northcentral Gulf of Mexico (nGOM) coast. Deaths were attributed to adrenal or lung disease in the dam, resulting in fetal distress with occasional in utero infections, including brucellosis. Unusually cold winters and increased freshwater discharge may also have contributed to the strandings. There has been no follow up assessment of perinatal stranding demographics since the close of the UME in 2014. This study defines perinate mortality trends on the nGOM coast from 2015-2019 for comparison to trends before (2004-2010) and during (2011-2014) the UME. Perinatal dolphins in this study stranded in Alabama, USA (where perinate mortalities were previously analyzed) during the peak calving season (Jan-May) and had straight length (SL) <115cm. Prior to the oil spill (2004-2010), there was an average of 3 perinate strandings per season (SL=101.4±3.6cm), with two (SL=110.5±4.5cm) in the season just prior to the spill. The first calving period following the oil spill (2011) perinate strandings increased to 26, most of which were late term aborted fetuses (SL=94.7±1.7cm). During 2012-2014, perinate strandings decreased to an average of 8 per season (SL=96.7±2.3cm), and following the UME (2015-2019) averaged 7 per season (SL=99.4±1.9cm). Necropsy and histologic examination on all fresh dead and moderately decomposed perinates from 2015-2019 showed fetal distress. There were occasional cases with in utero pneumonia (bacterial or parasitic infections), however, all lung tissue was PCR-negative for *Brucella*. These findings show high perinate mortalities continue along the nGOM coast, with late term abortions and signs of fetal distress. The underlying cause of these failed pregnancies remains unclear, but could include residual effects of the oil spill, infectious disease, or other environmental stressors negatively impacting the dams' health during pregnancy.

Variation in body condition in maternal female humpback whales over the course of the breeding season provides a useful tool for the comparative assessment of the quality of humpback whale nursery grounds

Dempster, Charlotte[1]; Cartwright, Rachel[2]

charlotte.l.dempster@gmail.com

In maternal female humpback whales, *Megaptera novaeangliae,* changes in body condition over the course of the breeding season potentially provides a useful tool for the comparative assessment of the quality of humpback whale nursery grounds. As capital breeders, maternal humpback whales utilize stored energy reserves to support the late stages of fetal development and the crucial early periods of lactation while effectively fasting. Consequently, energetic reserves are finite, conservation of available energy reserves is essential and high levels of disturbance during the earliest periods after parturition may impact both the immediate and future fitness of offspring. In this study, we used aerial photogrammetry, gathered using a small UAS to track changes in maternal body condition relative to the age of the calf. Limitations of the onboard altimetry included in the UAS were addressed by incorporating a calibration within each sample. Calves were classified as neonates and non-neonates based on several characteristics; the body length of the calf relative to the maternal female, color difference between calf and maternal female, and the presence of known neonatal features such as residual neck indentations. Body

length to surface area ratios of the maternal females were then compared to give body condition indexes at different stages of calf development. Initial analysis indicates a significant decline in body condition in maternal females between these two calf stages, from a mean body condition index of 1.56 (s.d. 1.5) for mothers with neonate calves to 1.43 (s.d. 0.7) for mothers with non-neonate calves ($p = 0.029$). As body condition details for the Hawaii Distinct Population Segment have yet to be compiled, these details provide an initial baseline that can be applied to track variations between seasons and, with further refinement of this protocol, potentially between different nursery regions that are used by maternal humpback whales.

Objective separation of body motion and orientation from accelerometer data

Animal-borne accelerometers can provide information on the behavior of marine mammals underwater, like measures of energy expenditure, three-dimensional movement and prey-capture attempts. Accelerometers measure the total *g*-force in three axes, consisting of both a static and dynamic component. The dynamic component relates to the active acceleration or body movement, like swimming. The static component relates to the animal's body orientation. Changes in body orientation are generally more gradual than active acceleration, and can therefore be estimated by applying either a smoother or filter to the raw accelerometer measurements. However, which the choice of filter or smoothing method and defining the smoothing window width or cut-off frequency remains subjective.

We propose a methodology to separate the static and dynamic component more objectively. It is based on the vectorial sum of the three static dimensions being equal to the gravitational force of 1*g* (=9.81 ms^{-2}). Therefore, the size of the smoothing window or cut-off frequency leading to a static component which is closest to 1*g* should yield the best approximation of this static component. This is tested on simulated data and accelerometer data from five species, with a main focus on harbor seals (*Phoca vitulina*).

The simulated data demonstrate the capacity of the method to correctly select the optimal smoothing window and cut-off filter frequency. In actual accelerometer, the exact value of optimal smoothing or filtering varies between species and types of behaviors. This suggest that a single pre-defined smoothing window or cut-off frequency which is currently used may not always be appropriate. The proposed methodology could improve estimates for body orientation and motion, and hence, lead to a more precise description of how marine mammals behave.

Identifying the northwesternmost reproductive site of the endangered Mediterranean monk seal (Monachus monachus) in the Eastern Mediterranean Sea

The Mediterranean monk seal is the most endangered pinniped species on Earth. After the most recent reevaluation of the species' status in 2015, the Mediterranean monk seal was listed by the IUCN as "Endangered" and population monitoring was identified as one of the most important research and conservation priorities. In 2017-2018, we carried out, for the first time, population-monitoring efforts in the Northern Ionian Islands in Greece, an area stretching from the island of Andipaxoi in the South to the islands of Othonoi and Ereikoussa in the North, including the adjacent coastlines of mainland Greece. Efforts included extensive surveys over 540 km of coastline in order to: a) evaluate habitat availability and suitability, b) confirm and evaluate habitat use by the seals and c) collect demographic data. Field data were collated with information on monk seal sightings collected through the National Monk Seal Rescue and Information Network. Our results indicate the presence of suitable habitat for the Mediterranean monk seal in the Northern Ionian Islands (i.e., 7 marine caves suitable for pupping and resting, 14 suitable only for resting); 11 seal sightings were recorded during the study, including that of a newborn pup. This finding indicates the presence of a reproductive monk seal group in the

area, which now represents the northwesternmost reproductive site of the species in the Eastern Mediterranean Sea. Considering the ongoing threats of habitat deterioration and increased human activity (mainly tourism-related) to the species in the area, in conjunction with the recent spate of extra-limital sightings of monk seals (and especially weaned pups) in neighboring Albania and Italy, we believe that effective conservation measures are urgently needed in order to: a) secure the fate of this newly-discovered monk seal pupping nucleus, and b) prepare the public for the reappearance of the species in the neighboring counties.

Features of diagnostics of diseases and causes of death of wild cetacea of the Black Sea.

In 2017 at seaside of Krasnodar region, based on publications of the media, reports of the local people, as well as on our own observations, a rather high number of deceasedcetaceans was found with had skin lesions in the form of erosions. It became the prerequisites for organizing systematic work on accounting ofstranded cetaceans and determining the possible causes of death in 2018-2019.

When dead animals were found, the degree of preservation / freshness/ decomposition stage of the corpse was noted, among other things. In cases when freshness was reliably known, for example, when recording the time of death of an animal, biological material was taken for subsequent microbiological, toxicological, and genetic research.

While studying the skin lesions of deceasedanimals, we found no injuries recorded in 2018 in any individual. However, more than 20 cetaceans showed damage characteristic forby-catch in fishing gear. These are characteristic scars and drawings left by the nets, as well as cut off fins and flukes. When studying the presence and amount of toxicants in the body of this individuals, all the studied substances were found in insignificant amounts: organochlorine compounds, synthetic, organophosphate pesticides and dichlorodiphenyltrichloroethane and its metabolites.

As a result of microbiological studies of material from the fallen harbour porpoise, bacteria were found in the material from the upper respiratory tract *Streptococcus iniae*- hemolytic, significantly predominant in seeding and *Staphylococcus epidermidis*- pathogenicity factors which have not been established. In the material from the surface of the skin and from the oral cavity bacteria of the *Staphylococcus, Escherichia, Providencia* were isolated. The presence in the respiratory tract of a fallen animal of hemolytic streptococcus in significant amounts may indicate the presence of infectious pathologies of the respiratory tract, which could cause the death of the animal.

Humpback whale winter distribution and core habitats in relation to SST in offshore and coastal areas off the coast of Ecuador.

Humpback whales migrate along the South American coast from feeding grounds off the Antarctic peninsula and Southern Chile to breeding areas off Peru, Ecuador, Colombia and Panama. In temperate and tropical regions, climate change, may cause shifts in cetacean distribution away from tropical waters towards higher latitudes; however, whether these shifts affect humpback whales in their wintering grounds, is unclear. With visual and acoustic surveys from the South to the North of Ecuador on board a sailboat in 2013 and 2014, we determined core habitat characteristics for humpback whales breeding off the coast of Ecuador in inshore and offshore waters. We analysed changes in distribution patterns in relation to El Niño Southern Oscillation (ENSO) events with Generalized Additive Models (GAMs) for the surveys and with long-term sighting data collected in a subtropical and a tropical breeding ground. Humpback whales were observed both in inshore and deep offshore waters with songs recorded as far as 100 km from the coast in depth of up to 2000m. They preferred shallow continental shelves off the coast with areas of relatively warm surface temperature (24-27°C) and within 10-20km from the coast. Sighting rates during years that had been preceded by ENSO conditions were significantly lower in subtropical breeding grounds than those in cooler years. Our data evidence that humpback whale distribution in their wintering grounds is influenced by local SSTs as well as region-wide phenomena (ENSO), and thus could indicate that in

the future their distribution may shift with warming ocean temperatures.

Inter-island variation in endocrine stress responses may be linked to anthropogenic pressures on the endangered Galapagos sea lion.

Pinnipeds are frequently exposed to a multitude of anthropogenic stressors, including habitat encroachment, noise or chemical pollution, and fisheries interactions. These potential stressors may lead to elevated glucocorticoids (predominantly cortisol) in individuals, which when sustained, can ultimately disrupt normal physiological function or behavior by altering energy mobilization and use. The Galápagos Islands provide a natural experiment to assess the physiological impacts of sustained disturbances on an endangered species found throughout the archipelago, the endemic Galápagos sea lion (GSL). Several islands are uninhabited or restricted, but others consist of localized hotspots of tourist visitation, human habitation near sea lion colonies, and consequently, exposure to pathogens from domestic or introduced species. We collected serum and compared both basal cortisol (n = 121) and the induced cortisol stress response (ISR) mounted during capture (n = 42) in juvenile GSL among several colonies with vastly different degrees of human influence. We also quantified thyroid hormones T4 and T3, glucose, and testosterone to determine associations between cortisol responses and how metabolism and reproductive hormones may be altered in stressed populations. Controlling for sex and body size, we found that GSL in a highly disturbed colony on San Cristóbal Island had both significantly higher basal cortisol concentrations and lower ISR. Lower ISR was also associated with decreased concentrations of thyroid hormone T3 and glucose, suggesting that individuals with a reduced ability to mount a stress response to a short term challenge had downregulated metabolism. Furthermore, testosterone was high in socially dense colonies (based on individual abundance), which likely reflect a more stressful and competitive environment amongst conspecifics. These results indicate that several aspects of sea lion physiology are modulated in areas of high disturbance and, together with metrics of spatio-temporal and environmental variation, should be considered when making human-wildlife conflict management decisions.

Whales of the deep: Horizontal and vertical movements shed light on humpback whale use of critical pelagic habitats in the western South Pacific.

Humpback whales (*Megaptera novaeangliae*) are known for their nearshore distribution during the breeding season, but their pelagic habitat use patterns remain mostly unexplored. In New Caledonia, an archipelago located in the western South Pacific, several offshore seamounts and banks are visited by humpback whales. Yet, the reasons why whales would aggregate and move between these offshore waters remain poorly known. From 2016 to 2018, 18 humpback whales were equipped with depth-recording satellite tags to shed light on environmental and social drivers of seamount association around New Caledonia. Shallow seamounts (< 500 m deep) spatially structured movement paths at small and large scale. Indeed, two males stopped over the Lord Howe seamount chain (3 to 7 days) during the first-ever recorded longitudinal transit between New Caledonia and the Australian East coast. Movement paths were modeled with Correlated Random Walks to estimate the position of dive events. Residence time was found to significantly increase with proximity to shallow seamounts, while dive depth increased within 100 km of these seabed features. Most of the 7,986 recorded dives occurred above 80 m (88.5%), but deep dives (> 80 m, max 616 m) were also regularly recorded (11.5%), including by maternal females. Deep dives often occurred in series and were characterized by U-shapes suggesting high-energy expenditure. Based on observed patterns of vertical and horizontal movements, we hypothesize that seamounts could 1) constitute navigational landmarks, 2) provide favorable conditions for opportunistic feeding, and 3) have acoustic properties facilitating male song propagation. At a broader scale, humpback whale use of seamounts is predicted from habitat models based on boat-based surveys conducted over the

entire Oceania breeding range. Given increasing anthropogenic threats to deep sea habitats worldwide, these new insights into the use of seamounts by humpback whales during the breeding season have both ecological and conservation

Outreach on the case of Arctic sealing: Opening up for a reframing of the sustainability discourse?

Whales and seals continue to be major resources for Arctic communities and hunting them a part of long-standing cultural traditions. However, the question of whether whales and seals can be sustainably harvested as living marine resources is typically seen as a topic too controversial to discuss in the public sphere. In 1992, the Faroe Islands, Greenland, Iceland, and Norway established NAMMCO - an intergovernmental organization to foster cooperation on research, conservation and management of marine mammals in the region, and to provide management advice (based on scientific evidence and user knowledge) for both their *conservation and use*. In the current climate of international public opinion, this leaves the organization with a particularly unique challenge regarding outreach and education. How to communicate not only conservation concerns, but also the potential sustainable use of marine mammals as living resources in a global perspective? This talk will describe how NAMMCO is approaching this unique outreach challenge through an ecosystem perspective. It will present a pilot study using Life Cycle Assessment (LCA) showing that consuming seal meat in Greenland results in lower greenhouse gas emissions and other advantages than pork imported from Denmark. However, the European ban on seal trade has significantly reduced income sources for many Greenlanders, who can no longer afford to hunt and are now turning towards these cheap but less sustainable protein imports. Furthermore, the high pollution levels documented in certain marine mammals have led to the Governments of Greenland and the Faroe Islands advising that they not be eaten, at least by certain segments of the population. The presentation of this case illustrates how raising questions about what is sustainable and environmentally damaging from an ecosystem perspective can help reframe outreach efforts in a way that opens up for new conversations about conservation and use for Arctic resilience.

Acoustic identification of odontocete cetaceans in coastal waters of the Southwestern Atlantic Ocean

This is a preliminary study to establish a library of odontocete whistles for a PAM in southeastern Brazil. Data were collected in two years in the northern coast of São Paulo state, specifically at the Canal de São Sebastião (CSS, 23°49' S; 45°24' W) and at the Anchieta Island (PEIA, 23°33' S; 45°04' W). A total of 30 detection events were recorded in the CSS and 137 in the PEIA. Seven acoustical variables were extracted from 5,644 whistles of detection events. The same acoustical parameters were extracted from whistles of *Orcinus orca* (*Oo*), *Tursiops truncates*, *Stenella frontalis* (*Sf*) and *Sotalia guianensis* (*Sg*) visually recorded through oceanographic cruises in the study area. PCA was used for analyses plotted with the averages of the acoustic parameters of the whistles of the four delphinids in relation to the whistles of each detection event, and simultaneously the prediction from the random Forest (RF) classification model. A total of 716 whistles and all the acoustical parameters extracted from the library identification were considered to train and validate the used model. The RF multivariate analysis presented 64% accuracy in species identification predictions. Based on mean decrease in accuracy, the most important variables for classification were duration, and the final, minimum, central and bandwidth frequencies. The RF analysis showed that *Oo* and *Sf* showed whistles with similar physical acoustic characteristics. The best species classification was *Sg*, with 91% accuracy predictions. The whistles identified in the detection events were incorporated into the RF model. The acoustic detector database was enriched in training data with 3,274 whistles of *Sg* and 12 whistles of *Sf*. The new RF model presented 89% accuracy in predictions, increased the accuracy for *Sg* identification to 98% and decreased it for *Sf*.

It is a match! evidence for whistle matching in common dolphins (Delphinus delphis) and Atlantic white-sided dolphins (Lagenorhynchus acutus)

Whistle matching has been defined in bottlenose dolphins as an exchange of the same whistle type between two or more animals. Although fairly well studied in bottlenose dolphins, which are known to copy signature whistles of close associates, little is known about whistle matching in other delphinids. We found strong evidence of whistle matching in common dolphins (*Delphinus delphis),* and possible evidence in Atlantic white-sided dolphins (*Lagenorhynchus acutus*), from recordings made in Wellfleet, Massachusetts, USA. In total, 6,287 hours of acoustic recordings (from 2014-2017) were analyzed. Delphinid vocalizations were found in 124 hours of recordings, of which approximately 75% were *D. delphis* and 25% *L. acutus*. Species were confirmed using sighting data when available; otherwise call contour parameters were used. Using conservative criteria for copying, such that whistles of the same contour overlapped each other, we found 157 likely matches and 20 possible matches in *D. delphis*, and only ten likely and four possible matches in *L. acutus.* Even after normalizing for recording time, *D. delphis* produced approximately 10 times more matches than *L. acutus*. By using the SIGID method, we made conservative estimates of how many of these whistles were signature whistles. In *D. delphis,* there were 35 signature whistle matches involving 15 distinct signature whistles. In *L. acutus,* nine whistle matches were signature whistles, involving three signature whistle types. We also observed two instances of chorusing, defined as repeated and overlapping occurrences of the same contour, in *D. delphis*. These data provide some of the first insights into whistle production in two poorly studied delphinid species, and suggest that there may be key differences in their communication patterns. Concurrent behavioral observations are needed in order to understand how whistle matching and chorusing function in the natural communication systems of these two species.

"Fast and judicious": Foraging kinematics of South African Inshore Bryde's whales.

South African inshore Bryde's whales (*Balaenoptera edeni*) face increased pressure from reduced prey availability and fishing gear entanglements, yet their foraging behaviors remain unknown. Investigating foraging kinematics is fundamental for assessing foraging energetics and for adopting efficient conservation efforts. To understand how they pursue and catch prey, we deployed 3D movement and camera tags on five Bryde's whales in Plettenberg Bay, South Africa, in April 2018. We identified 145 feeding lunges and 65 aborted lunges. Feeding lunges were divided into three phases: *acceleration,* which lasted 15.2 s (range: 2.1–81.8 s), *engulfment* (4.2 s, range: 0.7–22.1 s), and *filtration* (50.6 s, range: 32.7–54.1 s). Mean peak lunge speed was 5.2 m s^{-1} (range: 3.7–7.9 m s^{-1}) and mean minimum speed during filtration 2.5 m s^{-1} (range: 1.65–5.89 m s^{-1}). Foraging lunges occurred at an average depth of 50 m (range: 3–100 m). Individuals foraged at distinct depth strata and often spent a considerable amount of time searching for prey, the mean inter-lunge interval lasting 9.25 min (range: 0–75.4 min). Whales showed a strong right-sided rolling preference during acceleration (72% of feeding lunges) and highly acrobatic manoeuvres, primarily when feeding in waters <25 m (mean degrees rolled during lunge: 109°; range: 38–375°). This is the first fine-scale description of Bryde's whales lunge-feeding kinematics, showing that they lunge faster than other balaenopterids and often interrupt lunges before opening the mouth. Our results suggest that Bryde's whales have high energetic costs associated with foraging due to the relatively high speeds and acrobatic manoeuvres detected. These high-speed manoeuvres performed in shallow waters may explain the high rate of entanglements in coastal fishing gear. This study represents the first step towards understanding the energetics of foraging in Bryde's whales and will provide critical information for effective conservation management.

Brucella ceti and cetacean morbillivirus co-infection in striped dolphin from the Adriatic Coast of Molise region (Italy)

Cetacean Morbillivirus (CeMV) and *Brucella ceti*, are two neurotropic concern of cetaceans. Both are often co-infected pathogens. We herein report *B. ceti* and CeMV co-infection in a striped dolphin (*Stenella coeruleoalba*) stranded on the Adriatic Coast of Molise region (Italy) in February 2019. Many organic tissues and body fluids for a range of laboratory investigations were collected during postmortem examination in this dolphin (preservation code 2). According to the technique described in the OIE Manual of Diagnostic Tests and Vaccines, *Brucella ceti* was isolated from uterine exudate, mammary gland, liver, spinal cord, medulla oblongata, bladder, spleen and finally from a lung warm. The strain was subjected to identification and characterization. A co-infection by *Cetacean Morbillivirus* was demonstrated from lung, spinal cord, bladder and spleen. The phylogenesis of the viral strain is underway. Histologically *B. ceti* and Cetacean Morbillivirus were associated with severe lesions of meningoencephalitis and ganglioneuritis. The two pathogens were also detected by immunohistochemistry and immunofluorescence. It is difficult to dissert the individual roles played by each pathogen on the development of the central nervous system (CNS) lesions affecting. Noteworthy we obtained direct evidence of *B. ceti* within individual lung worm, which most likely carried the pathogen to the lung parenchyma from which *B. ceti* could have started its subsequent colonization of the other body tissue district including the dolphin's central nervous system.

Assessing sperm whale (Physeter macrocephalus) occurrence, distribution and group size in Southern Tyrrhenian Sea through photo-identification.

The sperm whale (Physeter macrocephalus) is one of the common species of the Mediterranean Sea however few studies have documented the occurrence and group characteristics of sperm whale in Southern Tyrrhenian Sea. The current study used photo-identification data collected by dedicated boat surveys between March-November from 2013-2018 to investigate occurrence, distribution and group characteristics (group size, sex and age class) of sperm whale in the Aeolian Archipelago (Southern Italy). Totally 42 sperm whales were sighted on 20 sightings and 24 individuals were photo-identified by mark types on tail and other body regions. The sex and age class was determined for 20 individuals(47,6%): 9,5%(n=4) were calves, 26,2% (n=11) immatures (10 males and 1 female) and 11,9% (n=5) adults (only females). A sperm whale was resighted in one case, on March 2013 and twice in 2014 (June and September). The mean (± St. Dev) group size was 2,1 ±2,01 ranging from 1 to 8 with the larger groups sighted in 2013 (6 individuals) and 2016 (8 individuals). The occurrence was higher in summer(n=9) and similar in spring (n=6) and in autumn (n=5) ranging from March to November months. The sperm whale encounters were classified as: (1) solitary individuals (60%); (2) social units (10%); (3) bachelor groups (0%) and (4) clusters (30%). The spatial distribution of sperm whale groups in the study area was assessed in the different seasons. These results the Aeolian Archipelago located in Southern Tyrrhenian Sea is an important stepping stone and potential breeding ground for Mediterranean sperm whales. Further results will be needed to estimate sperm whale distribution, abundance and behaviour in this area. Long-term photo-identification efforts and comparison of photo-id data from other Mediterranean areas is also needed.

Characterization of cetacean morbillivirus from striped dolphins (Stenella coeruleoalba) stranded along the Italian Adriatic coast , 2017-2019.

Cetacean Morbillivirus (CeMV) is a RNA virus infecting marine mammals. Nowadays, CeMV is regarded as an emerging threat being the cause of recent epidemics worldwide. In 1990-92, a CeMV (dolphin morbillivirus-DMV strain) outbreak in the Mediterranean Sea involved thousands of striped dolphins (*Stenella coeruleoalba*) with high mortality. Another major epidemic event was the CeMV outbreak in 2006–08 affecting two cetacean species along the Mediterranean coast: the striped dolphin, and the long-finned pilot whale (*Globicephala melas*). In this work, we describe the identification and the genomic characterization of CeMV strains identified, during the Italian national monitoring activities, in cetaceans stranded along the Adriatic coastline of the Abruzzi, Molise and Apulia regions from 2017 to 2019. During this period, a total number of six carcasses of striped dolphins (preservation code from 2 to 3) were necropsied and samples from several tissues were collected. Nucleic acids were purified from all tissues and the presence of CeMV RNA was investigated by PCR-based assays targeting the P, H and N genes of CeMV. Nearly all tissues of all individuals tested positive for CeMV RNA and sequencing of amplicons revealed a nucleotide identity of 99.9-100% among the identified strains. Phylogenetic analysis performed on a portion of the N sequence showed that CeMV sequences obtained, cluster with DMV strains recently identified in Portugal and Galicia and separated from the Western Mediterranean and Canarian sequences, including the early CeMV isolates of 1990-92 and 2007-08 outbreaks. Isolation and NGS of the identified strains is currently underway. Overall, molecular characterization and phylogenetic analysis showed that CeMV (DMV) sequences detected in Abruzzi, Molise and Apulia regions in 2017-2019 clustered with those recently identified in Portugal, Galicia (Spain) and Italy representing a novel DMV strain of Atlantic origin which entered the Mediterranean Sea and affected a naïve striped dolphin population.

Yes, personality matters: Personality and social organization in wild bottlenose dolphins.
Díaz López, Bruno
Bottlenose Dolphin Research Institute BDRI, O Grove, Galicia, Spain
Corresponding Author: bruno@thebdri.com

Many social animals show clear preferences to associate with particular individuals to facilitate survival and fitness. Understanding the mechanisms that determine who associates with whom is a recent challenge for behavioural ecologists. Although animal personality has been demonstrated in multiple taxa, and affects many aspects of an individual's behaviour, life history and fitness, very little is known about the relationships between personality and social organization. Combining long-term behavioural data and social network analysis, this study describes personality differences between wild bottlenose dolphins and quantifies, for the first time in marine mammals, the influence of personality on social structure. Personality traits were assessed by repeatedly measuring the reaction of individuals of a social community to novel and threatening conditions as a trade-off between a risk-prone behaviour (boldness) and a risk-averse behaviour (shyness). Social structure was examined based on personality while controlling for age, sex, gregariousness, habitat use, and number of cumulative sightings using Multiple Regression Quadratic Assignment Procedures and Generalized Affiliation Indices. Findings of this study reveal a non-random mixing of individuals in a social network based on their personality traits. A relationship between tie strength, temporal stability, and network centrality and personality was observed, with bold individuals having a central role in the social network with denser and more stable associations than shy individuals. Results of this study also denote a homophily based on personality trait that may increase foraging efficiency through cooperative foraging and social learning. This study provides a novel insight on how a marine mammal can adapt via phenotypic plasticity to environmental changes and highlights the importance to advance the understanding of ecological, evolutionary, and conservation implications of animal personality.

Toxicological and management implications of toothed whales having higher exposure to contaminants than carnivore species
Dietz, Rune[1]; Sonne, Christian[1]; Rigét, Frank[1]; Vorkamp, Katrin[2]; Desforges, Jean-Pierre[1]; Eulaers, Igor[1]; Rosing-Asvid, Aqqalu; McKinney, Melissa[3]; Letcher, Robert[4]

Contaminant loads of persistent organic pollutants (POPs) and mercury (Hg) are known to be higher in Arctic toothed whales (e.g. killer whales (*Orcinus orca*), narwhals (*Monodon monoceros*), belugas (*Delphinapterus leucas*) and pilot whales (*Globicephalus melas*) compared to Arctic carnivores like polar bears (*Ursus maritimus*) and seals, e.g. ringed seals (*Pusa hispida*), harp seals (*Pagophilus groenlandicus*) and hooded seals (*Cystophora cristata*). These differences are linked to Carnivora species, including Ursidae and Pinnipedia, having higher capacity to metabolize or eliminate contaminants than cetacean species. An example from East Greenland shows that killer whales have median concentrations of ∑PCB, ∑OHC (organohalogenated compounds), ∑BFR (brominated flame retardants) and ∑DDT being 3.8, 22.6, 7.1 and 229 fold higher, respectively, than polar bears collected in the same area and period (2012-2014) despite evidence that polar bears were feeding at a higher trophic position. The differences in the adipose POP concentrations may be linked to the differences in the liver microsomal enzyme activity and hence the ability to metabolize and excrete POPs arising from the phylogenetic development of cetaceans from a herbivore ancestor. For Hg, cetaceans lack the ability to excrete this metal through hair as compared to Ursidae and Pinnipedia, which leaves them with a higher Hg burden. These differences suggest implications of larger potential toxicological threats to toothed whales species generally from POP and Hg exposure. Furthermore, the consumption of toothed whales in Greenland, the Faroe Island and Canada by indigenous communities results in a larger human contaminant exposure and associated toxicological threat relative to consuming other marine mammals. This problem is being excacerbated by an increase in hunted toothed whale species and numbers in Greenland in recent years. This information should be taken into consideration by local management authorities when issuing quotas on marine mammal species for the different hunting regions within the Arctic.

Movements of gray seal (Halichoerus grypus) pups in the New York Bight and Gulf of Maine

The occurrence of Gray seals (*Halichoerus grypus*) in the northwest Atlantic has increased considerably in number and range during the last two decades. To understand the post weaning movement of gray seal pups required a partnership between the Atlantic Marine Conservation Society, National Marine Fisheries Service, Northeast Fisheries Science center, Marine mammals of Maine and Cummings School of Veterinary Medicine at Tufts University. This program will deploy satellite tags over two seasons (January through February) and focus on the post weaning movements of gray seal (*Halichoerus grypus*) pups. During the first year of the project eleven animals were tagged between January 26th to 29th, 2019. The eleven gray seal pups represented by six males and five females were tagged. Four of the animals were tagged with SPLASH tags (Time Depth Recorders) and seven with SPOT 6 (Position and Temperature Tags) which collect haul out behavior location and temperature. Three haul out sites in southern New England and Gulf of Maine were selected, Muskeget Island MA, Great Point Nantucket MA, and Seal Island ME. One animal moved as far south as Delaware Bay over 260 nautical miles from its tagging site, while another moved east off Nova Scotia. This talk will outline the project goals and progress, partners and direction for the second year of sampling.

SouSA: A nation-wide collaboration to improve the conservation of South Africa's Indian Ocean humpback dolphins (Sousa plumbea).

The Indian Ocean humpback dolphin is South Africa's most endangered marine mammal (Plön et al., 2016). Main threats in the country include shark-nets, noise pollution, overfishing, boat interactions and coastal development. Further development of South Africa`s Ocean Economy will likely increase pressure on the species even further. In response to a lack of empirical data on the species population status and threats at a national level in South Africa, a nation-wide research collaboration, the SouSA Consortium, was established in 2016 between 18 partners from 15 different institutions. The aim of the consortium is to generate and share data on a large geographical scale that would not be achievable by individual research groups, with the aim of improving the conservation status of the species in South Africa. The first collaborative study investigated movement patterns of individual humpback dolphins between research areas using existing photographic data (2000-2016) and created a national identification catalogue (Vermeulen et al. 2017). Only 247 individuals were identified nationally, some of which moved substantially between study sites. Overall, data suggest a total population size likely under 500 split into two subpopulations. Further projects under the Consortium relate to spatial and temporal patterns in skin disease and scarring in the existing photographic databases and the development of nation-wide static acoustic monitoring to investigate animal presence and individual numbers and movements using signature whistles. The Consortium strongly believes that Indian Ocean humpback dolphins should be considered a flagship species of the Western Indian Ocean coastline (Plön et al., 2016). We encourage the use of the SouSA framework for the establishment of an African or a global Consortium, in which collaborative efforts can be made to better understand the global aspect of the species' conservation status and main threats.

In the trenches: Year-round acoustic presence of sperm whales (Physeter macrocephalus) and underwater sound levels in the Hellenic Trench, Greece.

The sperm whales (*Physeter macrocephalus*) in the Mediterranean Sea make a small, genetically isolated and endangered population. About 250 individuals are estimated to inhabit the Greek Seas, concentrated along the Hellenic Trench in the eastern Ionian Sea. In contrast to other places in the world, both social groups and mature males occur sympatrically in these waters. However, information on the seasonal presence of this species in the eastern Mediterranean Sea is sparse. Primarily because observations are limited to visual cetacean surveys that are typically not conducted between November and March. In a first attempt to collect year-round baseline information on sperm whale occurrence patterns in Greek waters, two Passive Aquatic Listeners (PAL) were deployed for 19 months, at Pylos Station (36.8 N, 21.6º E) in the Hellenic Trench, and at Athos Station (40.0 N, 24.7º E) in the North Aegean Trough. Results revealed the year-round presence of sperm whales at Pylos Station with a higher number of detections observed during late spring and throughout the summer. No sperm whale vocalizations were detected at Athos Station. An ambient sound level analysis revealed higher winter and lower summer levels at both sites largely driven by local weather conditions. Results showed that marine life in the Hellenic Trench area was exposed to relatively high low frequency (< 1 kHz) sound levels. Ambient sound levels below 1 kHz are typically dominated by anthropogenic sources such as commercial vessel traffic. Ship strikes and noise disturbance constitute major threats for the small Mediterranean sperm whale population. The results of this study are useful for sperm whale conservation efforts in the region, most importantly in the light of the Greek Government's plans to open up offshore areas for fossil fuel exploration and extraction.

Building a dictionary of humpback whale song units as a tool for assessing stock interactions

South America hosts two stocks of humpback whales (*Megaptera novaeangliae*), stock A occupying Southwest waters of the Atlantic, and stock G, located in the Southeast Pacific. After breeding in these locations in the austral winter and spring, both stocks travel in the austral summer to the feeding areas located in the Magellan Strait, Corcovado Gulf and Antarctic waters. As being physically accessible to one another, feeding areas are the only possible meeting point of two stocks.·Male humpback whales use complex vocal displays to communicate throughout the year. These are known as songs, subjected to constant evolution. Here, to assess changes in South American humpback whale song, we have analyzed units as its simplest elements Units were used to build the first ever unit dictionary of these stocks and compare their songs. Unit dictionary is a common method in studying bird song, while rarely used in humpback whales. To build the dictionaries, multiple years of songs from both stocks were recorded on their breeding grounds, feeding grounds and during migration, by various researchers. Using units as the basis highly enlarged the amount of useable data from this diverse dataset. Additional adventage of this methodology is its simplicity, while likely potent to help uncover stock dynamics and interactions. Comparing dictionaries of these two stocks revealed high level of difference in song complexity, specifically stock G song units appear much more diverse. Further, stability in the number of different units varied between stocks, as stock A had a more stable number of different units used over the seasons. These findings highlight the importance of feeding grounds for cultural exchange and stock interactions, possibly upholding the dynamics of humpback whale culture altogether. Used dataset is the outcome of the largest collaboration effort in humpback whale acoustics in South America to date.

Population genomics of the Atlantic spotted dolphins (Stenella frontalis) across the Atlantic Ocean.

The Atlantic spotted dolphin (*Stenella frontalis*) is endemic to the tropical and subtropical Atlantic Ocean. The most comprehensive analysis conducted so far based on the mtDNA control region marker identified different populations in the Eastern North Atlantic (ENA), Western North Atlantic, Gulf of Mexico, and Western South Atlantic (WSA). In order to better investigate the relationships between some of these populations, we used Double Digest restriction-site-associated DNA sequencing method to obtain genome-wide Single nucleotide polymorphisms (SNPs). We successfully genotyped 73 individuals representing the following geographical regions: ENA (Canary Islands, n= 7), Caribbean (Colombia, n=5; Guadeloupe Island, n=1), WSA (Brazil, n= 61; Uruguay, n=1). Three different datasets with different number of SNPs (ranging from 9,450 to 83,512 SNPs) were used to test the patterns of genetic differentiation and to evaluate specifically the genetic distinctiveness of WSA population. Our clustering results and population differentiation analyses suggests there are at least three regional groups (Southeastern Brazil, Colombian Caribbean, and an oceanic group). Our findings revealed that genetic similarity is primarily correlated with geography and, to a lesser extent, environmental conditions. Indeed, we detected a fine-scale population structure among Southeastern Brazilian individuals. This substructure is comprised of a group that inhabits the inner and midshelf (10 – 80 km from the coast) of the Southeast Brazilian Bight (SBB), and another group that occupies the outer shelf (80 – 120 from the coast). Dolphins of this latter group have a similar genetic makeup to individuals from geographically distant locations, including the Canary Islands and Colombian Caribbean individuals. Furthermore, individuals associated with inner and midshelf waters have a restricted geographic distribution that is suggestive of a demographically distinct population. These findings are meaningful and should be considered in management and conservation decisions, especially in the Southeastern Brazil, where anthropogenic pressure faced by marine organisms is increasing.

What if fishermen are doing their homework? Implications of communication gaps in cetacean bycatch knowledge. The case of longliners in Cape Verde.

Doblado Martin, Sonia; Parada, Juana; Rodríguez, Alexandre; Viðarsson, Jónas R.
Long Distance Advisory Council (LDAC), MADRID, Spain
Corresponding Author: sonia.doblado@ldac.eu

Bycatch is generally seen as one of the most important threats for marine mammals, so better data is needed to understand the impact it has on their populations. Collection of bycatch data has been a demand to fisheries operators from the scientific and environmental sectors, in order to further investigate the interactions between the fisheries industry and cetaceans. But what if the data needed is already being collected?

Here we analyse the case of ORPAGU, a Spanish long-line operator targeting for swordfish and blue shark in Cape Verde. ORPAGU has been voluntarily collecting data for accidental catches of non-targeted marine megafauna, including marine mammals, turtles and birds. They do register as well cetacean sightings from their vessels. An enormous amount of information that, once collected, doesn´t get used due to communication gaps between institutions. During our research on the governance structure for fisheries in the area, we found that, as no governmental institution (from Flag State, Coastal State or EU) includes on its protocol the requirement for this data to be submitted, it doesn´t get analysed or made publicly available for other institutions (i.e. scientific institutions) to use. This leads not only to data being underused, but to fishermen feeling their efforts have no recognition and making them less keen to participate in any future conservation study. This case illustrates the fact that existing communication gaps between sectors, along with governance, should be thoroughly studied and identified when analysing accessible bycatch information for a specific area.

As part of the H2020 project Farfish, we use data collected by ORPAGU to present research examples on how this data could be statistically analysed and what information could be obtained from it, including species encountered.

Assessing summer body condition of humpback and blue whales using an Unmanned Aerial System (UAS) in Skjálfandi Bay, Northern Iceland

Numerous and varied anthropogenic activities have the potential to disturb cetacean populations, mediated by behavioural and physiological responses. However, predicting the fitness consequences of such disturbance, requires

knowledge of baseline body condition and its variation within a population. Moreover, measuring fluctuations over time allows potential monitoring of the impact of stressors on animal health and fitness. Historically, tissue samples, beached cetacean carcasses, and active whaling have been used to study body condition as a proxy of whale health. Recently, more modern techniques like unmanned aerial system (UAS, *i.e.*, drones) are being to be used to assess body condition, representing an affordable and unobtrusive method. These studies have largely been conducted in breeding grounds where waters are clear. However, monitoring body condition in feeding grounds is essential to elucidate patterns in energy acquisition, which may in turn determine the impact of anthropogenic stressors. In this study, UAS imaging will be used to monitor body condition of humpback (*Megaptera novaeangliae*) and blue whales (*Balaenoptera musculus*) in Skjálfandi Bay, northern Iceland, an important summer feeding ground. A DJI Phantom 4 UAS will be deployed from a five-metre research vessel in order to capture aerial images of single animals. Measurements of length and widths at 5% increments followed by calculations of relative whale surface area (pixels^2) will be completed using R. Following this, absolute values will be calculated using the height of the UAS above the animal, determined with an inbuilt pressure sensor. Errors in UAS altitude, measurement accuracy and image clarity will be calculated using covariance and bootstrap resampling methods. This will allow assessment of the feasibility of this method to accurately measure body condition in cetaceans in a northern feeding ground. This method will be applied to real-time measurement of energy acquisition during the feeding season and its variation within a population.

How wrong and how useful? Using a fully censused population of killer whales to test the robustness of population models.

Population models are useful tools to estimate life-history parameters and abundance trends, to make predictions and to test management scenarios. However, the survey and demographic data informing these models are often characterized by considerable uncertainty (e.g., incomplete time series, abundance estimates with large errors) and therefore numerous assumptions must be made. For instance, it is frequently assumed that individual members of a population are identical and can be lumped together (e.g., surplus production models). Models including sex and age-structure are more realistic but the required individual-level information is not always available. Therefore, we examined what can be learned from data-rich situations to inform data-poor systems. The population of northern resident killer whales is censused every year in Canadian Pacific waters, and information is available on sex, age and reproductive status of nearly all individuals. We used this dataset to test the robustness of several models that use varying degrees of information on population structure. First, we compared the ability of these models to reproduce the known "truth" in terms of numbers, trends and composition. Second, we tested their sensitivity to artificially deteriorated data (increasing uncertainty of abundance estimates and increasing intervals between surveys). Finally, we investigated common assumptions of density dependence mechanisms, the ability of models to estimate carrying capacity and the inter-annual variability in vital rates. Our results show that even simple models can adequately reproduce the observed population trends of a natural system, but struggle to explain fine-scale variations and predict future trends. Vital rates are shown to be more variable than usually assumed for cetaceans and highlight the trade-off between precision and frequency when allocating survey efforts. Our results also confirm the difficulty for any model to simultaneously estimate carrying capacity, growth rates and the shape of density-dependence relationships.

First detection of microplastics in wild northern fur seals, Callorhinus ursinus, throughout their eastern Pacific range.

Microplastic pollution is increasingly reported in marine mammals and bioaccumulation may present

risks to animals feeding at higher trophic levels. Documentation of plastics in marine mammals often results from examination of stranded, sick, or captive animals that may not be representative of healthier, free-ranging individuals. Further, examination of animals routinely consumed by humans is lacking. We investigated microplastic pollution in wild northern fur seals (*Callorhinus ursinus*), a species subject to subsistence harvest in Alaska. We examined 44 feces from three sites encompassing the seal's eastern Pacific range: St. Paul and Bogoslof Islands, Alaska and San Miguel Island, California. Physical sieving of individual feces to 250µm was followed by wet peroxide oxidation to digest organics and density separation of remaining material using a 5M sodium chloride solution. The resulting suspended low density material was re-sieved, dried, and visually inspected at 40X magnification. Polymer composition of select microplastics recovered was determined using Fourier-transform infrared spectroscopy (FTIR). Extensive field and laboratory contamination control measures were implemented inclusive of procedural blanks, ambient air controls, and substrate samples, among others. A total of 398 microplastic fragments and 186 microplastic fibers were recovered from the 44 feces. Fifty-five percent of feces (24/44), but no controls, contained fragments (range 1 to 86 fragments/feces, mean 16.6, sd 19.1). Most (82%) fragments were <1mm in size. There was no difference in the probability of presence of fragments in feces by location ($p = 0.28$). Fragments tested using FTIR were low density polyethylene. While fibers were recovered in feces, they were also found in controls indicating likely contamination, highlighting the pervasiveness of synthetic fibers, and precluding conclusions regarding fiber origin. Fecal analysis documented the widespread presence of microplastic fragments in wild northern fur seals, a pinniped of cultural and conservation importance, throughout their eastern Pacific range.

Unexpected dietary shifts resulting from fishing intensification in marine mammals with gape-limited mouth.

Aquatic predators are usually gape-limited and cannot fully exploit prey populations when dominated by the larger size classes. In small-gape marine mammals, the morphology of their rostral region largely determines their feeding mode and the maximum size of their prey. However, fishing may increase the availability of resources for small-gape marine mammals by reducing the average size of prey, even if total fish biomass decreases.

Here, we analyse changes throughout time in the isotopic niche of three sympatric marine mammal species –Franciscana dolphin (*Pontoporia blainvillei*), South American fur seal (*Arctocephalus australis*) and South American sea lion (*Otaria flavescens*)– from the Río de la Plata estuary to test the hypothesis that fishing modify the diet of small-gape predators by reducing the average size of prey.

We found that the three species differ largely in mouth gape being the palate breadth of Franciscana dolphins intermediate between those of sea lions (the broadest palate breadth) and fur seals (the narrowest palate breadth). Furthermore, we observed that Franciscana dolphins have undergone a dramatic dietary change since the 1970s and currently forage at the same trophic level than sea lions despite major differences in mouth gape. Conversely, there has been little change in the isotopic niche of sea lions and fur seals. At the same time, fishing modified the size class distribution of some demersal fish species, which likely improved accessibility to Franciscana dolphins. Change in the trophic level of Franciscana dolphins has resulted in a major change of the topology of the three species in the isospace. In the 1950s, Franciscana dolphins and fur seals overlapped largely, but currently the three species have different isotopic niches.

In conclusion, the impact of fishing on marine mammals goes beyond the simple reduction in prey biomass and the response is species-specific and largely mediated by mouth gape.

Using RNA/DNA ratios and carbon/nitrogen stable isotopes to assess the nutritional condition and trophic ecology of two cetacean species in an oceanic habitat.

Environmental variability can have detrimental effects on individuals' physiology. In this study, the RNA/DNA ratios (RDs) were used for the first time to assess the nutritional condition of two abundant marine top predators, the common bottlenose dolphin *Tursiops truncatus* and the short-finned pilot whale *Globicephala macrorhynchus* in Madeira Island (Portugal). In addition, carbon ($\delta^{13}C$: $^{13}C/^{12}C$) and nitrogen ($\delta^{15}N$: $^{15}N/^{14}N$) stable isotopes (SI) were determined in order to obtain information on cetaceans' trophic ecology and habitat residency. To accomplish these aims, between 2017 and 2018, cetaceans' skin samples were collected from free-ranging animals along with muscle tissue samples from their potential prey. RDs showed that both species are in good nutritional condition, with higher values (ANOVA, $P<0.05$) being recorded in bottlenose dolphins. In fact, SI ratios differed between the cetacean species (PERMANOVA, $P<0.05$), with bottlenose dolphins presenting lower average (±SD) $\delta^{13}C$ (-18.6±0.4‰) and $\delta^{15}N$ values (10.2±0.7‰) than pilot whales ($\delta^{13}C$: -17.3±0.5‰; $\delta^{15}N$: 12.5±0.6‰). These, together with the stable isotope mixing model results (95%CI), suggest they assimilated different prey or different proportions of the same prey, and that bottlenose dolphins present a more diversified/opportunistic feeding behaviour. RDs and SI were similar between sexes, and only small differences were observed between seasons, which could be due to having sampled animals with different residency patterns in different seasons. Higher RDs (ANOVA, $P<0.05$) were recorded in visitor pilot whales, and visitor and transient whales presented higher ranges (PERMANOVA, $P>0.05$) in both $\delta^{13}C$ and $\delta^{15}N$ than resident whales, which suggests different feeding strategies or habitats in animals with distinct residency status. It is shown that the integration of nucleic acid derived indices and isotopic analysis provide a robust approach to infer the ecophysiology and food web dynamics of marine mammals.

Clinico-pathological findings in juvenile fur seals (Arctocephalus australis and A. tropicalis) stranded in São Paulo, Brazil, 2018: Preliminary results.

Four Otariidae species have been reported as occasional or frequent vagrants along the coast of Brazil. There is limited available information on health and disease aspects of stranded fur seals in Brazil yet admission of debilitated animals is common mainly during austral winter in southern regions. Increased stranding rates were recorded during the winter season in southeast Brazil (Iguape [IG], Ilha Comprida [IC] and Ilha do Cardoso-Sao Paulo state) during 2018 (n=23 *vs* n=2 in 2017). This study aimed at reporting the clinico-pathologic findings including antemortem laboratory diagnostic analyzes and most likely causes of stranding and/or death (CSD) in five juvenile South American fur seals (*Arctocephalus australis*) and one juvenile Subantartic fur seal (*A. tropicalis*) admitted for rehabilitation and/or stranded dead in IG and IC, in 2018. Four animals stranded alive and two stranded dead. All animals were male and all but one had poor body condition. The main hematological conditions on admission were: dehydration (n=3); normocytic normochromic anemia (n=2); leukocytosis with neutrophilia and lymphocytopenia (n=2); and hypoproteinemia (n=1). Gross and microscopic pathologic examinations revealed a variety of lesions, predominating hemodynamic disturbances, endoparasitism and inflammatory processes of suspected infectious nature. One animal was

serologically positive for *Leptospira interrogans*. One animal was PCR-positive for *Sarcocystis* sp. and two were PCR-positive for *Neospora* sp. All animals were negative for canine distemper virus, *Brucella* spp., and *Toxoplasma gondii* on serological and molecular analyses. The most likely CSD were: starvation (n=3); aspiration pneumonia (n=1); asphyxia (n=1); and presumed systemic infectious disease (n=1). These findings add to the current knowledge on these two species and may be valuable to first responders, clinicians and diagnosticians.

A celebration of 25 years of marine mammal research on the west coast of Scotland

Dudley, Becky[1]; Hartny-Mills, Lauren[2]; Lomax, Alison[2]

The Hebridean Whale and Dolphin Trust (HWDT) is a marine conservation charity that has been leading the way for the conservation of cetaceans on the west coast of Scotland through robust long-term monitoring programmes for the last 25 years. Through our community sightings network, HWDT has collated over 28,000 sightings records from 3,284 individual contributors. The launch of the Whale Track smartphone application and website in 2017 capitalised on technological advances in citizen science, providing a quick and convenient way for users to report sightings, doubling the rate of reports. Our research vessel, *Silurian*, has been monitoring cetaceans through dedicated visual and acoustic surveys using standard line transect methodology (Buckland at al., 2001), as well as photo-identification techniques, since 2003, generating one of the largest databases of its kind in UK waters. *Silurian* has travelled 112,707 kilometres, recording 33,514 animals during 14,337 sightings of 16 different species and collected over 6,000 hours of underwater recordings. Since January 2019, dedicated surveys have been conducted during the winter months, providing crucial year-round monitoring for the first time in our history. Our research has critically advanced the understanding of resident and migratory species in Hebridean seas, and has established the west coast of Scotland as one of the most important areas for harbour porpoise (*Phoceona phocoena*) in Europe (Embling et al., 2010; Booth et al., 2013). It has helped identify important areas contributing to the identification of Marine Protected Areas (MPAs) for harbour porpoises, minke whales and basking sharks and is being used to detect trends and changes in the marine environment, such as the increase in underwater noise pollution (Findlay et al. 2018) and monitoring emerging threats like entanglement. Long-term monitoring of this nature remains our priority, ensuring we can continue to provide the evidence needed to inform effective conservation measures.

Species distribution modelling of fin whales (Balaenoptera physalus) in the North Atlantic section of the Arctic Ocean

Duengen, Diandra[1]; Burkhardt, Elke[2]; El-Gabbas, Ahmed[1]

Understanding the dynamics of cetacean distribution in ecologically vulnerable regions is essential to interpret the impact of environmental changes on species ecology and ecosystem functioning. Species distribution models (SDMs) are helpful tools that link species occurrences to environmental variables in order to predict a species' potential distribution. Studies on baleen whale distribution in polar regions are comparably rare, mainly due to financial and logistic constraints. Here we use SDMs to predict habitat suitability for fin whales (*Balaenoptera physalus*) in Arctic waters.

A combination of opportunistic and systematically collected visual observations from 2007 to 2018 was used. Opportunistic data were collected during ten RV Polarstern cruises in the Arctic Ocean (including the Barents-, Norwegian and Greenland Sea). Complementary visual data were obtained from open source databases. Environmental variables were chosen based on ecological relevance to the species, comprising both static and dynamic variables. We used MaxEnt software to model the distribution of fin whales, using presence-only data as a function of carefully chosen environmental covariates. MaxEnt's predictive performance has been shown to be consistently competitive with the highest performing methods.

We were able to reveal important factors affecting the distribution of fin whales in the Arctic Ocean and how they respond to them. Results demonstrate the effective use of SDMs to predict species distributions in highly remote areas, constituting a cost-effective method for targeting future surveys and prioritizing the limited conservation resources. Results can be applied in a variety of purposes,

such as designing marine protected areas and support the further use of opportunistic data to understand the ecological drivers of species distribution.

Citizenry, science, and conservation: Power of the people.

Citizen science networks add to the knowledge of presence and distribution of many cetacean species. They can coordinate, compile and accurately log data over wide spaces and long time scales, adding significantly to the body of data on whale and dolphin species. This can add directly to, or complement, more formal scientific endeavors.

More recently we have seen the involvement of interested citizens to promote specific areas of research, conservation efforts of specific species, and create political pressure for greater protection. From what was originally engagement in research, the broader public now creates pressure points that directs research funding for better science and conservation programs.

We have engaged in several types of interactions with citizen groups, such as sighting networks, intern programmes, and public media. By drawing on those cases we present examples of the positive effects, as well as some of the pitfalls that may be encountered. We also examine how interested citizens have, through their purchasing and footfall, media messages and social 'trending', have created platforms for change. Public engagement encourages an interest of marine research to a wide audience, and plays an expanding role in research.

Underwater noise levels around the Port of Saint John

rose.fisher@oceansonics.com

The Bay of Fundy is an environment rich in its biological diversity and highly productive ecosystems. The area is a hot spot for several species of whales, dolphins, seals, porpoise and shorebirds. Shipping contribution to ambient noise levels have increased as much as 12 dB over the past decades. With increased shipping in the Bay of Fundy and resulting increased noise levels from vessel traffic it is important to monitor underwater noise especially in areas frequented by at-risk species such as the North Atlantic Right Whale (Eubalaena glacialis). Noise monitoring can provide a baseline sound profile and data on how an area changes acoustically over time. For these reasons, an underwater noise monitoring project was created to monitor noise levels in the Bay of Fundy, around the Port of Saint John. Port of Saint John is Canada's third busiest port (by tonnage) and the fourth busiest cruise destination. Industry is important to the area as many livelihoods rely on the traffic in and out of the bay and port. For this reason, the underwater soundscape was studied focusing on vessel traffic as it entered port. Acoustic data was collected by hydrophones at multiple sites deployed outside the harbour over three years (2015-2017) creating a long-term acoustic profile of the area. Ambient noise measurements of the areas were compared over time. Emphasis was placed on 1/3-octave bands 63 & 125 Hz, associated with shipping activity by the Marine Strategy Framework Directive. Results will be interpreted to provide information on the baseline ambient noise measurements and noise pollution levels around the port. Results include detected marine mammals and vessel noise measurements. Results provide data not only for researchers, but for regulators, as well as baseline noise measurements for future environmental assessments of the area.

Descriptive epidemiology and pathology of the 2018 leptospirosis epidemic in California sea lions (Zalophus californianus).

Leptospirosis, caused by *Leptospira interrogans* serovar Pomona, is endemic in free-ranging California sea lions (*Zalophus californianus;* CSL) with seasonal disease

outbreaks and periodic epidemics of high morbidity and mortality. Beginning July 2017, there was a marked increase in CSL admissions at The Marine Mammal Center with clinical signs of renal insufficiency including azotemia, hyperphosphatemia, hypokalemia, and hypernatremia. Based on standard age class criteria for this species, the greatest prevalence of infection was observed respectively among juveniles, followed by sub-adults, yearlings and then adults. The epidemic curve for juveniles peaked in August 2018 while that for sub-adults peaked in October 2018. Of 356 cases admitted July 2017 through December 2018, 92% were male and 56% were juvenile. Survival of juveniles was higher compared to other age classes (P<0.001). There was no effect of sex. Fewer yearlings and adults in the study precluded a determination of age-specific disease characteristics, so, an age class-specific pathology comparison was based on two age groups: (1) combined yearlings and juveniles and (2) combined sub-adults and adults. The first had significantly (X^2 8.225, p=0.0041) higher survival post admission than the second. At necropsy, lesions ranged in severity from nephritis with malnutrition and dehydration to an advanced uremic syndrome (nephritis, buccal and gastric ulceration, pulmonary edema, dermatitis and occasionally, cerebral edema). The full range of lesion severity was observed in young animals (group 1). However, for older CSLs, significantly more presented with the advanced uremic syndrome ($X^2$5.451, p= 0.0196). Further characterization of the immune response to infection is underway to investigate whether this could account for this disparity in pathologic presentation.

Satellite-linked telemetry study of a rehabilitated and released Atlantic spotted dolphin in The Bahamas provides insights into broader ranging patterns and conservation needs

Despite dedicated longitudinal studies, lack of information on ranging patterns of "resident" dolphins can limit our ability to apply conservation directives at the appropriate scale. Here, we present satellite-linked-telemetry data on movements over 108 days (1,067 Argos locations) for an adult male Atlantic spotted dolphin (*Stenella frontalis*) in The Bahamas. On August 26th, 2018, this dolphin live-stranded in the Berry Islands, approximately 110 km east of Bimini, where photo-identification studies began in 1997. This individual (called "Lamda") was known to researchers in the Bimini area since 2013 where he was seen nine days prior to stranding. Lamda was transported to Dolphin Cay at Atlantis in Nassau on August 30th where he was diagnosed with pneumonia, gastric ulceration, gastritis, myopathy and dehydration and treated with vitamins, antibiotics and swimming physiotherapy. On October 29th Lamda was airlifted to the Bimini area, instrumented with a SPOT6 Finmount location-only satellite-linked tag and released. He moved south rapidly, covering 410 km in 48 hours, ending up near Cuba, well beyond what was previously considered his normal range. Lamda stayed in this southern area (3,572 km^2) for 13 days but there were no opportunities to document behaviors or potential associations with other dolphins. Over the next 16 days, Lamda returned to Bimini, and on January 7th, 2019, was observed in a group with other known Atlantic spotted dolphins. He remained in the Bimini area (1,203 km^2) until his tag stopped transmitting on February 14th. Assuming Lamda's movements are representative of ranging patterns by non-rehabilitated dolphins, these data provide insights that have important implications for conservation of this species. Notably, the majority of Lamda's locations were in the Bimini area where there is pressure from increasing tourism, and his locations in the southern area overlap with existing petroleum licenses where test drilling is scheduled in 2019.

Occurrence and photo identification of harbour porpoises in North Pembrokeshire, Wales.

Photo-ID methods have been used to study cetacean populations since the late 1970's. Despite its success in other species, photo-ID is not commonly used to study harbour porpoises. This is most likely due to the challenges of photographing small, typically boat shy cetaceans who exhibit subtle surfacing behaviours and their lack of

obvious unique markings. Harbour porpoise populations are often studied at larger-scales, studies on smaller scales are often in relation to specific variables such as areas of high tidal energy. The species is seldom studied at individual or local levels. This has resulted in loose estimates of population size and dynamics and a lack of species protection in regards to the designation of Special Areas of Conservation.

Recently harbour porpoise photo-ID studies have developed and have large potential for success. The Pembrokeshire coast is an area of high harbour porpoise sightings. This high abundance and activity has allowed for the photography of individuals from land-based vantage points. This study photographs individual animals from four sites around North Pembrokeshire. Photos have been collated and organised into an identification catalogue. The catalogue currently contains 101 individually marked porpoises. New individuals per month range from 0-9, with on average 2.8 individuals identified each month. Sightings of individuals range from 1-18, with an average of 2.1 sightings per individual. 30% of individuals have been sighted on more than one occasion suggesting patterns of site fidelity or residency.

This study describes the early process and the preliminary results of an on-going photo-ID study on harbour porpoises. Already the study highlights the complexity of local occurrence and movement, something not identified with larger scale studies and has shown the potential that photo-ID studies can have when contributing to the overall conservation of the species, emphasising the need to continue this form of study.

A quantitative approach for analyzing surface interval behaviors of baleen whales in drone video

Foraging in baleen whales is energetically intensive and requires a surface interval resting period between each foraging dive. Whales take advantage of such events to replenish oxygen stores and conserve energy. Here we provide a methodological approach for annotating unoccupied aircraft system (UAS)-based aerial imagery to encode and analyze exhibited surface behaviors. Using a Freefly ALTA 6 UAS, video data were collected synoptically with photogrammetric still imagery in Monterey Bay, California during August 2017. During these flights, foraging and surface interval events of blue whales (Balaenoptera musculus) were recorded along the perimeter of the Monterey Bay Submarine Canyon system. This initial study evaluates a subset of 5 flights containing behavior of 6 blue whales, having a mean surface interval of 1 minute and 14 seconds. Using the Behavioral Observation Research Interactive Software (BORIS) suite, we developed an ethogram and encoded surface interval behaviors for each individual exhibiting a solo swim event. Six primary behaviors were identified and designated as either a point- or state-event to address questions related to event frequency and duration. We then employed a discrete-time Markov model, using the coded behaviors, to identity conditional probabilities of each behavior's occurrence, conditioned on prior behaviors. We find that exhalation events remain 100% probable after primary surfacing events, and shallow dive and deep dive events also occur with high probabilities (60%-70%) after propulsion activities, such as fluking and pectoral strokes. In summary, this study demonstrates a quantitative approach to identifying parameters governing blue whale surface behavior, an approach that can be extended to other marine mammals. We find that BORIS is an effective tool for generating species-specific ethograms when used alongside embedded imagery to encode and analyze observed surface behaviors in UAS video data.

Population recovery of Arctocephalus philippii in the Juan Fernández Archipelago, southeastern Pacific.

The Juan Fernández fur seal inhabits the Juan Fernández Archipelago (33º43'S; 79º52'W) and the

Desventuradas Islands (26º19'S; 80º00'W). Due to intense hunting during the 19th century by British and American sealers the population was nearly lead to extinction. In 1964 a few fur seals were registered by local fishermen, while Aguayo & Maturana (1969) censused 170-192 in Robinson Crusoe Island and 300 individuals were counted in 1975 in San Ambrosio Island (Desventuradas). In 2015, UICN moved the species from the category of 'Near Threatened' to 'Least Concern'. The colonies are located within the Archipielago de Juan Fernández National Park. In this context the Corporación Nacional Forestal (CONAF) has implemented a monitoring program for the species in the park since 2001. The surveys were performed during the austral summer using small boats to get to the colonies. The estimated population abundance was about 30,000 individuals in 2001, with sustained growth reaching 50,000 in 2007; 134,000 in 2012 and 220,000 in 2018. In the 2018 survey 24 colonies (19 rookeries) were registered in Robinson Crusoe Island and 7 (6 rookeries) in Santa Clara Island. 25% of the population were pups In Robinson Crusoe and 10% in Santa Clara. The population of Juan Fernández fur seals is recovering rapidly and the species is listed as Least Concern by UICN. Nevertheless, little is known about the population status in the Desventuradas Islands, therefore a survey of these islands is urgently needed. It is important to highlight that the Juan Fernández fur seal, *Arctocephalus philippii* is the most abundant sea lion population in the southeastern Pacific.

We thank the financial support of CONAF and CIGREN.

Accounting for localization errors in models of behavioural responses of minke whales to sonar activity during Navy training

Sound is an important sensory input for many marine mammals, and the introduction of anthropogenic noise into the marine environment may affect the behaviour of these animals. We assessed behavioural responses of minke whales to mid-frequency active sonar by comparing whale tracks during periods of Navy training with tracks during baseline periods. In particular, we have assessed how measurement errors in the localization process can affect these inferences.

Whale tracks are derived from passive acoustic monitoring on the Pacific Missile Range Facility, Kauai, Hawaii. Localizations obtained from acoustic detections are subject to measurement error that increases with distance from the hydrophone array. These errors are estimated by time-of-arrival information and knowledge of hydrophone geometry. We assessed the influence that localization errors have on behavioural inferences by comparing three models that account for error in different ways. First, we fitted a hidden Markov model to tracks that have been smoothed to remove measurement error, a process widely used in telemetry analyses. Second, we fitted a two-stage model that uses a continuous-time movement model to simulate tracks that are regular in time and compatible with the established range of localization error; each of these is then passed to a hidden Markov model for subsequent analysis, with inferences combined over tracks. Finally, we fitted a recently proposed multistate formulation of the continuous-time correlated random walk that allows the two stages above to be combined.

Results indicate that, while outputs from the three approaches differ, there is evidence of faster, more directed movement during sonar exposures than in the baseline period. Smoothing over localization errors tends to artificially inflate the significance of results, while larger localization errors can pose a problem for two-stage approaches. Correctly estimating and accounting for localization error in subsequent analysis of tracks is key to drawing justifiable inferences about behavioural responses.

Characterizing the seasonal and geographic distribution of North Atlantic right whales (Eubalaena glacialis) using an expansive spatial network of passive acoustic moorings

Seasonal distribution of North Atlantic right whales (NARW) north of 45°N latitude is mostly unknown due to a lack of systematic monitoring along most of the eastern Canadian continental shelf. In 2017, an unprecedented NARW mortality event occurred in the Gulf of St. Lawrence (GSL, ~48°N) involving 12 documented deaths, several of which were due to ship strikes and fishing gear entanglements. The GSL was a previously unidentified habitat for the whales, and this event demonstrates the importance of identifying the contemporary spatio-temporal extent of this species' distribution. The objectives of this study are to 1) describe seasonal distribution patterns of NARW in Canadian waters; 2) identify areas of NARW presence outside of monitored aggregation areas, and 3) demonstrate the advantages of using passive acoustic monitoring (PAM) technologies to provide information on the presence of NARWs. To achieve this, we analyzed PAM data collected by 73 moorings and 14 gliders (~20,800 recording days) deployed across the Atlantic Canadian continental Shelf between 42°N and 58°N during 2015 through 2017. Daily NARW acoustic presence was assessed using manual validation of auto-detected upcalls with a low frequency whale detection and classification system. Generalized linear models will be used to analyze seasonal and regional variation of NARW acoustic presence. Results from the first 34 analyzed deployments demonstrate the dynamic and widely varying geographic presence of NARWs. The period that NARW were present in Canadian waters generally decreased from south to north. For example, NARWs are present on the Scotian Shelf (45°N) nearly year-round (95th percentiles on daily presence occur between 01-Jan and 05-Dec), whereas NARW were present in the Cabot Strait (ca. 50°N) for eight months, from May through December. This assessment of range-scale variability in NARW vocal presence demonstrates the potential of PAM to facilitate efficient monitoring and sustainable management of the species.

Combining near-field acoustic records and genetic identity of an individual eastern North Pacific blue whale off the central Oregon coast.

Populations of blue whales worldwide have been described from acoustic calls and genetic markers. Although these data sources have been used independently to assign individual whales to a population, a direct link between call signal structure and genetic identity remains undescribed. The question remains, what is the concordance of acoustic call types with genetically identified populations, given call variability? Here we present acoustic records and a genetic profile of a blue whale sampled ~27 miles offshore of Oregon. One of two sighted whales was biopsied, while their vocalizations were recorded using a drifting hydrophone. An assignment test using a DNA profile consisting of mtDNA haplotype, sex, and up to 15 microsatellite loci identified the whale as male and confirmed an eastern North Pacific (ENP) origin through comparison to reference databases. A spar buoy with a suspended hydrophone (High-Tech Inc.) was deployed ~50 m from the whales, producing a 68.7-min record containing 28 “B” and 6 “A” calls with prototypical ENP blue whale call structure. Maximum call received levels were ~110 dB re µPa2-Hz-1 at ~90 Hz. Assuming 187 dB as a call source level, this received level implies a signal loss of ~77 dB, and thus a ~7 km range from the hydrophone to the vocal whale. GPS tracking shows the boat remained in an elliptical area (r~10 km) while circling the pair, consistent with the sampled whale as the call source. Although it is not possible to confirm the identity of the calling whale, our results are consistent with previous studies showing the ability to link acoustic call types and the whale’s sex, while offering the potential to assign an individual to a population. We plan to link acoustic information and genetic identity from a larger dataset of blue whales from southern California to better understand their population structure.

Sex, age, and hormone correlates of phthalate exposure among common bottlenose dolphins (tursiops truncatus) from Sarasota Bay, FL

Phthalates are a class of manmade chemicals added to personal care products, cleaning products, cosmetics, and plastics to enhance properties such as lubrication, flexibility, and fragrance. Phthalates are of increasing concern to human and environmental health because of their ubiquitous use and potential for endocrine disruption. Phthalates are easily metabolized and excreted in urine, thus monitoring for urinary phthalate metabolites using liquid chromatography/tandem mass spectroscopy is indicative of exposure to parent compounds. Recently, a pilot study reported phthalate exposure in 71% of bottlenose dolphins sampled in Sarasota Bay, FL (N=17; 2016-2017), suggesting prevalent environmental exposure. The most frequently detected metabolites (monoethyl phthalate, MEP; mono-2-ethylhexyl phthalate, MEHP) were from parent compounds added to personal care products and plastic, with concentrations sometimes exceeding reported levels for humans (geometric means: total phthalates = 2.9 ng/mL; MEP = 5.4 ng/mL; MEHP = 1.0 ng/mL). In humans, phthalate exposure can vary by age and sex; however, variation relative to demography is currently undetermined for bottlenose dolphins. Similarly, endocrinological impacts are unknown. To address these knowledge gaps, comparisons of phthalate metabolite concentrations between age classes (i.e., juvenile vs. adult) and sexes will be performed (Mann Whitney U test, α=0.05) using urine collected from bottlenose dolphins sampled during additional years of Sarasota health assessments (2011-2019). Additionally, associations between serum hormone concentrations (e.g., thyroid, testosterone, estradiol) and urinary phthalate metabolites will be evaluated using correlation tests (α=0.05). To our knowledge, this is the first study to explore these relationships in free-ranging cetaceans. Additionally, this work provides potentially critical context for preliminary findings of phthalate exposure in Sarasota Bay dolphins by examining demographic differences in exposure and relationships with established biomarkers of dolphin health.

First report on Antarctophthirus microchir (Anoplura: Echinophthiriidae) from free-ranging "urban" South American sea lions (Otaria flavescens) by using a novel non-invasive method.

Ebmer, David
Institute of Parasitology, Justus Liebig University Giessen, Vienna, Vienna, Austria
Corresponding Author: david.ebmer@gmx.at

Consisting of five different genera, the family Echinophthiriidae belongs to the phthirapteran suborder Anoplura, the sucking lice, and exclusively parasitize mammals with a semiaquatic lifestyle, such as pinnipeds and the North American river otter. Findings of *Antarctophthirus microchir* were reported from all six species of the subfamily Otariinae, the sea lions, showing a wide geographical distribution in both hemispheres. Between March and May 2018, an "urban" bachelor group of South American sea lions (*Otaria flavescens*) living in a freshwater biotope of the southern city Valdivia, Chile, was examined for their ectoparasite fauna applying a novel non-invasive method for parasitological research in marine mammals. Therefore, a lice comb, screwed on a telescopic rod and fixed with Tesa® tape, was used for epidermal sample collection (fur coat hair, lice, nits and skin tissue samples) from living animals. During sample-taking process, *A. microchir* was detected in 4/5 individuals. Interestingly these specimen were exclusively found at the junction between the back and hind flippers. The current findings constitute the first report of *A. microchir* infestation in this unique synanthropic colony of South American sea lions. Findings on different life stages proved the complete life cycle of *A. microchir* to occur on this bachelor group, despite inhabiting a freshwater habitat and in absence of females or pups. The non-invasive "telescopic lice comb" opens new possibilities to collect epidermal samples, such as fur coat hair, lice, nits and skin tissue, for a wide spectrum of research without troubling the animals.

Monitoring small cetaceans using passive acoustics to inform cross-border conservation efforts

The waters of the cross-border region between Scotland, Northern Ireland and the Republic of Ireland host internationally important populations of marine mammals. In this region, noisy or

physically disturbing human activities may pose a threat to these species. Because the impacts of these activities are not delineated by national boundaries, two European Union (EU) funded projects in this region are utilising a network of buoys to monitor and inform the conservation of protected areas and species.

Cetaceans are explicitly protected throughout European waters, and furthermore EU Member States are required to designate Special Areas of Conservation (SAC) for particular species. In addition to Northern Ireland's Skerries and Causeway SAC, Scotland recently designated the Inner Hebrides and Minches SAC, one of Europe's largest marine protected areas (MPA), for the conservation of harbour porpoises. Scotland is also working on proposals for the creation of MPAs for other cetaceans.

These protected sites will require monitoring plans, so two complementary projects, COMPASS and MarPAMM (funded through EU INTERREG VA programme), are using moored passive acoustic recorders to provide a low cost, long duration monitoring option for echolocating cetaceans such as dolphin and porpoise species. Passive acoustic monitoring using echolocation click detectors (Chelonia C-PODs) can collect data continuously for several months, to allow exploration of temporal trends which visual surveys cannot provide.

Here, the initial results from the COMPASS project will be presented and discussed, plus the opportunities of additional data from MarPAMM. We highlight general differences in occurrence between monitoring locations and some initial habitat preference modelling. We introduce the seasonal patterns in occurrence of both harbour porpoise and dolphin species, with two of the monitoring locations demonstrating some particularly high rates of porpoise occurrence, and discuss how these data might be used to inform the conservation of species in this region.

The plastic cetaceans – strandings linked to plastic ingestion around the world.

Eisfeld-Pierantonio, Sonja[1]; Pierantonio, Nino[2]; Simmonds, Mark Peter[3]

The accumulation of plastic in the marine environment is a major threat to marine biodiversity. Species are directly impacted through ingestion or entanglement causing injury or death and associated toxicological effects cannot be excluded. Although a drastic rise in the number of reported events during the last decades has been noted for cetaceans, a clear understanding of which debris are important and the extent of impacts remain elusive, due partly to the lack of standardised procedures. Building upon recommendations from international fora, we present a review of available information detailing the ingestion of debris by cetaceans on a global scale. Evidence clearly suggests plastic bags, sheeting, food wrappers, portions of plastic bottles, disposable plates, cups, and miscellaneous broken pieces of polystyrene and other single use items are the most frequently observed marine debris found in stranded cetaceans. Portions of nettings, fishing gear, floats, monofilament lines and hooks are the most commonly found fishery-related items. The ingestion of plastic debris often seems to be a contributing factor in mortalities, although an increasing number of cases exist where large amounts of plastic within the stomach were identified as the cause of death. Identifying the type and origins of marine debris is challenging, but key to understanding the nature of the interactions between cetaceans and marine debris. In this context, this work highlights the crucial role of post-mortem examination in understanding the nature and effects of plastic ingestion on cetaceans and emphasises the necessity of adoption of standardised procedures during necropsies. Given the complex nature of marine plastic pollution, we also recognise that management policies must be inclusive of all stakeholders to match the scale and severity of the issue. Our work therefore will contribute useful information to a multidisciplinary effort to reduce the severity of plastic ingestion on cetaceans.

Modelling habitat suitability of whales in the Southern Ocean

Detailed information on cetacean distribution is crucial to identify large-scale conservation actions and management decisions. Understanding the

ecological drivers behind their spatial patterns in the Southern Ocean is complicated by whales' mobility and the logistic restrictions in collecting data in polar environments. Species distribution models have become essential tools in ecology and conservation. They relate information on species occurrence with environmental predictors thought to influence its habitat use, to predict its potential distribution and explain environmental drivers of the observed patterns.

In this study, we compiled opportunistic presence-only data for seven whale species in the Southern Ocean from multiple sources. A quality-controlled data set was then used to model species distributions using Maxent software (under the point process modelling framework). Environmental predictors were prepared from multiple *in-situ* and remotely-sensed sources, based on our experience of the study area and species ecology. We estimated the best combinations of Maxent's parameters & evaluated model performance on a species-specific spatial block cross-validation to maintain spatial independence between training and testing data. For each species, block size and their spatial allocation into cross-validation folds was objectively determined according to how much spatial-autocorrelation exists at occurrences.

For each of species, we 1) predicted circumpolar potential distribution, 2) determined the most important variables, and 3) showed the relationship between habitat suitability and environmental variables. We believe that our results would be of great importance to explain the habitat preference of species in the Southern Ocean, for the first time for the majority of studied species. However, we argue that these models can only represent a hypothetical, mean state (which actually never becomes manifest) of the potential distribution of the species in space, and hence another set of dynamic models are required to consider the high dynamic environment in the Southern Ocean and the migratory nature of whales.

Occurrence of cetaceans in the Dardanelles Strait, Turkey in 2018

The Dardanelles Strait, which is a part of the Turkish straits system connecting the Mediterranean and Black Sea basins, serves as an important transitional zone for marine life. Three odontocete species are known to occur in the area: bottlenose dolphin (*Tursiops truncatus*), common dolphin (*Delphinus delphis*) and harbour porpoise (*Phocoena phocoena*). Visual and acoustic surveys aimed at monitoring the cetacean presence in the area were conducted between March and November of 2018 from pile driving platform located near the eastern end of the strait at approximately 10 km distance from the Marmara Sea. Observations took place on 117 days resulting in a total of 308 hours and 28 minutes of visual observations and 176 hours and 40 minutes of acoustic monitoring. A total of 52 sightings of cetaceans were recorded, 43 of which were visual, and 9 were acoustic. Of the visual sightings, the individuals in 27 sightings were identified as bottlenose dolphins (*Tursiops truncatus*) and the rest of the visual sightings were unidentified delphinid species. Across the study period the highest encounter rates were recorded during the months of June and July (0.18 and 0.11 per hour, respectively). Average group size was highest in April with 11 individuals per group. It was possible to identify the behaviour of the animals for 40 of the sightings, 28 of which were feeding events, while the during the rest of the sightings the animals were observed travelling. The information gained from this study shows that the animals utilise the Dardanelles strait mainly for feeding on fish that migrate seasonally between the Aegean and Marmara seas. Further studies are needed to better understand the cetacean populations in the area in order to identify the main threats and implement necessary conservation measures.

Harbor porpoises (Phocoena phocoena vomerina) catching and handling large fish on the U.S. West Coast.

The harbor porpoise is a cryptic species, and information on their behavior is limited. This study describes the chase and capture of large fish by harbor porpoises (*Phocoena phocoena vomerina*) in the Salish Sea off Fidalgo Island, Washington (salmonid species, 2017/2019) and San Francisco Bay, California (American Shad, *Alosa sapidissima*, 2016/2017). For all capture events similar behavior was observed; the porpoise accelerated after the fish, swimming in a circle at

the same spot, diving and coming out of the water head first carrying the fish cross-wise in its mouth. While the catch of the large prey was visible just below the surface, it remains unknown whether the porpoise eventually consumed the fish. We also document a harbor porpoise that drowned in drift net gear that had fed on salmonid species in Cook Inlet, Alaska (2014). The female harbor porpoise had a large amount of salmon (likely Pink salmon, *Oncorhynchus gorbuscha*) in her stomach and sticking out of her mouth. Salmonid species and American Shad have not been documented as prey items for harbor porpoises along the U.S. West Coast and Salish Sea, despite diet studies that have spanned over 30 years. These species are, on average, larger than typical prey species known to be consumed by harbor porpoises. The morphology of the upper respiratory tract in odontocetes may make them more vulnerable to an esophageal obstruction by large prey items that can lead to asphyxiation, and indeed cases of harbor porpoises dying from asphyxiation have been documented. As harbor porpoises have a very high metabolism, the high nutritional pay off may be worth the possible risk of catching a larger prey item. Little is understood about wild harbor porpoise behavior and reports such as this helps to better understand their behavioral repertoire and ecological relationships.

Physiological and behavioural responses of wild harbour porpoises to a commercial seal scarer

Increasing noise levels from human activities at sea have diverse effects on marine mammals, varying from masking of signals to stranding of animals. Still, it is less known if noise induces physiological responses. Acoustic deterrence devices, such as seal scarers (SS), are increasingly used to deter animals from fishing gear, and to displace animals away from pile driving operations to avoid hearing damage. Even so, little is known about the extent of behavioural disruption and physiological stress they may cause. Here, we investigate the fine-scale physiological and behavioural responses of harbour porpoises exposed to a commercial SS (Lofitech, Norway) in inner Danish waters. Harbour porpoises bycaught in pound nets were tagged with suction cup-attached DTAGs recording electrocardiogram, sound, and movement (GPS, depth, 3D-accelerometry, 3D-magnetometry). 15 minutes after release, animals were exposed for 15 minutes with received levels of 110-138 dB re 1µPa RMS, resembling levels at distances up to 9 km at sea, assuming spherical spreading. They responded strongly to the SS by increasing fluking rate and speed, swimming either near the surface or bottom. Concomitant heart rate measurements showed an increased from 60 to 160 beats min-1 while the porpoise was breath-holding, presumably due to the increased exercise of the avoidance response. One porpoise immediately reduced biosonar click output levels by 10 dB during exposure, greatly reducing the detection range of obstacles such as fishing gear. We thus demonstrate that sound exposure can directly or indirectly evoke significant physiological responses in cetaceans, which may profoundly impact blood gas management and breath-hold capability. We conclude that harbour porpoises react strongly well beyond 1 km from the SS, where risk of pile driving induced hearing damage is very small. Future use of lower SS source levels will therefore achieve the desired deterrence of porpoises while reducing risk of undue negative effects.

Under pressure – Surviving 10 years of human impacts on the smallest population of dolphins in Southern Africa – Namibia's common bottlenose dolphins

Elwen, Simon[1]; James, Bridget[2]; Gridley, Tess[3]
(1) University of Pretoria, South Africa, Hatfield, South Africa

Corresponding Author: simon.elwen@gmail.com

Namibia is home to a small, isolated population of bottlenose dolphins, subject to a range of threats including mariculture, boat-based tourism and harbour construction. We summarise findings of a decade of research by the "Namibian Dolphin Project" in Walvis Bay, a key habitat within the dolphin's range. We apply a multi-disciplinary and cost-effective approach including land and vessel-based surveys, photographic mark-recapture, focal behavioural follows, long term static acoustic monitoring and strandings response. The population numbers around 82 individuals based on photographic mark-recapture estimates (2008-2012), with no clear population trend (Elwen et al. 2019). Strong social subdivisions are apparent, with groups exhibiting differential habitat use. SOCPROG network analysis indicates a small semi-resident group dominated by young males and

a larger group dominated by breeding females, the latter observed more regularly during prey-rich winter seasons (Indurkhya, 2012, Pouplard 2015). Within Walvis Bay, clearly differentiated feeding and resting areas (Jylhä-Vuorio 2017) have remained stable but area use within the bay has constricted concurrent with increasing anthropogenic impacts. Foraging during low-productivity summers often occurred around oyster farms, suggesting an 'artificial reef' effect. The acoustic repertoire is divided into 7 broad sound types (Gridley et al., 2015) with repertoire richness strongly related to behavioural activity, group size and dispersion (Badenas 2015). Whistle frequency and duration reflect emotional arousal and a response to tour boat presence (Heiler et al. 2016). A catalogue exceeding 50 stereotyped signature whistle types has been identified though the SIGID bout analysis approach (Janik et al., 2013). From this, acoustic mark-recapture has been tested to understand individual movement. Development of spatial capture-recapture (SCR) using acoustic labels is underway. The population has shown remarkable resilience during a decade of increasing impacts. However,r the small size and behavioural adaptions shown indicate its longevity remains on a conservation knife edge.

Eavesdropping on Northern Resident killer whales: Passive acoustic monitoring reveals overlap with endangered Southern Resident killer whales in proposed critical habitat.

Resident killer whales are primarily known from their predictable occurrence in the inland waters of Washington and British Columbia, but little is known about their occurrence in coastal waters. As a part of an effort to examine year round movements and identify critical habitat for endangered Southern resident killer whales, autonomous passive acoustic recorders were deployed at fifteen sites spanning the Washington coast from 2015 to 2017. While the primary focus was to monitor endangered Southern resident killer whales, both northern (NRKW) and southern resident killer whales (SRKW) were detected throughout the year. SRKW were detected on 213 days at ten locations, whereas NRKW were detected on 135 days at seven locations during the same period. NRKW were detected in every month of the year, while SRKW were not detected during the month of August. Occurrence peaked from March to May for both populations, with a smaller peak in late summer/early fall. 90.4% of NRKW detections were at the northernmost sites, while only 21% of SRKW detections were at these sites. SRKW were most frequently detected at nearshore sites (84% of all detections), while the majority of NRKW detections were at mid-shelf and deep sites (96% of all detections). A suite of measures of sound production was further analyzed to investigate differences in acoustic behavior between the two populations, and no significant differences were found. Previous studies have indicated that Chinook salmon is the preferred prey of both NRKW and SRKW, and the temporal overlap of both populations may indicate that they are targeting the same salmon runs returning to their natal rivers. As the southernmost resident killer population, SRKW have the narrowest selection of Chinook salmon available to them. It is important to understand the role that competition may play in limiting the recovery of SRKW.

Diving behavior and movements of a Sowerby's beaked whale tagged near Norfolk Canyon

Engelhaupt, Dan[1]; Engelhaupt, Amy[2]; Aschettino, Jessica[1]; Bell, Joel[3]

The Virginia Capes (VACAPES) Operating Area offshore of North Carolina, Virginia, and Maryland plays a vital role in the U.S. Navy's training and testing operations given its complex bathymetry and proximity to the world's largest navy base, Naval Station Norfolk (NSN). Advancements in satellite-monitored tagging technology allow scientists to improve their understanding of marine species including cryptic beaked whales that occur in these waters. In September 2018 during a multi-year U.S. Navy-funded survey to provide a more detailed assessment of species occurrence, diversity, and habitat use near the continental shelf break and Norfolk Canyon, a group of three Sowerby's beaked whales (*Mesoplodon bidens*) was sighted 125 km from shore in 1,219 m of water. During the encounter a Wildlife Computers SPLASH10 dive/location LIMPET-configured tag designed to collect medium-scale movements and

dive behavior was deployed on an adult Sowerby's beaked whale. This was the first 'dart' tag deployed to date on this species across all oceans. Over the course of the 14-day tag duration, the individual travelled primarily over deeper (>1000m) waters east of the outer continental shelf break to the north approximately 135 km from the original tagging location near Norfolk Canyon. A total of 123 dives were recorded with 52 considered foraging deep dives (mean dive depth = 738 m) and 71 classed as non-foraging shallow to mid-water 'bounce' dives (mean dive depth = 220 m) based on strong similarities in diving patterns to other species of beaked whales. Mean foraging dive duration was 30 min, mean bounce dive duration was 14 min, and mean surfacing event was 6 min. Information gathered to date provides researchers and regulators with a vital glimpse into multi-day movement and dive behavior by such a challenging to study species.

Intensive illegal hunting of the African manatee (Trichechus senegalensis) for subsistence and traditional medicine in southeastern Nigeria, West Africa.

African manatees were once common in river systems of southeastern Nigeria, but now are mostly only seen when killed for bushmeat. Due to the difficulty of studying this shy species in numerous waterways, very little is known about its biology or ecology, and threats have never previously been quantified in Nigeria. From October 2008 to September 2018, we conducted intensive threat surveys combined with undercover investigations of manatees hunters' activities, seasonal trends, the manatee bushmeat trade and consumption patterns in three range states (Akwa Ibom, Cross River and Rivers) focusing particular attention on three river systems: the Cross, Qua Iboe and Imo and their tributaries, creeks and associated flood plains that all empty into the Atlantic Ocean. Our results reveal intensive and unsustainable poaching across the region for the expanding bushmeat trade for subsistence and commerce, traditional medicines, other cultural beliefs and sorcery. African manatees were also killed during industrial development and urbanization in some critical habitats. Overall, illegal hunting pressure increased steadily from 2010 to 2017 with a peak in mid-2016. Over the decade of this study we recorded 104, 31 and 66 manatees killed and traded in the Cross, Imo and Qua Iboe Rivers respectively. We documented an expanding market in northeastern Nigeria with the value of manatee meat increasing from 60,000 naira in 2008 to 400,000 naira in 2018, indicating that manatee meat consumption is increasing while the population is likely in rapid decline. Based on our results, we believe the current trend of manatee poaching and trade is likely to drive the species towards extinction in this region unless serious conservation actions are taken to reverse it. The results of this study will be used to work with and strongly encourage Nigerian government wildlife authorities to enforce existing laws and regulations protecting the species in Nigeria.

Yawn-like behavior in Tursiops spp.

Yawning is an involuntary action, which starts with slow gaping and inspiration (phase-1), maintaining maximum opening of the mouth for a while (phase-2) and ends with quick closure of the mouth following expiration (phase-3). Yawning has been widely reported in vertebrates, suggesting yawning as an evolutionarily conserved behavior. Here we report yawn-like behavior in captive and wild bottlenose dolphins (*Tursiops* spp.) underwater without inspiration and expiration which does not fit the classical definition of yawning. In a seventeen-day (119 h) observation of three captive bottlenose dolphins in Minamichita Beach Land, Japan, 1814 cases of mouth-opening behavior were reported. Obvious intentional behaviors (e.g. threat from other dolphins or human visitors) and short mouth-opening behaviors (< 0.3 s) accounted for 246 cases of unintentional mouth-opening activity. We then selected 54 mouth-opening activities with phase-1 duration > phase-3 duration (definition of human fetal yawning). Ten naive observers reported 5 yawn-like activities as described by Human Observer Classification Method. These 5 yawn-like actions were characterized by maximum

gaping along with phase-1 being longer than phase-3. Level of physical activity was low within 20 minutes before and after yawning, suggesting that dolphins yawn during drowsy states like humans. Five cases of yawn-like behavior were observed in 386-day (1816 h) underwater videos of wild Indo-Pacific bottlenose dolphins, Mikura Island, Japan, using the same attributes of yawn-like behavior, viz. maximum gape and phase 1 > phase 3. No significant differences were found between captive bottlenose dolphins and wild Indo-Pacific bottlenose dolphins in total durations as well as each phase. It may be concluded that bottlenose dolphins exhibit yawn-like behavior without respiration, which is supported by the "arousal hypothesis" of human yawning.

Humpback whale call use across time, space and context.

Recent studies have investigated whether humpback whale non-song sound types ("calls"), which are produced by both sexes and all age classes across the migratory range, may be transferred genetically. Certain humpback whale call types are shared by allopatric populations and some are stable across years and decades, indicating that some calls may be fixed within the humpback whale repertoire. However, the repertoires of many humpback whale populations, particularly at high latitudes, have not been described, and a comparison of call types between allopatric populations in contrasting points on the migration (i.e., breeding and foraging grounds) has not been conducted. The first goal of this study was to classify the humpback whale call repertoire on the Newfoundland foraging ground and investigate inter-annual repertoire stability using recordings from 2015 and 2016. The second goal was to compare calls from the Hawaiian breeding ground in 1982 to those from the Newfoundland foraging ground in 2015, to determine whether five call types (whups, growls, swops, droplets, teepees) are shared between discrete, allopatric populations. To meet these objectives, we manually classified calls into types and then used classification and regression tree analysis and random forest analysis to validate manual classifications. The five call types were identified in the Hawaii dataset as well as in both Newfoundland datasets, and at least two other call types were found in both Newfoundland datasets that have not been previously described. Use of the five call types on a contemporary feeding ground and a historic breeding ground supports the hypothesis that some calls are innate, while the occurrence and stability of these five call types supports the hypothesis that certain call types are fixed in the humpback whale repertoire. In addition, findings provide further evidence for call types that may be useful for global passive acoustic monitoring efforts.

Variations on the same theme: Bowhead whale versatility and stereotypy within a song sharing framework.

Bowhead whale singing behaviour has been studied for more than 3 decades and recently researchers described an unprecedented song repertoire diversity that rivals those of the most prolific songbirds. Unlike the better studied humpback whales, bowhead whales do not appear to share songs at the population level, but several studies have reported song sharing at a reduced scale of several individuals. However, there has been little discussion to date regarding variability and stereotypy in bowhead whale singing display and how this influences our understanding of the acoustic ecology of this endangered species. Here, we present 13 song groups sharing similar hierarchical structure and units from an unstudied wintering ground off Northeast Greenland. Semi-automated procedures assisted in identifying unit types and in exploring patterns of variability both at the song structure and at the unit level. Multidimensional maps performed well at defining unit types, showing 15 well separated clusters corresponding to units labelled manually, and revealed the presence of subtypes. Song groups presented variability in unit diversity, ranging from 2 to 6 units per song, and consistency in the association of units in 2 main phrases. Different units presented either high or low degree of variability over their acoustic parameters, suggesting that bowhead whales keep consistency in some units while using a continuum in frequency and modulation parameters for other unit types. Our results demonstrate that bowhead whales can

display contrasting levels of variability inside a shared song framework. Those findings emphasize the need to account for variability in song analysis and indicate that shifting from song toward units or phrase-based analysis as it has been suggested for humpback whales, could allow to identify and track similarities in songs over larger temporal and geographical scales.

Effects of cold on skin temperature in Florida manatees (Trichechus manatus latirostris).

Corresponding Author: erdsack@mote.org

Cold stress is one of the major threats to Florida manatees. Every year Cold Stress Syndrome (CSS) affects and kills Florida manatees during prolonged or intense cold weather periods. In contrast to other marine mammals, manatees lack essential thermoregulatory anatomical and physiological adaptations: sparse thermal insulation, the lack of arteriovenous anastomoses in the skin, and limited capabilities for shivering/non-shivering thermogenesis are only a few of the causes for sensitivity to cold.
So far, CSS has been associated mainly with exposure to water temperatures below approximately 20°C. However, the impact of low air temperatures on manatee physiology and manifestation of cold stress is not known.
In a long term study we have been investigating the impact of air temperature on skin temperature in two adult male Florida manatees, held in an outdoor sea water tank at constant water temperature. For 2.5 years and under varying environmental conditions we have been collecting skin temperature measurements at 25 spots distributed across the entire body surface. Measured skin temperatures in the smaller, more active individual have been consistently higher than those in the larger less active manatee. Within individuals, average temperature varied by less than 1°C between measuring spots. Interestingly, the temperature distribution pattern between measuring points has been congruent in both individuals. This congruent and consistent temperature pattern is another indicator for manatees' lack of control of peripheral heat loss, causing their low tolerance of cold. The pattern may reflect underlying anatomical conditions, such as distribution, number and size of blood vessels, and distribution of blubber composition and thickness, requiring further investigation.
Our measured values indicate an impact of air temperature on skin temperature in both manatees. However, more cold air data are necessary for a sound conclusion, which we anticipate to obtain during the coming winter.

A new cetacean monitoring programme along fixed transect using ferries as platforms in the Strait of Gibraltar

Since January 2018, fixed transect surveys for monitoring cetaceans in the Strait of Gibraltar were carried out using ferries as opportunistic platforms. The Strait is an Important Marine Mammal Area (IMMA) as well as one of the busiest areas for maritime traffic in the Mediterranean. Presence of cetaceans was monitored along the two ferry routes Algeciras-Ceuta (A-C) and Algeciras-Tanger Med (A-T), following the approach proposed by the "Fixed Line Transect using ferries as platform for observation in the MEDiterranean network" (FLT MED). At least two trained observers located on the bridge of the ferries were scanning both sides of the vessel, encompassing an angle of 180° and recording cetacean sightings. Five surveys per season were undertaken during the year for both routes with a minimum of one survey per route each month, depending on sea conditions and platforms availability. From January 2018 until March 2019, 2381.75 km for a total of 68 hours on effort were travelled on 35 routes (20 of the route A-C and 15 of A-T). Overall 142 encounters of around 3109 animals were logged. During surveys, 7 species of cetaceans were identified on both routes, short-beaked common dolphin was the most common one followed by striped and bottlenose dolphin, short-finned pilot and sperm whales. Fin and killer whales were encountered just along the transect A-T. Moreover, 44 and two sightings of unidentified small- and medium-sized cetaceans were also logged. Preliminary results show a high encounter rate along the routes in the IMMA Strait of Gibraltar highlighting the benefits of using ferries as platforms for research, enabling systematic year-round monitoring over large spatial scales at low cost.

Five years studying blue whales in Southern Chile.

Blue whales (*Balaenoptera musculus*) are the largest cetacean species and as such, they were major targets of the whaling industry, which led to tremendous declines in their populations during the 20th century. It is estimated that their population was depleted as much as 90%, resulting in an Endangered listing by the IUCN. In this period, more than 4000 individuals were caught in Chilean waters. Nowadays, the greatest abundance of blue whales in Chile is in Northern Patagonia, in the Chiloense Ecoregion (CE). This region is one of the most important blue whales feeding and nursing grounds discovered to date in the Southern Hemisphere.

Between 2014 and 2018, 5 scientific expeditions collected information to study the ecology, foraging and acoustic behaviour of blue whales in the Gulf of Corcovado (CE). Photo-identification allowed identification of 79 blue whales, with some site fidelity. Some animals were found to be in poor body condition. Twenty three blue whales were tagged using digital acoustic tags (DTAGs) to analyse their diving; maximum depth was found to be 139 meters. Acoustic data on tags were also analyzed, and a method to identify the calling individual using accelerometers was proposed. Genetic analysis of 30 samples identified 13 male blue whales, 10 female blue whales and 7 non-determinates. Prey mapping was done during focal follows of tagged blue whales, identifying aggregations of zooplankton in the middle of the water column (during daytime hours), typically in a layer between 40 and 100 m depth. Chemical and physical profiles of the water column indicated that most sightings have been in areas with a stratified water column with freshwater influence (lower salinity).

Finally, our surveys have shown great biodiversity, with more than 11 species sighted or detected by acoustic recorders, showing that this area is important habitat for marine mammals in Chile.

The project MISTIC SEAS I selected common species and Management Units (MUs) in European Macaronesia islands (Azores, Madeira and the Canary Islands) and defined thresholds and environmental targets to help determine the Good Environmental Status (GES) of this functional group in Macaronesia following the requirements of the Marine Strategy Framework Directive (MSFD). MISTIC SEAS II, designed and implemented pilot monitoring programmes to estimate abundance baseline values of those MUs. Those programmes aimed: (a) COASTAL, examining a Robust-design mark-recapture sampling framework for bottlenose dolphins and (b) OCEANIC, testing line-transect sampling methodology to obtain design and model-based abundance estimates for spotted dolphins. Mark-recapture abundance estimates of bottlenose dolphin were 640 individuals (CV 0.25) for Azores, and 164 (CV 0.03) for Madeira. Insufficient sightings were available for the Canaries. Mark-recapture estimates were also obtained for short-finned pilot whales in Madeira and Canaries. Results of the OCEANIC program allowed obtaining the first baseline estimates for Azores and Canaries, and updated values for Madeira. Model-based abundance estimates of Atlantic spotted dolphins were 2,324 individuals (CV 0.15) for Azores, 34,851 (CV 0.18) for Canaries and 725 (CV 0.41) for Madeira. Further abundance estimates were obtained for another fifteen species or group of species for which there were enough sightings, although not for all archipelagos. A STRANDING programme analysed the strengths and weaknesses of the existing stranding networks, suggested improvements and designed protocols for life-history analyses. Vessel collision was the main anthropogenic cause of death in the Canary Islands, primarily for sperm whales. Project results were used to assess GES in Macaronesia, and reported as part of the MSFD second cycle. In addition, the project demonstrated the feasibility of implementing the pilot monitoring programmes and provided common protocols and additional information on distribution, habitat use and on the threats faced by cetaceans in the region.

Interactions between the south american sea lion and pair trawl fishery in southern brazil

sergioestima@yahoo.com.br

The southern coast of Brazil is a foraging ground and resting site for South American sea lions (*Otaria flavescens*). Strandings of sea lions are frequent and part of this mortality is associated with fisheries interactions. The aim of this study was to describe the interactions between *O. flavescens* and the bottom pair trawl in southern Brazil. Twenty three fishing trips were surveyed by observers onboard pair trawl vessels operating in the continental shelf, from the Uruguayan border (33º44'S) to Laguna (27º52'S), between November 2011 and April 2019. A total of 1048 sets, in depths ranged from 10 to 83 meters, were recorded. The interaction was registered in 46% of the sets, with a mean of 5.3 sea lions/set (SD= 5.0). The interactions were observed in all seasons, but in the austral summer the number of sets with interaction was higher (48%) and lower in the spring (12.4%). On the other hand, the average number of sea lions/set was higher in spring (6.2 animals/set) and lower in winter (4.1 animals/set). In most of the sets (74%) the interaction occurred during the day. The interactions occurred during the hauling, where in 92% of these events, the sea lions were eating the fish trapped in the net or discarded. Damage to the net occurred in four sets only, but without significant loss of the catch. Furthermore, we recorded incidental captures of 12 dead and one alive specimens of *O. flavescens*, four males (Total Length (TL)= 116, 150, 186 e 193cm), seven females (TL= 111, 149, 156, 174, 174, 177, 182cm) and two individuals of unidentified sex. The interactions between *O. flavescens* and pair trawls are frequent and occur throughout the year, with few losses in catches. These interactions represent a threat to this species due to the high fishing effort in the region.

Abundance and site fidelity of common bottlenose dolphins off a remote oceanic island (Reunion Island, southwest Indian Ocean)

Estrade, Vanessa[1]; Dulau, Violaine[2]

(2) GLOBICE-REUNION, Saint Pierre, Reunion
Corresponding Author:
vanessa.estrade@globice.org

This study represents the first comprehensive assessment of the common bottlenose dolphin

population dynamics and residency around Reunion Island (southwest Indian Ocean). Understanding the dynamics and movement patterns of this local population is essential to guide effective conservation efforts, notably in a context of growing dolphin-watching activities. Dedicated surveys based on photo-identification method were conducted over a 6 years period (2010-2015). The species was present year-round, in groups of 24 individuals on average (1-150). Jolly-Seber mark-recapture models resulted in a population estimate of 256 individuals (95%CI = 193 - 340) and an annual apparent survival rate of 0.83. Three main residency patterns were described: residents (29.0%), occasional visitors (56.2%) and transients (14.8%), suggesting that the majority of the population showed a moderate-to-high level of residency in the study area. Models based on the lagged identification rate indicated emigration and re-immigration to the survey area, with some individuals occupying the study area for 3-4 years (1333 days), and remaining outside for an average of 635 days, probably exhibiting larger home range and extensive movement behavior. Genetic studies and comparison of bottlenose dolphin photo-identification catalogues among Mascarene Islands (Reunion Island, Mauritius, Rodrigues) and Madagascar would help understanding the level of dispersal and connectivity among local populations from the southwest Indian Ocean, and hence assessing the level of vulnerability of the Reunion population.

The challenges for assessing favourable conservation status in coastal bottlenose dolphins

Under the EU Habitats Directive, European Member States are obliged to designate sites as Special Areas of Conservation (SACs) for the maintenance, at a favourable conservation status, of particular vulnerable species, within their territorial waters. One such species is the bottlenose dolphin, with emphasis upon coastal populations given their increased exposure to human pressures and the fact that they often exist as small, apparently discrete populations. Determining whether a species is at favourable conservation status requires an assessment of population trends. Using two survey approaches (visual line transects by vessel with Distance sampling and Photo-ID Capture-Mark-Recapture studies), trends in bottlenose dolphin abundance are examined over an 18-year period both within and beyond two designated marine protected areas. Numbers using the sites have fluctuated over the last two decades, the time period over which an assessment is made profoundly affecting any conclusions reached over trends observed. Furthermore, the two methods yielded different patterns of variation. Photo-ID studies provided estimates with lower CVs especially when a Robust Design model is used that allows for the population to be open to immigration and emigration. Movement, not only between but also within years, occurs between the SACs and the wider region. This highlights the importance of determining population structure at the appropriate spatial scale, since even within the study area, groups of animals show different degrees of site fidelity and movement. Although a recent decline has been observed, the change in numbers over the last ten years has not reached the 30% threshold advocated for assessment whether the species in the region is no longer at favourable conservation status.

Temporal stability of social behavior in bottlenose dolphins (Tursiops aduncus)

Evans, Taylor[1]; Krzyszczyk, Ewa[1]; Mann, Janet[2]

Corresponding Author: tcc55@georgetown.edu

Interest in stable behavioral phenotypes has shaped studies of both human and non-human animal behavior, and more recently evolutionary processes. In particular, social phenotypes are emerging as critical drivers for disease spread and information transfer as well as fitness, and thereby

have a major impact on populations. Yet the stability of behavioral phenotypes, essential by definition, has rarely been measured over developmentally significant lengths of time. Here we investigate the stability of social phenotypes in individual wild bottlenose dolphins (*Tursiops aduncus*) from infancy to adulthood, and within the adult period, spanning decades. Using survey data from a 36 year study of Shark Bay dolphins, we quantified several measures of social behavior for 51 dolphins (32 females, 19 males) who have been sighted extensively from infancy to adulthood (≥20 surveys per life history period). While repeatability differed by measure, we found clear evidence that individuals exhibit stable social phenotypes through long periods of time. The percentage of time an individual spent alone and the percentage of time in large groups (>7 dolphins) were highly repeatable across life history stages ($r = 0.74$ and 0.76, respectively), while time in small groups (2-6 dolphins) showed negligible repeatability ($r = 0.13$). We also found that social strategy was influenced by age class and sex. Calves spent more time alone than juveniles or adults ($p < 0.01$), and females spent more time alone than males ($p < 0.001$). Males also spent more time in large groups than females ($p < 0.01$). Social phenotypes may also interact with ecological specializations. Several ecotypes (such as sponging, a case of tool use) are also stable over decades, at least among females. This is the first study to demonstrate stable social phenotypes in a wild cetacean, and is a critical addition to long term data on behavioral phenotypes.

Heavy metals in bones from Harbour Porpoises (Phocoena phocoena) from the Western Black Sea Coast

During the last few years, the Western Black Sea coast has documented increase in the number of stranded marine mammals, particularly the harbour porpoise (*Phocoena phocoena*). This species is subject to threats such as exposure to contaminants, fishery by-catch and introduced new marine species. The aim of this study was to analyse spatial and age trends in bone metal concentration in harbour porpoises from the Western Black Sea Coast. Selected heavy metals (Cu, Pb, Zn, Cd and Ni) were measured in bones of 33 harbour porpoises stranded along the Bulgarian Black Sea Coast from 2017. Spatially, we found higher metal levels in the harbour porpoises stranded in the Northern region compared with those from the Southern region. The effect of aging was evident only for Zn content – the levels were higher in juveniles than in adults. The obtained results suggested that heavy metal contamination represent an important threat encountered by harbour porpoises.

Genetic structure analysis of northern fur seals (Callorhinus ursinus) using MIG-seq method.

The northern fur seal (*Callorhinus ursinus*) is widely distributed across the North Pacific, and a portion of the species feeds in the waters around Hokkaido, Japan, from winter to spring. Recently, the fishery damage caused by this species has increased around Hokkaido, and management measures are needed. To address this problem, it is necessary to clarify their genetic background for the management. Although the species has been considered as one population based on previous population genetics studies, this conclusion might be due to the small number of polymorphic markers used. In this study, population genetics analysis was performed using the multiplexed inter-simple sequence repeats genotyping by sequencing (MIG-seq) method on subsamples of six populations (Tyuleny; n = 16, Lovushiki; n = 16, Srednego; n = 16, Bering; n = 16, Bogoslof; n = 16 and San Miguel island; n = 15) used in previous reports. This method provides genome-wide single-nucleotide polymorphism genotyping using the next-generation sequencing platform. 161 polymorphic sites under Hardy-Weinberg equilibrium were detected. The STRUCTURE analysis, which used all specimens, yielded the highest delta K value of 5.87 for K = 2 (delta K values for K = 3 to 5 ranged from 1.85 to 3.47), whereas the value of K with the highest log-likelihood was K = 2 (log-likelihood = -16207; those for K = 1 and K = 3 to 6 ranged from -16759 to -16262), indicating the presence of two genetic groups (Evanno et al. 2005). By comparison,

previous research, using seven polymorphic microsatellites, suggested K = 1. Our results suggest that the MIG-seq method is more suitable for determining the origin of northern fur seals visiting Japan.

No free lunch: Estimating the biomass and ex-vessel value of target catch lost to depredation by false killer whales (Pseudorca Crassidens) in the Hawaii longline deep-set tuna fishery.

Fader, Joseph[1]; Read, Andy[2]
(1) Duke University Marine Lab
(2) Duke University, Beaufort
Corresponding Author: joseph.fader@duke.edu

False killer whales depredate bait and catch of Hawaii deep-set longline fishing vessels, resulting in economic losses for the fishery and increasing the likelihood of hooking or entanglement of whales in fishing gear. Observers from the National Marine Fisheries Service monitor 20% of all trips in this fishery and collect data on depredation and bycatch of marine mammals. Odontocete depredation on captured fish is distinctive and can be scored reliably by observers. Typically, the entire fish posterior of the gills is consumed, leaving the head attached to the gear. Our goal in the present analysis was to estimate the biomass of fish lost to odontocete depredation and associated economic losses to the pelagic longline fishery. Depredation occurred in 6% of sets from 2004-2017, involving a total of 12,577 hooked fish. Most (61%) depredated fish were bigeye (*Thunnus obesus*) or yellowfin (*Thunnus albacares*) tuna, followed by dolphinfish (*Coryphaena* spp.), billfish (Istiophoridae spp.), and wahoo (*Acanthocybium solandri*). We used length-weight relationships from intact fish caught on the same or nearby sets to estimate the biomass of depredated fish. We estimate that an average of 71.8 metric tons (range 45.0 – 104.0 t, sd = 19.0) of tuna was lost to depredation by odontocetes annually from 2004-2017. Using available market records from the Honolulu tuna auction, we estimate that odontocete depredation cost the fleet an average of USD 840,890 (ex-vessel value) per year from 2012-2017 (range USD 693,910 – 1,025,783, sd = 148,010). These losses do not account for the opportunity costs associated with depredation of bait nor the time and expenditures of additional fishing effort to make up for lost catch. We discuss our results in the context of overall longline fishing in the central North Pacific, where the US fleet represents 5-10% of total fishing effort.

Fine-scale oceanographic drivers of foraging in California blue whales

Animals integrate information from their environment to find food, but the environmental cues that drive this process are difficult to study and remain less understood. At broad spatial scales (e.g. the California Current), blue whale (Balaenoptera musculus) movement may be driven by memory, yet blue whales are known to target highly dynamic prey patches at fine spatial scales. To better understand how movement and sensory processes connect across different temporal and spatial scales, we analyzed surface location, diving, temperature and feeding data from 9 high-resolution multi-sensor tags (mean duration 14.34 days) from 2016-2018 to quantify blue whale foraging in relation to fine-scale oceanographic features measured by concurrently sampled high frequency radar (2-6 km, hourly resolution) along the California Coast. We show that blue whale feeding bouts were associated with anti-cyclonic oceanographic features (i.e. negative sea surface vorticity) at the scale of daily movements. Tag-derived dive-temperature profiles revealed that the water columns associated with negative sea surface vorticity exhibited a substantially deeper thermocline than areas of positive vorticity, implying that localized downwelling may be an important foraging cue for blue whales. This approach will now be applied to a larger dataset that includes 64 individual tag deployments from 2014-2018 to validate these findings and test other variables. These results give insight into the drivers of animal movement at sub-daily scales and may have important implications for spatial ecology and conservation of endangered marine species.

Persistent Organic Pollutants and Mercury in estuarine coastal bottlenose dolphins (Tursiops truncatus) of the Gulf of Guayaquil, Ecuador: A first ecotoxicological assessment.

The bottlenose dolphin is the most common cetacean found in the coastal waters, estuaries and mangroves of Ecuador; however, as a vulnerable species, its population size is gradually declining in the Gulf of Guayaquil, where anthropogenic factors including habitat degradation, uncontrolled dolphin watching, maritime traffic, sediments dredging, bycatch and environmental pollution are suspected to affect the population health of this species. Very little is known concerning contamination by persistent organic pollutants (POPs) and mercury in bottlenose dolphins from the west coast of South America. To address this research gap, the first assessment of total mercury (THg) and POPs, including polychlorinated biphenyls (PCBs), organochlorine pesticides (OCPs), and polybrominated diphenyl ethers (PBDEs), in bottlenose dolphins in mangroves (El Morro Mangrove Wildlife Refuge) of the Guayaquil Gulf, was conducted in Ecuador in 2018. Using biopsy dart collection technique, nine dolphin samples (i.e. skin and blubber), were obtained for contaminant analysis. POP concentration ranged 0.60-16.4 mg/kg lw, while THg ranged 1.40-4.0 mg/kg dw. The dominant POPs were OCPs (51% of ∑POP), followed by PCBs (43.5%) and PBDEs (5.54%); particularly, *p*,*p*'-DDE, the main DDT metabolite and a potent anti-androgenic, accounted by 44% of ∑POP, ranging 0.12 to~9.0 mg/kg lw, followed by PCB 153 (8%) and PCB 180 (5%). BDE 47 accounted by 2% of ∑POP. While the POP concentrations are lower to those found in dolphins from other regions of the world (e.g., PCBs were much lower, ranging 0.3-6.0 mg/kg lw, to those measured in dolphins along the southeastern coast of USA), the THg concentrations are lower or within the concentration range found in dolphins from the USA southeastern coast. Our finding shows that bottlenose dolphins are exposed to contaminants and can be used as sentinel species of ecosystem health to monitor pollution in the region to support ecotoxicological risk assessment and inform pollutant management.

Regional variation in humpback whale song within the western Indian Ocean

The humpback whale is one of the best-studied mysticete species, but its movement patterns within the southwestern Indian Ocean (SWIO) breeding ground are complex and yet poorly understood. Photographic identification, genetic and satellite tracking data have revealed some population structure between different sub-regions. Male humpback whales sing a song shared at the population level that is useful for defining population structure and connectivity, and thus we might expect some differentiation in SWIO song structure based upon population subdivisions. To assess this, autonomous recorders were deployed at four sites in the SWIO, off Réunion Island, northeast and northwest Madagascar, and Tanzania, during austral winter 2018 in order to define spatiotemporal patterns of song occurrence and compare song structure among sub-regions. Quality of recording and presence of songs were noted for the first 20 minutes of each hour (8083 spectrograms manually reviewed, for a total of 2694 hours of recording for the first three sites, with Tanzania currently under analysis). The daily occurrence of songs was assessed for each site to describe the temporal distribution pattern of whales. Songs were recorded from late June to early October, with higher occurrence observed in NE Madagascar. High quality samples of song sequences were selected from all sites, defining early, mid and late season periods. All phrase types recorded in Reunion were shared with Madagascar, and there also appears evident temporal variation that may be distinct to the different sub-regions. Results suggested a high connectivity between Reunion and Madagascar during the breeding season as would be expected from previous photographic and satellite telemetry data, but also the potential for introduction of novel song material into Madagascar, possibly from another population. Adding data from Tanzania, as well as further quantitative analysis will provide a better understanding of humpback whale population connectivity within the western Indian Ocean.

Preliminary estimates of vital rates from Cuvier's beaked whales on a military training range

Vital rates are key inputs to Population Consequences of Disturbance (PCoD) models used to estimate impacts of sub-lethal stressors that may reduce fitness over time. We report preliminary vital rate data from an ongoing photo-identification study of Cuvier's beaked whales (Zc) at the Southern California Antisubmarine Warfare Range, where military sonar and explosives are tested regularly. From 2006-2018, 222 unique individuals were photographed on or near SOAR. Eighty-four whales were photographed on 2-9 separate days (mean = 3.3) and over periods of up to 11 years (mean = 3.6). Each whale was classified to age and sex each day it was photographed using genetic, life history, and visible trait data (e.g. presence of teeth, pigmentation patterns, scarring density), as available. By adapting published methods for aging and sexing Zc from photographs for use with sub-optimal photo sequences, the age and sex of only 5% of whales could not be classified with at least some confidence. The age classified sample included 86 adult females, 52 adult males, 12 sub-adult females, 22 sub-adult males, 16 unsexed juveniles, and 20 unsexed calves, as of the most recent sighting. Seventeen individuals (9 female, 6 male, 2 unknown sex) transitioned through an age class (14 sub-adult to adult, 1 juvenile to sub-adult, 2 calf to juvenile), providing sex-specific data on maturation rates. Twenty females had one calf, two had two calves, and seven mother-calf pairs were resighted together over periods from 1-954 days, providing insights into calving rates and time-to-weaning. The sparseness and variability of these data, despite concerted effort to collect them, underscores the importance of establishing photo-ID studies promptly when the need for vital rate data is apparent; it also elevates the importance of comparable long-term data from other study sites to evaluate whether vital rates for impacted populations warrant concern.

Surface drifting helium balloons posing ingestion and entanglement risks to marine mammals and turtles in the New York bight, USA.

Global plastic production has increased from 1.5 million tons in 1950 to 348 million tons in 2017. Plastic pollution has become a major threat to the marine environment. The impact of plastic on marine mammals, turtles and seabirds has become a cause for concern as ingestion and entanglement has been recorded. This study shows the abundance and distribution of surface drifting helium balloons in the New York Bight, USA. Additionally, this study looked at the abundance and distribution of marine mammals and turtles in the same study area during the same time period. The data were collected by Protected Species Observers onboard the RV Ocean Researcher from June to December 2018 during a geophysical survey for the Empire Wind project. In the study area (321 km^2), over 791 individual balloons were counted in 628 sightings. There were 421 sightings of marine mammals and turtles resulting in a total of 2388 individuals. Sightings of marine mammals included humpback whale (*Megaptera novaeangliae*), fin whale (*Balaenoptera physalus*), minke whale (*Balaenoptera acutorostrata*), bottlenose dolphin (*Tursiops truncatus*), short-beaked common dolphin (*Delphinus delphis*) and gray seal (*Halichoerus grypus*). Turtle species encountered included green (*Chelonia mydas*), Kemp's ridley (*Lepidochelys kempii*), leatherback (*Dermochelys coriacea*) and loggerhead (*Caretta caretta*) turtle. The distribution of surface drifting helium balloons overlapped with sightings of marine mammals and turtles. This poses ingestion and entanglement risks to species using the New York Bight as a core habitat or migration corridor. In conclusion, this study demonstrates the exposure of marine mammals and turtles to the high levels of surface drifting helium balloons in the New York Bight. Humpback whale, fin whale and all turtle species observed in this study are listed under the Endangered Species Act. Therefore, monitoring the impact of plastic pollution on marine mammals and turtles is essential.

Seasonal presence and annual return of female humpback whales (Megaptera novaeangliae) in the north-eastern coast of Madagascar.

Corresponding Author: ainaramaf@gmail.com

The dynamics, distribution and size of the humpback whale (Megaptera novaeangliae) population in the Southwestern Indian Ocean region remain poorly documented. The Sainte Marie channel, such as the other coastal waters in Madagascar, is one of their migration areas and was described as an important site for breeding and calving. Photo-identification data collected between 2009 and 2018 on touristic boats in the Sainte Marie channel were analyzed to determine females return rates and site fidelity to this area. The capture-recapture technique was used and the recaptures were visually identified by comparing the photos within year and between years. Females were defined by the presence of a calf beside them. A total of 2,263 unique individuals were identified from 3,386 processed photos. The results showed a very low degree of site fidelity (R = 0.017) and almost no fidelity from females (R = 3.3. 10-6). Within year recapture intervals have shown that humpback whales using the Sainte Marie channel remain on average 13 days. A total of 33% of the individuals photographed in Active Surface Groups were subsequently recaptured with calf in a mother-calf groups, showing the diversification to their social structure. The maximum recapture interval 31-days show a high degree of mobility of individuals during the breeding season. Citizen science is a basic and an accessible method for the photo identification of cetaceans, especially species frequenting coastal areas; in this study it allowed to make a first determination of the seasonal and annual presence of female humpback whales in the Sainte Marie channel. Keywords: Humpback whale (Megaptera novaeangliae), females, return rates, site fidelity, photo-identification, population dynamics, Sainte Marie channel.

Genetic diversity of Atlantic spotted dolphin (Stenella frontalis) from Southwest Atlantic Ocean and global genetic differentiation

Recent molecular studies have shown fine-scale population structure in highly mobile cetacean species with continuous distributions despite the continuity of the marine environment. Here we assessed the genetic diversity and differentiation of the Atlantic spotted dolphin (*Stenella frontalis*), endemic to warm and pelagic waters of the Atlantic Ocean. We evaluated 463 bp of the mtDNA control region of 24 specimens from the Brazilian coast (Southwest Atlantic Ocean). Seven haplotypes were identified and haplotype diversity (*h*) and nucleotide diversity (π) were 0.7935+/-0.0662 and 0.006863+/-0.004099, respectively. One haplotype (H1) encompasses the majority of specimens (N = 10). We also compared 270 sequences of the Atlantic Ocean, the Brazilian coast (this study + three published sequences) and 243 published sequences from six other locations (Azores/Madeira, Bahamas, Gulf of Mexico, Puerto Rico, Caribbean Sea, Northwest Atlantic Ocean). We identified 122 haplotypes and the haplotype diversity was higher for Bahamas (1.0000 +/- 0.0000, n=1) and lower for Brazilian coast (0.8063 +/- 0.0501, n=27), the nucleotide diversity was higher for Northwest Atlantic Ocean (0.126364 +/- 0.061569, n=49) and lower for Puerto Rico (0.000000 +/- 0.000000, n=1). Pairwise F-statistics revealed significant differentiation among locations (Brazilian coast with Azores/Madeira, with Gulf of Mexico, with Northwest Atlantic Ocean, with Caribbean Sea; Azores/Madeira with Northwest Atlantic Ocean), and, among divisions of the Atlantic Ocean (Southwest Atlantic Ocean, Northeast Atlantic Ocean and Northwest Atlantic). These results suggest genetic isolation of the Brazilian coast population from the majority of the North Atlantic Ocean locations (east and west). These results highlight the importance of studies of population genetics in micro-scale even for species with high mobility and continuous distribution as the Atlantic Spotted dolphin.

Does common dolphin distribution respond to changes in prey availability and environmental conditions?

Celtic Sea waters were designated as a Whale and Dolphin Sanctuary to protect their high cetacean biodiversity. The southern part of Ireland is considered a foraging hot-spot for fin, minke and humpback whales, and common dolphins, this last species being the most abundant. These top-predators feed extensively in the area on herring and sprat during autumn and winter. While the information available about the Celtic sprat stock is insufficient to assess its status, the herring stock has not recovered from the significant depletion that it suffered in 2013. Currently, the herring biomass, fishing mortality and recruitment are all outside sustainable limits. The associated fishery lost its Marine Stewardship Council sustainability certificate in 2018. The effects of these fluctuations on higher trophic levels are still unknown. The objectives of this study are to analyse spatio-temporal trends in abundance and distribution of common dolphins and prey species derived from acoustic fish surveys carrying cetacean observers over 14 years and investigate the drivers behind them. Responses of dolphins (in terms of presence and local abundance) to changes in prey availability are explored. During the study, 16.732 km of survey effort were completed and there were 1226 cetacean sightings including 796 of common dolphins. Generalized Additive Models were used to relate common dolphin sightings to environmental conditions and acoustic indices of fish abundance. While dolphin presence and sightings rate were related to several environmental variables (e.g. depth, chlorophyll concentration) no relationship was found with herring density and only a very weak positive relationship with sprat density. Results suggest that acoustically measured local fish density is a poor predictor of dolphin presence and abundance at the scale considered in this study. Results on cetacean abundance and distribution from this study are nevertheless potentially valuable to inform indices of biodiversity under the EU Marine Strategy Framework Directive.

Sleepless whales: Characterization of cetacean melatonin receptors and clock genes, and associated behavioral activity patterns.

Fasick, Jeffry[1]; Beyes, Danielle[2]
(1) The University of Tampa, St. Petersburg, Florida
(2) The University of Tampa, Tampa, FL
Corresponding Author: jfasick@ut.edu

Circadian rhythms, ranging from biochemical processes to behavioral responses, are ubiquitous in nature and are generated by a biological clock at the cellular/molecular level. The core oscillator operating this clock is composed of an autoregulatory transcription-translation feedback loop controlled by a set of clock genes that are entrained to day and night rhythms by solar irradiation. Although most mammals possess well defined diel behavioral rhythms, baleen whales are believed to be arrhythmic with regards to behavioral activity. To elucidate the underlying molecular mechanisms that would result in arrhythmic behavior, the melatonin receptors, MTNR1A and MTNR1B, the enzymes controlling the synthesis of melatonin (*Aanat* and *Asmt*), as well as the clock genes (*Clock*, *Bmal*, *Per1 & 2*, *Cry1 & 2*, and *Rev-Erbα & β*), were examined for function by analyzing six high coverage cetacean genomes: minke whale (*Balaenoptera acutorostrata*), sperm whale (*Physeter macrocephalus*), baiji dolphin (*Lipotes vexillifer*), finless porpoise (*Neophocaena phocaenoides*), beluga whale (*Delphinapterus leucas*), and orca (*Orcinus orca*). Results from this study show the lack of MTNR1A genes in all cetaceans examined, as well as considerable mutations in the MTNR1B, *Aanat* and *Asmt* genes, suggesting cetaceans lack the biochemical processes to synthesize and bind melatonin. The eight clock genes examined appear to be functional in most species, however, three single point mutations were identified in three different genes from three different species suggesting pseudogenization. We have reviewed previously published telemetric data for a variety of behaviors including foraging, resting, traveling and exploring that reported behavioral activities for more than 24 hrs. Although there were clear incidents supporting arrhythmic behaviors, the majority of behaviors were defined as being rhythmic. However, when these individual behaviors were incorporated together into an artificial 24 hour day, the results strongly suggest that the animals are active throughout a 24 hour period with intermittent sleep bouts.

Recent advances and challenges in marine mammal impact assessments for underwater noise

Faulkner, Rebecca[1]; Farcas, Adrian[2]; Merchant, Nathan[3]

rebecca.faulkner@cefas.co.uk

Growth in the blue economy is driving increases in noise-generating activity, notably the construction

of offshore wind farms and other marine infrastructure, seismic surveying of oil and gas deposits, and shipping. Policymakers and regulators are increasingly aware of the impacts of underwater noise on marine mammals, and require clear and up-to-date scientific guidance to assess the risk of proposed activities, particularly in relation to species and habitats with statutory protections.

Here, we review recent developments in risk assessment of underwater noise pollution which we have encountered through our roles as scientific advisors to UK Government and regulatory bodies in England and Wales, and as technical consultants producing environmental impact assessments (EIAs) for developers in other jurisdictions.

We use case studies to assess the implications for EIA of updated noise exposure criteria for hearing impairment in marine mammals in relation to previous guidance. Since both auditory frequency weightings and noise exposure thresholds determine the extent of effect zones produced for permanent and temporary threshold shift (PTS and TTS), it is necessary to run modelling scenarios to understand the interaction of these frequency-dependent factors with source spectrum and sound propagation characteristics. Based on typical EIA scenarios, we use noise modelling techniques to demonstrate the relative differences in risk assessment yielded by the updated guidance for each of the five marine mammal functional hearing groups.

Assumptions of animal behaviour are also instrumental in determining PTS/TTS effect zones, and the parameters used to describe fleeing responses strongly affect the assessment outcome. Similarly, the application of noise abatement technologies can greatly influence the assessment of risk, although their use is often not included in assessments. We explore the influence of these factors on EIA for noise-generating activities, and review the scope for future advances and developments in risk assessment as our scientific understanding evolves.

Conflicting physiological adaptations between thermoregulation and diving energetics in elephant seals

Favilla, Arina[1]; Horning, Markus[2]; Costa, Daniel[3]

Corresponding Author: afavilla@ucsc.edu

Deep-diving marine mammals face significant thermoregulatory challenges living in a highly thermally-conductive environment and encountering steep vertical temperature gradients. They are well-insulated to conserve heat, but dissipating heat may result in a conflict between the dive response and thermoregulation as both are affected by the regulation of peripheral blood flow. To coordinate these physiological adaptations, marine mammals may have a temporally-delayed thermoregulatory response during normal diving behavior. We assessed this hypothesis by equipping freely-diving juvenile northern elephant seals (*Mirounga angustirostris*; n=2) with custom-built heat flux (HF) biologgers over short at-sea trips. Skin temperature and HF measurements from two sensors were analyzed relative to diving behavior and water temperature. While skin temperature at both locations remained within 2.5°C of water temperature, significantly greater skin temperatures and heat loss at the axilla ($p<0.0001$) suggest this region serves more as a thermal window than the flank. HF patterns revealed heat is lost throughout most of the dive at an average rate of 74.4 W/m^2, and a transition to heat gain occurs at the end of the ascent phase near the thermocline, and then peaks at the surface with an average magnitude of 131.2 W/m^2. Average HF throughout the dive was independent of dive depth or duration; however, average heat gain during the post-dive interval was positively correlated with both dive depth and duration ($p<0.001$). These results support our hypothesis and suggest peripheral cooling prevents conflict with the dive response and may be partially compensated by post-dive heat gain in shallow, warmer waters particularly for longer dives. Work is continuing using modified HF biologgers that incorporate additional measurements to explore the mechanisms underlying these thermoregulatory responses. This will lay the foundation for comparing the plasticity of physiological adaptations during normal and disturbed diving behavior to better predict and mitigate the effects of anthropogenic disturbances.

In the path of floodwaters: Short-term effects of Hurricane Harvey on bottlenose dolphins (Tursiops truncatus) in upper Galveston Bay, Texas.

Fazioli, Kristi[1]; Mintzer, Vanessa[2]; Guillen, George[3]

In late August 2017, Hurricane Harvey's historic rainfall over Southeast Texas inundated the Galveston Bay estuary system with a volume of freshwater equal to the average annual inflow. As a result, salinity levels in the bay declined rapidly from an average of 14ppt to <1ppt, altering aquatic habitat in the weeks following the storm. Long-term photo-identification monitoring efforts since 2013 provided an opportunity to evaluate the effects of this extreme flood event on the bottlenose dolphins *(Tursiops truncatus*) inhabiting upper Galveston Bay. We evaluated dolphin encounter rates for the months preceding and following Hurricane Harvey, as well as visual prevalence and extent of dolphin skin lesions, typically presenting as ulcerated or degraded epidermis. Encounter rates of dolphins in the study area decreased from 1.09 dolphins per linear kilometer (d/km) in August 2017 before the storm to 0.29 d/km in September 2017 (compared to September 2016 encounter rates of 0.91 d/km). While most dolphins evacuated the upper portion of the bay, many remaining individuals shifted habitats from shallow open bay to ship channels where salinity levels were higher at depth. Encounter rates increased when surface salinity rose to 10-11ppt after almost 8 weeks. Skin lesions significantly increased in both prevalence within the population and extent of body coverage during the freshwater flood event. As salinity recovered, the extent of lesions decreased, while the prevalence of lesions remained elevated over pre-storm levels at least four months after Harvey. This study provides an important step toward understanding the effects of flood events on estuarine dolphin populations in the Gulf of Mexico. With the predicted increase in the frequency of intense storms due to climate change and planned storm management infrastructure projects in Galveston Bay, continued research is imperative to manage the availability of habitats where dolphins can find refuge during these events.

Identification of potential signature whistles from free-ranging common dolphins (Delphinus delphis) in South Africa.

Fearey, Jack
University of Cape Town, Cape Town, Western Cape, South Africa
Corresponding Author: jack@fearey.com

Conveying identity is important for social animals to maintain individually based relationships. Communication of identity information relies on both signal encoding and perception. Several delphinid species use individually distinctive signature whistles to transmit identity information, best described for the common bottlenose dolphin (*Tursiops truncatus*). In this study, we investigate signature whistle use in wild common dolphins (*Delphinus delphis*). Acoustic recordings were analysed from 11 encounters from three locations in South Africa (Hout Bay, False Bay, and Plettenberg Bay) between 2009 and 2017. The frequency contours of whistles were visually categorised, with 29 signature whistle types (SWTs) identified through contour categorisation and a bout analysis approach developed specifically to identify signature whistles in bottlenose dolphins (SIGID). Categorisation verification was conducted using an unsupervised neural network (ARTwarp) at both a 91% and 96% vigilance parameter. For this, individual SWTs were analysed type by type and then in a 'global' analysis whereby all 497 whistle contours were categorised simultaneously. Overall the analysis demonstrated high stereotypy in the whistle structure and temporal production of common dolphins, consistent with signature whistle use. We suggest that individual identity information may be encoded in these whistle contours. However, the large group sizes and high degree of vocal activity characteristic of this dolphin species generate a cluttered acoustic environment with high potential for masking from con-specific vocalisations. Therefore, further investigation into the mechanisms of identity perception in such acoustically cluttered environments is required to demonstrate the function of these stereotyped whistle types in common dolphins.

Summary of recorded cetacean stranding in Krasnodar region of Russian Federation in 2018 and 2019.

Fedorova, Oxana[1]; Denisenko, Tatyana[2]

Stranding of cetaceans on the Black Sea Coast in Russian Federation are being monitored by different scientific organisations. However in the literature there are mainly publications about strandings on the territory of the Crimea. As for Krasnodar region there was little information about the numbers of stranded animals of all three species of cetaceans living in the Black Sea. With many strandings happening around Krasnodar region it became necessary to record the rate and patterns of stranding, which led to organization of stranding network to perform systematic work on recording of stranded cetaceans and determination of possible causes of death in 2018 - 2019.

The monitoring of strandings was carried out on 450+ kilometers of the Black Sea coast (from Sochi

(border with Abkhazia) to Taman Bay) during 1 year (April of 2018 - April of 2019). In addition, several strandings that took place in Abkhazia were recorded. Cetacean stranding detection methods included: 1) Social media 2) Mobile Hotline; 3) Coastal patrols; 4) Messages from the current network of volunteer-observers; 5) Obtaining information from the State Supervisory Services; 6) Receiving data from travel companies.

As a result of research we recorded 196 deceased cetaceans on the coast of Black Sea. Highest number of strandings was recorded in April of 2019 with 67 individuals. According to the data we collected the following numbers of each species were recorded:

Harbour porpoise (Phocoena phocoena) - 93;

Common dolphin (Delphinus delphis) - 49;

Black Sea Bottlenose dolphin (Tursiops truncatus) - 15;

unidentified species - 39.

14% of all deceased cetaceans had clear signs of entanglement in fishing gear. Majority of carcasses were in advanced decomposition stages, therefore no signs of fishing entanglement were present.

The development of stranding monitoring network led to more accurate data on numbers of stranded cetaceans in Krasnodar region.

Cultural tradition in Baird's beaked whales (Berardius bairdii)

Socially transmitted behavioral patterns – cultural traditions – were observed in many whale species from large baleen whales to small dolphins. However, no traditions have been described so far in beaked whales – elusive and poorly studied group of toothed whales. We studied Baird's beaked whales in the coastal waters of the Commander Islands (Russia) for eleven years (2008-2018). Among 184 Baird's beaked whales identified in the Commander Islands, about one third came to the study area regularly year after year, while other animals were registered only once over the study period. Baird's beaked whales are normally sighted in deep-water regions, but 60 out of 446 encounters in our study area occurred in rather shallow waters (100-300 m). All of the shallow-water encounters were represented by 'resident' animals that have been regularly sighted in the Commander Islands, while 'transient' whales have never been observed in shallow waters. About half of the shallow-water encounters involved groups consisting of females with calves. We hypothesize that 'resident' animals familiar with the area are targeting some specific prey (for example, Pacific cod, Pacific halibut or rougheye rockfish) which is abundant on the shelf of the Commander Islands at depths of 50-350 m. 'Transient' whales unfamiliar with the area follow the typical foraging behavior for this species: they hunt prey along the shelf slope at depth (typically 700-1800 m). The observed difference in behavioral patterns between 'resident' and 'transient' animals suggests that hunting in the shallow waters is a cultural tradition of the local Baird's beaked whale community, maintained through the social transmission of knowledge on the prey distribution in the coastal waters of the Commander Islands. Shallow-water foraging can be especially beneficial for females with calves because it is less energy consuming. The study was supported by the RFBR grant 18-04-00462.

Application of molecular techniques to the diagnosis of Cetacean Morbillivirus and Herpesvirus in beaked whales stranded in the Canary Islands.

The aim of this study was to perform an *evaluation* of population *health* among beaked whales stranded in the Canary Islands, focused on *Cetacean Morbillivirus* (CeMV) and *Herpesvirus* (HV). A total of 54 beaked whales, stranded between 1999 and 2017, were analyzed, including 34 Cuvier's beaked whales (*Ziphius cavirostris*) and 20 specimens belonging to the *Mesoplodon* genus. The analyzed samples included skin, lung, liver, intestine, mesenteric or mediastinal lymph node, kidney, spleen and brain. A real-time polymerase chain reaction (PCR) was carried out for CeMV, with primers designed from a partial consensus sequence of the phosphoprotein gene obtained from a dolphin morbillivirus (DMV) detected in a bottlenose dolphin (*Tursiops truncatus*), a pilot whale morbillivirus detected in a short-finned pilot whale (*Globicephala macrorhynchus*) and a CeMV detected in a guiana dolphin (*Sotalia guianensis*), amplifying a product of about 150 base pairs (bp). A conventional nested PCR was performed for HV, amplifying a fragment of the DNA polymerase gene of the Herpesviridae family of about 200 bp. Only 1/34 animal (2.9%) was positive for DMV in the *Ziphius cavirostris* group. The sequence showed a 100% homology with a sequence detected in a striped dolphin (*Stenella coeruleoalba*) stranded in Portugal in 2007 (GenBank Acc. No.: KP835995); and 4/34 animals (11.76%) were positive for HV, with sequences showing the highest homology with an alphaherpesvirus 1 sequence detected in a Cuvier's beaked whale stranded in the Mediterranean in 2012 (GenBank Acc. No.: KP995682). *Mesoplodon* genus was not positive for CeMV, while 3/20 animals (15%) were positive for HV, with sequences showing the highest homology with an alphaherpesvirus detected in a Blainville's beaked stranded in the Canary Islands in 2004 (GenBank Acc. No.: JN863234). This study increases the knowledge about viruses affecting beaked whales, being primary pathogens causing diseases, and even death, in some cases.

Presence of rake marks in common bottlenose dolphins (Tursiops truncatus) across age and sex classes: What's normal?

Common bottlenose dolphins live in a fission-fusion society with a complex social structure that changes across their lifespan. Rake marks (i.e., epidermal scratches delivered by conspecific's teeth) are obvious, long-lasting indicators of social interactions and can vary in severity from superficial to deep. The presence or absence of rake marks is one way of assessing the degree and kind of interactions in which individuals engage, but little is known as to what constitutes a normal number of rakes or whether differences should be expected between age and sex classes. This study seeks to describe normal rake coverage in the long-term resident Sarasota Bay bottlenose dolphin community measured during health assessments. The entire bodies of 24 temporarily-restrained dolphins (13 male, 11 female, ages 2-33 yrs) were examined and their rakes mapped, counted, and categorized by depth. Adult males had the most rakes (M=32.1, SD=14.9), followed by subadult males (M=20.5, SD=3.5), subadult females (M=11.5, SD=3.5), adult females (M=8.2, SD=6.6), male calves (M=8.0, SD=1.0), and female calves (M=3.3, SD=2.8). Males had significantly more rakes than females (p=0.0004), and adult males had more rakes than younger males (p=0.047). Overall, 7.77% of the rakes were categorized as "deep" (i.e., dermis visible), and this was similar across sexes. Information on normal rake coverage for all age and sex classes of free-ranging dolphins provides an indicator of the quality of recent social engagements of individuals observed in the ocean, stranded dolphins, and dolphins living in aquaria.

Ringed seals at the edge of their geographic range undergo acute seasonal and annual blubber depth changes compared to core populations.

Ecological theory suggests that demographic responses by populations to environmental change vary depending on whether they occur centrally or peripherally within a species geographic range. Here, we test this prediction by assessing ringed seal (*Pusa hispida*) body condition response to long-term and seasonal environmental changes. We compare a population located at high latitudes in core species range (central) with a population located at the southern extremity of the species range (peripheral). First, we examined long-term patterns in sea ice and a climatic index, key environmental variables shown to influence ringed seal demography. For the central region, ice conditions shifted in the early 1990s to increasingly warmer conditions; whereas a later shift in 1999 occurred in the peripheral region. We chose to test for seasonal and annual changes in seal blubber depth over the recent environmental period since the shift (after 1990 and 1999 in the central region and peripheral region, respectively). Although both central and peripheral seals responded to similar environmental changes associated with initiation of spring, duration of open water, and the North Atlantic Oscillation; only peripheral seals varied in blubber depth with season and year. Central seals displayed minimal changes in body condition by season and year while peripheral seals varied considerably with season displaying a 20-60% amplitude change in body fat with a phase shift to earlier initiation of fat accumulation and loss relative to central seals. Lack of variation in central seal condition by season and year may indicate an evolved match between species adaptations and environmental perturbations. Knowing how different populations respond to environmental change depending on geographic location within a species range can assist in managing population specific responses to climate warming.

Dermatophitosis by Trichophyton spp. causing generalized skin lesions in a bottlenose dolphin (Tursiops truncatus): First report in a free-ranging cetacean.

A male calf bottlenose dolphin (*Tursiops truncatus*) stranded alive in Tarifa (Cádiz, Spain). After several attempts of reintroduction, the animal was transported to a rehabilitation centre (Regional Government of Andalusian). It was still dependent on the mother's milk and its body condition was progressively declining. After being under human care for eleven days, the animal finally died. A complete standardized necropsy was performed and tissue samples were collected and fixed in 10% neutral buffered formalin for histopathological analysis. Grossly, multiple rounds to oval, sometimes rectangular, irregular, slightly raised and discolored skin lesions were diffusely distributed from the head to the caudal peduncle of the specimen. A peripherical and central depression of the skin was a characteristic feature of the lesions. Histologically, a regular hyperplasia was observed characterized by the presence of mitotic figures at the basal layer (stratum germinativum). A slight interstitial edema was present at the mid-superficial layers of the stratum spinosum and a marked hyperkeratosis with abundant death cells was present at the upper layer (stratum externum) of the epidermis intermixed with some tortuous empty or slightly basophilic tracks. The PAS and the Grocott stains revealed the presence of abundant hyphae-like structures within the hyperqueratotic layers. These hyphae positively reacted with an anti-*Trichophyton* antibody, and it came out negative with a panel of other primary reagents against different fungi. Dermatophytes are fungi that grow on the outermost layers of the skin of animals, including muco-cutaneous membranes, genitalia, external ears, as well as dead skin or hair. Infections caused by dermatophytes, seem to be rare in marine mammals, and therefore also in cetaceans. Up to date a single case of *Trichophyton* spp. isolated from widespread superficial nodules on the trunk of an Atlantic bottlenose dolphin kept in captivity in Japan has been reported.

An integrated framework to assess the carrying capacity of whale-watching tourism and the case of Praia do Forte, Northeastern Brazil.

Whale-watching has been increasing around the world and there is growing concern about its potential effects on the targeted animals. In order

to be sustainable it is important to determine its carrying capacity. Based on a literature review on sustainable whale-watching management and the concept of tourism carrying capacity, we propose an integrated framework that includes an evaluation of biological , social and economic aspects, considering the stakeholders involved and the current management capacity in place at a specific locality. The case of Praia do Forte, northeastern Brazil, is analyzed under this framework, considering tourist satisfaction and operator questionnaires, the current scientific knowledge on the targeted humpback whale population and the legislation and management measures in place. during 2015, 284 trips took place with 3,117 tourists. In the same year, 50% of tourists interviewed had their expectations fully satisfied and 96% would go whale-watching in Praia do Forte again. The activity employed a total of 39 permanent staff and an additional 14 temporary staff during the whale-watching season, of which 26 are from the local communities. All operators considered the activity financially viable and profitable for their companies and expected it to expand in future years. Three out of five operators believed there could be more boats operating in Praia do Forte. Operators also pointed out the lack of involvement or support from public authorities in the development, marketing and management of this activity as a limiting factor. The humpback whale population targeted has been recovering from exploitation at an estimated 7.4 to 15.2% annual rate and reoccupying former breeding areas along the Brazilian coast. Based on this analysis we consider that whale-watching in Praia do Forte is currently below its carrying capacity, however, we recommend limiting the activity to its current level, until more data and management capacity become available.

Veterinary pathology of stranded cetaceans in Canary Islands (06-12)

The occurrence of disease in aquatic organisms will be probably one of the long-term consequences of climate change and environmental degradation. Cetaceans are regarded as sentinel species to monitor marine and marine-terrestrial interface ecosystems wherein humans are strictly integrated. Cetaceans are exposed to environmental stressors either anthropogenic, e.g., chemical and acoustic pollution, fisheries, maritime traffic, tourism industry, and non-anthropogenic, hereafter 'natural,' e.g., biotoxins, pathogens (bacteria, fungi, parasites, viruses). . Some of these pathogens have epizootic potential, are zoonotic or display complex pathogeneses in which biotic, e.g., genetic stock, immunologic dysfunction, and abiotic, e.g., chemical pollutants, may play a major role.

This study describes the pathologic findings and most probable causes of death (CD) of 224 cetaceans stranded along the coastline of the Canary Islands (Spain) over a 7-year period, 2006–2012. Most probable CD, grouped as pathologic categories (PCs), was identified in 208/224 (92.8%) examined animals. Within natural PCs, those associated with good nutritional status represented 70/208 (33.6%), whereas, those associated with significant loss of nutritional status represented 49/208 (23.5%). Fatal intra- and interspecific traumatic interactions were 37/208 (17.8%). Vessel collisions included 24/208 (11.5%).

Neonatal/perinatal pathology involved 13/208 (6.2%). Fatal interaction with fishing activities comprised 10/208 (4.8%). Within anthropogenic PCs, foreign body-associated pathology represented 5/208 (2.4%). A CD could not be determined in 16/208 (7.7%) cases. Natural PCs were dominated by infectious and parasitic disease processes. Herein, our results suggest that between 2006 and 2012, in the Canary Islands, direct human activity appeared responsible for 19% of cetaceans deaths, while natural pathologies accounted for 81%. These results, integrating novel findings and published reports, aid in delineating baseline knowledge on cetacean pathology and may be of value to rehabilitators, caregivers, diagnosticians and future conservation policies.

Marine habitat use by the Mediterranean monk seal population of Madeira archipelago

The Madeira archipelago is home to one of the few surviving Mediterranean monk seal populations in the world. Information about marine habitat use, range of movements, and foraging areas for this population has never been available due to the difficulty of tagging individuals. The development of ankle bracelets and Fastloc GPS to tag monk seals at the Cabo Blanco monk seal colony opened the possibility to also tag individuals from the Madeira population. Using the same methodology, 5 bracelets equipped with GPS tags and Time Depth Recorders were deployed on 4 different individuals (3 breeding females and 1 adult male). One of the bracelets was lost and the others were recovered after deployment durations of 378, 355, 355 and 30 days. The full archive of dive behavior was available for all the deployments, resulting in 1115 monitoring days. The maximum depths recorded were 393 m for an adult male and 429 m for a breeding female, but most of the dives (82.26%) were shallow < 50 m. Only 0.39% of the dives were to depths > 200 m. We identified 4 distinct dive types: traveling, shallow and deep bottom foraging, and bottom resting. The foraging dives occurred, on average, at 26 m and 102 m. Fastloc GPS antennas suffered from heavy damage due to abrasion with stones. Consequently, only 193 and 98 days of at-sea locations were obtained for 2 deployments of breeding females. The resulting GPS locations were distributed around Desertas and Madeira main island, but inside the 200 m depth contour. This suggests that monk seal foraging habitat at this archipelago is within this shelf area, which is limited to only 743 km2. The quality of the marine environment and fisheries management in this area may play a key in the recovery and sustainability of this endangered population.

To be or not to be: The role of absences when modelling cetacean distributions.

Fernandez Morron, Marc[1]; Sillero, Neftali[2]; Yesson, Chris[3]

Ecological niche models are a key element to apply effective management and conservation decisions. However, when working with cetaceans, obtaining accurate estimates of species' niches might be challenging, due to the species motility and the environment dynamism. While the concept of presences is quite straightforward (a place where the organism has been observed), absences might strongly differ. Methodological absences are the result of bias and scarceness in the survey information and represents the most important source of uncertainty for the study of species distributions. We used a theoretical framework (20 cetacean-based virtual species with distinctive habitat preferences and encounter rates) to better understand the role of absences when modelling cetacean distributions. We simulated a real-world survey to last 4 months per year over 4 years. Occurrence data (presence/absence) for the virtual species were pooled together with a set of environmental variables, 3 modelling approaches were used: presence-only (PO), presence-background (PB) and presence-absences(PA). The overlap between the constructed models and the virtual species on the geographical and environmental space was used to measure the accuracy of the projections. In general, results showed that PB models (specifically Maxent) were more accurate. However, differences were found between specialists and generalist species. For specialists, both PA and PB produced good estimates, with some variation related with the species prevalence (suitable area occupied by the species) and dynamism. On the other hand, PA algorithms (e.g. GAMs) for the generalist species produced highly over-fitted predictions, while PB methods produced good estimates. PA tended to model the sampling effort and not the species distribution. Therefore, the prevalence and the ecological specialization of the species studied can strongly affect the results of the algorithms used. As a precautionary approach, we recommend the use of several algorithms, together with overlap metrics to obtain a metric of the predictions reliability.

Stranding records of the Guiana dolphins Sotalia guianensis (van Bénéden, 1864) in the Amazon estuary, northern coast of Brazil

The Guiana dolphin *Sotalia guianensis* is restricted to bays, estuaries and shallow waters along the western South Atlantic and Caribbean coast, occurring in Central and South America. In the Amazon estuary (north coast of Brazil), this dolphin is one of the cetaceans most affected by incidental catches in gill nets, and consequently the most observed in strandings. This report is a preliminary approach about Guiana dolphin strandings in the Amazon estuarine regions of Marajó Island and northeast Pará State, recording between the years 2005 and 2016. We analyzed the annual frequency of strandings, and its seasonality variations based in the local rainy (December - May) and dry seasons (June - November). In addition, we estimate the age composition of 80 of the most preserved stranding specimens, by counting the Groups of Growth Layers (GLG) in teeth, to associate with the seasonal stranding pattern. During the twelve years of monitoring were recorded 608 strandings specimens: 70 females, 71 males and 467 of unknown sex. The lowest number of stranding occurs in 2016 (N=18, Mean=3±2SD), and a maximum number in 2013 (N=124, Mean=10±6SD). The stranding specimens ages ranged from one to 35 years old (Mean=12±7SD), and the more frequent ages were 2 and 10 years. The age classes from six to 18 years included 55% of the analyzed sample, containing only physically immature specimens frequently stranded in the rainy season. Changes in the strandings seasonality pattern were observed over the years. In six years, a major proportion of strandings (56 - 70%) occurred in the rainy season while in the other six years a dry season has the greater values (56 - 98%). These stranding seasonality changes and a number of immature specimens recorded are probably related to variations in the fishing activity/effort over the years in the Amazon estuary.

Using passive and active acoustics to explore spatio-temporal patterns of behaviour in coastal bottlenose dolphins and their prey

Cyclic patterns of top predators are predicted to be related to those of their prey. However, obtaining direct evidence of predator responses to prey behaviour remains challenging. We aimed to characterise seasonal, tidal and diel patterns of behaviour in a coastal population of temperate bottlenose dolphins and compare these to the spatio-temporal variation in the occurrence and/or behaviour of their prey. We used a 2010-16 dataset from passive acoustic devices (CPODs) to characterise variation in dolphin presence at three high density inshore sites in NE Scotland. Data revealed site-specific cyclical patterns in dolphin presence, with a strong tidal effect at one but not all sites, and a strong interaction between season and diel patterns. Notably, dolphin occurrence became highly nocturnal in autumn, which we predicted was due to an influx of wintering Clupeiid prey that exhibit nocturnal vertical migrations. To test this, we conducted monthly transects through 2018 at two study sites using a Simrad echosounder and 38kHz transducer. In addition, we repeated earlier studies that used a vertical array to estimate dolphin dive depths, with the aim of exploring whether dive depths also varied seasonally and nocturnally. There was marked short-term and seasonal variation in the 3D spatial distribution of prey schools that was related to observed seasonal and diel patterns of dolphin occurrence. However, we found no evidence of tidally related changes in prey at the site that exhibited strong tidal use by dolphins; most likely because these are probably related to changes in occurrence of large migratory prey that were less likely to be detected in echosounder surveys. Our findings demonstrate the value of integrating passive and active acoustics to better characterise predator-prey relationships in these coastal environments, but also highlight the need to consider other approaches to characterise the full range of prey available.

Hematological abnormalities in stranded Guadalupe fur seals (Arctocephalus townsendi)

Guadalupe fur seals (Arctocephalus townsendi; GFS) are endemic to the west coast of North America from Mexico to Washington State and were hunted to near extinction by the early 1900's. The population is now protected and has been increasing, however information on health is limited. A total of 78 GFS pups and yearlings that stranded alive in California between 2015 and 2018 during an Unusual Mortality Event were treated at The Marine Mammal Center (Sausalito, CA, USA). All were emaciated and the majority were considered anemic (hematocrit <35%: Hct) based on similar species blood value ranges. Anemia in stranded otariids often occurs secondary to malnutrition, trauma, parasitism or chronic disease, and usually resolves with improved nutrition and supportive care. However, progressive, severe anemia (Hct as low as 7%) occurred in five GFS with no evidence of concurrent disease during rehabilitation. Diagnostic testing varied but generally included fecal parasitology, radiography, ultrasound, and gastroscopy. Bone marrow aspirate and biopsy were performed in two cases. Infectious disease testing of (Sarcocystis, Toxoplasma, Neospora, Leptospira, Mycoplasma and Bartonella) was negative. Three animals recovered; two died: cause of anemia was not identified in any of these five cases. Trace element analysis from these five animals showed a severe decrease (10-fold or greater) in serum copper (range 0.2-1.78 to <0.02-0.16 ug/ml) with wide-ranging iron levels (42-109 to 27- 227 ug/dl) between admission and prior to release (n=3) or death (n=2). Samples from an additional 31 stranded GFS were analyzed for trace elements and 10 anemic GFS also had a large decrease in copper levels (0.52-1.45 to 0.04-0.19 ug/ml) and a similarly wide range of iron levels (30-158 to 41-195 ug/dl). Copper deficiency-associated anemia is rarely reported in humans and other species but should be considered in stranded GFS with persistent anemia where other cause is not identified.

North Pacific killer whales and climate change: Past, present and future.

A rapid increase in global annual temperatures leads to decreasing ice cover, causing many ecosystem effects including Arctic and sub-Arctic species range shifts. Killer whales are increasing their presence in the Arctic following ice cover loss. The impact of killer whales on marine ecosystems differs dramatically depending on ecotype: 'resident' R-type killer whales feed mainly on fish, while 'transient' T-type whales feed mostly on marine mammals. We examined the distribution and genetic diversity of R- and T-type killer whales in the western North Pacific in order to gain insight into their range shifts during and after the Last Glacial Maximum (LGM) and to predict the potential effects of climate change on their range.

R-type whales prevail in the coastal waters of eastern Kamchatka, Commander and Kuril Islands and in the central Okhotsk Sea, where deep waters occur close to shore. In contrast, T-type whales dominate the coastal waters of Chukotka and Okhotsk Sea, represented by wide shallows covered with ice in winter. The diversity of the complete mitochondrial haplotypes of both R- and T-type killer whales was lower in the western North Pacific than in the Aleutian Islands and the eastern North Pacific, suggesting the founder effect. We hypothesize that during the LGM killer whales were driven from the western North Pacific by unfavorable ice conditions, and re-colonized it later. This suggests that North Pacific killer whales avoid ice-covered areas but can re-colonize them soon after the ice retreats. Habitat preferences provide an indication that range expansion in the Arctic will likely involve mostly T-type killer whales and consequently increase the predation pressure on marine mammals to a greater extent than on fish stocks. This should be considered in further studies and prediction models highlighting Arctic marine ecosystem change, which is relevant to management of marine protected areas (MPAs).

Minke whales (Balaenoptera bonaerensis) in the Antarctic Weddell Sea – Spatial and temporal patterns derived from long-term passive acoustic monitoring

Antarctic minke whales (AMW) (*Balaenoptera bonaerensis*) occur in open as well as ice-covered waters throughout the Southern Ocean. Their low visual detectability and ice-associated habitat makes the species difficult to study using traditional visual methods. The recent identification of AMW vocalizations allows investigation of year-round spatial-temporal patterns of AMW occurrence in seasonally ice-covered areas by passive acoustic monitoring. Here we present AMW occurrence patterns based on 9 years (2008-2016) of recordings from 21 locations throughout the Atlantic sector of the Southern Ocean (Weddell Sea). Analyses were based on manual detection of daily presence of the bio-duck call, a characteristic acoustic signal attributed to AMWs.

We used generalized additive modeling (GAM) framework to investigate how vocal activity relates to month, ice conditions and recording latitude. AMWs were present from May to December at all but one recording locations, with highest presence occurring between August - November (>80% of days per month with bio-duck calls present). In general, acoustic presence of AMW in the Weddell Sea increases with local sea-ice concentration. At the southernmost recording locations, AMWs were present up to ten months of the year. This indicates at least a part of the AMW population remains in the Weddell Sea during austral winter.

We hypothesize that the bio-duck call has a function in a mating context and that the Weddell Sea may not only serve as a feeding ground for this species, but also provides a suitable breeding habitat for AMWs.

This long-term study, covering a large spatial scale, provides for the first time year-round information about AMW acoustic behavior in the Weddell Sea. These findings add new information about the AMW behavior and distribution in the Southern Ocean, providing valuable insights for management and conservation.

Risk of auditory damage and displacement from acoustic deterrent devices (ADDs) used in aquaculture

Acoustic deterrent devices (ADDs) are used to mitigate seal depredation on finfish aquaculture sites through the emission of loud acoustic signals. On the Scottish west coast, ADDs use is widespread, and these devices are considered to be a significant and growing source of underwater noise pollution, with detections of ADD noise increasing over the last decade. Given the frequency ranges (2-40 kHz) and source levels (greater than 185 dB re 1 µPa [RMS]) reported for these devices, there is a risk that ADDs could adversely affect the behaviour and physiology of seals and cetaceans.

To understand the risks of acoustic impacts on harbour porpoise and seals, this study aimed to predict the extent of ADD noise from aquaculture sites across the west coast of Scotland. An energy flux model was used to calculate transmission loss around aquaculture sites known to be using ADDs. This model was coupled with sound source levels of ADDs to identify high noise areas which overlap with sites designated for species protection, and to predict the potential for auditory damage in marine mammals, based on the 2018 NOAA criteria.

Received levels of ADD noise were predicted to remain high (>100 dB) even at considerable distances from aquaculture sites (>20km). Predicted ranges for seals and cetaceans to incur temporary (TTS) and permanent (PTS) threshold shifts were considerable. For example, an ADD signal with a sound pressure level of 194 dB re 1 µPa (RMS) could cause PTS in harbour porpoise if they remained within 3 km of the source for 24 hours. Maps of ADD noise highlighted several areas of concern for auditory damage to porpoise and seals. This work highlights the potential for auditory damage from ADDs on the west coast of Scotland, and the possibility of noise-induced displacement leading to exclusion from biologically important habitats.

Conditioned hearing suppression in dolphins warned of impending noise

Finneran, James
U.S. Navy Marine Mammal Program, San Diego, California
Corresponding Author: finneran@spawar.navy.mil

Some species of marine mammals can learn to reduce their hearing sensitivity as a way of "self-

mitigating" an impending noise exposure. At present, however, the underlying mechanisms and the spectral and temporal properties of such conditioned hearing suppression remain poorly understood.In this study, the ability of dolphins to self-mitigate noise exposures was investigated by examining changes in auditory brainstem responses (ABRs) to tone bursts presented before, during, and after a warning sound and intense tone. Measurements were conducted with trained bottlenose dolphins under water and in air. During underwater testing, binaural ABRs were measured in two dolphins as intense tone frequency and tone burst frequency and level were systematically varied. During in-air testing, monaural ABRs from each ear were measured in two additional dolphins as the intense tone level was varied. Results showed frequency-specific attenuation of ABRs after pairing the warning and more intense tones, with ABR threshold shifts (reduction in hearing sensitivity) as large as 40 dB. Suppression of ABRs occurred within a few seconds, and could be maintained for at least 31 s. Once the warning sound was no longer paired with the intense tone, ABRs returned towards baseline values. During in-air testing, ABRs originating in each ear were similarly attenuated when the warning/intense sounds were presented via a contact transducer located on the right lower jaw. Results indicate a neural mechanism originating at the level of the cochlea or auditory nerve, which suggests the involvement of efferent nerve projections to the cochlea. Self-mitigation of impending noise exposures may allow marine mammals to reduce noise impacts if they are warned of impending high-intensity noise; for example, by ramping up exposure levels. The potential for self-mitigation should also be considered when interpreting marine mammal temporary threshold shift data.

Using unmanned aerial vehicles (UAVs) to investigate the effect of tourism activities on cetaceans: An aerial perspective on humpback whale behavioral responses to swim-with interactions in Vava'u, Kingdom of Tonga.

The use of Unmanned Aerial Vehicles (UAVs) is revolutionizing marine mammal research. These include Vertical Take-Off and Landing (VTOL) UAVs, which have been successfully tested for several applications, such as cetacean behavioural surveys. This study represents the first empirical assessment of the effects of in-water tourism interactions on cetacean behaviour using UAV methodology. The Kingdom of Tonga is one of the few countries permitting "swim-with-whales" activities. The Vava'u archipelago, in particular, is one of the most important breeding and calving ground for Oceania humpback whales (*Megaptera novaeangliae*), where the local swim-with-whales industry focuses primarily on mother-calf pairs. Research on swim-with-cetaceans tourism indicates that these kinds of interactions affect cetacean behaviour and can lead to negative effects on the animals involved.

Eighty-two VTOL UAV surveys took place in Vava'u during the 2016 and 2017 whale breeding seasons from both dedicated research and swim-with-whales platforms. Whales' behavioral state was assessed from aerial videos recorded flying at 30 m altitude and the behavioral budgets in presence and absence of swim-with-whales tourism activities were compared. Whale calves' dive time, respiration and diving rates, and the time spent at the surface without the mother were also recorded. Results indicate that in-water tourism activities significantly altered humpback whale activity budgets in Vava'u. In particular, mother-calf pairs decreased the proportion of time spent nurturing (P<0.001), while time spent travelling increased two-fold (P=0.001). Furthermore, calf's respiration rate decreased significantly and the proportion of time alone spent at the surface increased more than four-fold (P=0.001). Finally, whale agonistic displays directed towards swimmers were observed. These findings highlight how UAVs can be a valuable tool for the assessment of cetacean behavioral responses to human activities and reinforce the need for a precautionary management of swim-with-whales tourism in Tonga and other countries, where these types of interactions are permitted.

Use of MOTE systems to augment argos data collection and maximize temporal resolution of GPS locations for a narwhal tracking study in Milne Inlet, Nunavut.

The potential effects of commercial shipping on narwhal movement along an active shipping route in Milne Inlet, Nunavut, were investigated by analyzing animal-borne tag data relative to AIS-based ship movements during the 2017 open-water season. High-resolution spatial and temporal data is required to effectively resolve fine-scale behavioural responses of narwhal relative to vessel distance. Location data was obtained from 15 narwhal outfitted with Argos satellite biologging tags (SPLASH-10 backpack tags with Fastloc GPS technology; Wildlife Computers) over a period of 33 to 94 days during the 2017 open-water season. Two Wildlife Computers MOTE installations (ground-based receiver stations) were used to augment successfully received tag transmissions in the local study area. The inclusion of MOTE data roughly doubled the data retrieved, compared to that collected by Argos satellites alone. Analysis of the realized Argos, MOTE and Fastloc data performance from 2017 allowed for an estimate of the highest potential rate of successful Fastloc GPS fixes and highest data throughput possible. When balancing data collection with data recovery, it was estimated that up to 12 successful Fastloc GPS locations may be recovered from a one-hour period. Tag programming in 2018 was modified to allow for collections of Fastloc GPS data at this maximum potential rate. Current analysis of 2017 movement data indicates that narwhal elicit behavioural responses to ships moving at distances up to 5-km, corresponding to an exposure period of approximately 30 minutes. This finding highlights the need for narwhal GPS location data with increased (sub-hourly) temporal resolution.

Utilizing next-generation sequencing to identify prey DNA in western north Atlantic grey seal (Halichoerus grypus) diet.

Traditional studies of pinniped diets rely on analysis of hard parts, or material surviving digestion, collected from scats. However, hard parts analysis can be biased because 1) seals can consume soft parts of large prey items, excluding hard parts, 2) certain prey possess fragile otoliths or other parts which degrade easily, and 3) some prey lack identifiable hard parts. Alternative methods such as fatty acid and stable isotope analyses of pinniped tissues are limited as they frequently can only identify prey with coarse taxonomic resolution. To counter these limitations and collect novel data on USA grey seal (*Halichoerus grypus*) feeding habits, we utilized next-generation sequencing of vertebrate prey DNA from seal scat using 16S amplicons. Our overall aim was to better understand grey seal foraging ecology amidst rising social, political, economic, and ecological controversies with increased seal abundance in the Gulf of Maine. We collected seal scat (N = 82) from two breeding colonies in Massachusetts, USA, and assigned seal sex to scat samples using a revised PCR assay. We detected 27 prey groups, 21 of which resolved to species level. Sand lance (*Ammodytes* spp.) was the most frequently consumed prey group (N = 70/82, 85.4%), consistent with previous studies, but Atlantic menhaden (*Brevoortia tyrannus*), the second most frequently consumed species (N = 32/82, 39.0%), was not previously documented in USA grey seal diets. We found site effects on prey alpha and beta diversity, and the presence of several prey groups, whereas effects of seal sex were important only in the occurrence of one prey group (Rajidae). Our results indicate a metabarcoding approach to deciphering seal food habits can yield important new ecological insights, but traditional analyses of hard parts from pinniped scats does not underestimate consumption of species (*e.g.*, *Gadus morhua*, *Salmo salar*) that are particularly economically important in this system.

Dammed to extinction? The precarious status of Southern Resident Killer Whales.

londonafletcher@gmail.com

As an 11-year-old with a keen eye to the planet's future, I have become involved in a flagship environmental issue for the region in which I live: Southern Resident killer whales (SRKW, *Orcinus orca*). Here, I and my collaborators review the status of this endangered population. The current estimate of abundance for SRKW is 75 animals in 3 pods, down from 98 in 1995. Reproduction is low, with only 6 calves born since 2015. Neonatal survival is also low, with approximately 70% of all calves dying in their first year. In addition, recent aerial photogrammetric images have shown that the body condition of some individuals is poor and indicative of nutritional stress. Various factors have been invoked as explanations for the decline in SRKW, including pollution, noise, harassment from whale watching vessels, and insufficient prey. Of these, the lack of prey is widely regarded as the principal factor affecting recovery. SRKW preferentially target

fat-rich Chinook salmon, the abundance of which has declined, in large part because of anthropogenic degradation of habitat. In Puget Sound, only 22 of at least 37 historic Chinook populations remain. The remaining wild Chinook salmon are at 10% of their historic numbers. The single most effective conservation action to assist SRKW would be breaching of four dams on the Snake River to restore free passage of spawning salmon; yet despite broad agreement on the importance of this, it remains seemingly politically intractable. Considerable funding has been proposed by the Governor of Washington State for SRKW recovery, but unless salmon populations are restored, SRKW will likely continue to decline.

Abundance and terrestrial habitat preferences of the Guadalupe fur seal (Arctocephalus philippii townsendi) at Isla Guadalupe, México

Corresponding Author: zintonisa@hotmail.com

Guadalupe Island has the largest colony of Guadalupe fur seals (*Arctocephalus philippii townsendi*), located 240 km off the western coast of the Baja California Peninsula, in the northeastern Pacific Ocean. During the 19th century, the Guadalupe fur seal was hunted intensely, causing a severe population decline. It is currently protected in Mexico. Populations have been monitored occasionally since the 1970s and their numbers have increased. All counts have been performed from boat or on land, and no aerial count for this taxon has been reported. In this work, the population abundance of the fur seal colony on Guadalupe Island was estimated through a correction function for the population estimates, by comparing boat counts and the simultaneous taking of images from an UAV (Unmanned Aerial Vehicle). A total of 29,972 organisms were counted in photographs taken from the UAV, while observers from the boat counted 11.4% less. Aerial monitoring was significantly more efficient than boat monitoring for the total count of organisms ($p<0.05$); however, detectability by categories is not affected by the increase in the number of organisms ($p>0.05$). In addition, observations were made from land on three beaches south of the island to determine terrestrial habitat preferences during the day, both by categories and by substrates. The response of the population density (individuals km^{-2}) to the daytime environmental temperature was inferred by categories and substrate. The model suggests that tolerance to the increase in atmospheric temperature, and therefore the need to enter water for thermoregulation, varies according to the age / sex category. The density of pups, females and subadult males on land decreases faster with the increase in temperature, while that of adult males is maintained at slightly higher temperatures. No preferences were found for any type of substrate in relation to the increase in temperature.

Small-scale patterns of distribution and ecotoxicological features in bottlenose dolphins (Tursiops truncatus) in the southern Gulf of Mexico

The Flora and Fauna Protection Area Laguna de Términos in Campeche, Mexico, has great ecological importance due to its biotic diversity, as well as being the most important area for bottlenose dolphins (*Tursiops truncatus*) in the southern Gulf of Mexico. However, this area has environmental issues, among them, the extraction of hydrocarbons, urbanization and agricultural activities that bring on the presence of pesticides in water, sediments and species of this coastal lagoon. The aim of this study was to identify the distribution zones and critical habitats for dolphins using ethological variables, delimit their home range using telemetry tracking in six adult specimens and finally, describe the spatial relationship between the dolphins and the presence of organochlorine pesticides, (mainly DDT and chlordane) in sediments and blubber of the dolphins tracked by telemetry. The results show three important sites for feeding of this species based on ethological records, as well as differences in the pollutants profiles of the six tracked specimens, such differences match with the spatial pattern of these compounds in sediments within the lagoon. These are the first results that combine data on patterns of marine mammal distribution and toxicology in the southern Gulf of Mexico and suggest that the distribution patterns of dolphins affect the concentrations of organochlorine pesticides on blubber on a small scale, these differences are usually found in populations that are located hundreds of kilometers.

Increase in large whale entanglements in 2018 in the Pacific northwest reflect improved reporting and changes in whale occurrence

Entanglements are one of the leading human-caused mortality risks to large whales. Off California, entanglement reports to the entanglement network increased dramatically around 2015, resulting in considerable management attention to this issue. A similar increase did not occur in the Pacific Northwest (Washington and Oregon), an area where there are generally fewer reports, until 2018 when the network received 19 credible reports (15 confirmed), with evidence of additional unreported large whale entanglements. This was a marked increase over previous years, in which the number of entanglement reports had always been under 10. Of these entanglements in the Pacific Northwest in 2018, humpbacks were the most commonly reported (n=12), followed by gray whales (n=6). Here, we examine potential causes for this increase, including heightened public awareness, dedicated survey effort, and changes in whale occurrence. From 2016 to 2018, we increased education and outreach efforts with an emphasis on timely reporting and documentation engaged local fisheries, management and the public. Research survey effort that directly resulted in some 2018 reports was also higher in 2018 than in previous years, due to a combination of NOAA ship surveys and small boat effort. Humpback whale numbers have also increased throughout the Pacific Northwest with an expansion of distribution into the Salish Sea and evidence of whales remaining for longer periods. In 2018, several hundred humpback whales were documented in the Strait of Juan de Fuca coincident with a gillnet fishery in that area. For gray whales, 2018 represented a year with increased sightings of emaciated animals lingering in areas of high fishing activity as well. We propose that the increase entanglement reports in 2018 represent a combination of better reporting for this region as well as shifts in whale occurrence bringing them into greater contact with fishing activities.

Harbour seals and ship noise: Quantifying the potential for masking of mating calls in Kattegat, the Baltic Sea, by acoustic modelling.

Underwater mating calls of harbour seals overlap in frequency with noise from ships and are thus prone to masking by the noise. The potential masking can be quantified by the excess level, which is the difference between total and natural ambient noise. The excess level is linked to the range reduction factor, which expresses the relative decrease in maximum communication range. An excess level of 20 dB translates – all else being equal – into a decrease in maximum communication range of 90%, under the simple assumption that communication signals propagate with a spherical spreading loss without absorption. A decrease by 90% or more is likely to affect mating behaviour, if it occurs for substantial parts of the breeding season. Therefore, excess level and thus potential for masking of seal calls, was modelled for the 25 major haul-out sites in Kattegat.

Natural ambient noise and ship noise was modelled independently by the acoustic propagation platform Quonops. Natural ambient noise was modelled on wind and wave statistics for July 2018 and ship noise based on AIS positions obtained for the same period. Results showed that 5% of the breeding site area (assumed within a 5 km radius around each site) was exposed to an excess level of 20 dB or more for 50% of the time. This corresponds to 5% of the population exposed above 20 dB for 25% of the time, if animal abundance is taken into account. Largest potential impact was on the sites close to both deep water and shipping lanes.

The suggested masking index has considerable potential as a simple, yet intuitive risk indicator in impact assessment of low frequency ship noise on aquatic animals, as it expresses the magnitude of the overlap (in time and space) between the ship noise and the animals.

Islands in the stream: Movement patterns of satellite-tagged pilot whales in the south Atlantic bight.

To improve our understanding of the spatial ecology of short-finned pilot whales (*Globicephala macrorhynchus*) in the western North Atlantic, we deployed eight satellite-linked depth-transmitting tags off Jacksonville, Florida in June 2016 and November 2018. Tags transmitted up to 47 days (mean=32±11). Location data were processed with the Douglas Argos-filter to remove unrealistic positions. All tagged individuals exhibited a distinctive, repeated cyclical pattern of movement. Individuals followed the Gulf Stream north over the Blake Plateau, then moved east out of the Gulf Stream and returned south, before repeating the cycle. This pattern differs considerably from that observed in short-finned pilot whales tagged off Cape Hatteras, North Carolina (n=54), most of which demonstrate a strong affinity for the continental shelf break, including the region's canyons. However, two short-finned pilot whales tagged off Cape Hatteras in 2017 moved into the South Atlantic Bight (SAB) and exhibited movement patterns similar to those tagged off Florida. Hierarchical switching state-space models indicate that the whales tagged off Florida exhibited a low proportion of area-restricted search over the Blake Plateau (individual mean=0.23), but it is possible that the whales were foraging as they were being passively advected by the strong northward flow of the Gulf Stream. The mean depth of dives across individuals was 357m, over a mean depth at model-predicted locations of 745m, suggesting that whales were foraging in the mesopelagic realm. Telemetry tracks and photographic matches of well-marked individuals demonstrate that pilot whales in the SAB move to several adjacent areas, including North Carolina and the Bahamas, but individuals in the SAB appear to respond to the unique set of environmental features in the region. Taken as a whole, our findings indicate that short-finned pilot whales are adept at matching their foraging strategies to their local environments in the western North Atlantic.

Discharge water effects study consumed by the inhabited dwellings in ecosystem systems from the Mediterranean area, within the circular economy and climate change circle.

Fonseca, Carme
UNESCOSOST, UPC, barcelona, Barcelona, Spain

This research work connects different Global Objectives of Sustainable Development, SDGs (United Nations, 2018):

- Nº.6 Clean water and sanitation.
- Nº 9 Industry, innovation and infrastructure.
- Nº11 Sustainable cities and communities.
- Nº14 Life below water.
- Nº17 Alliance to achieve the objectives.

Water is a scarce resource essential for shared life among all the living beings that inhabit it, we must work for its conservation; overpopulation, climate change and poor management of resources have a negative impact on water and ecosystem services linked to it, this affects the economy of the country. Water resources should be included in the management policies of the countries as an added value of the circular economy of these, currently it's not considered.

This work analyzes the water cycle in a house and its effects in the ecosystemics systems from the mediterranean area using a simulation program developed by PolyhedraTech, improving it the habitants from the inhabited nuclei can decide which are the best strategies to improve their use of clean water, taking into account its effects in the circular economy, minimizing the impacts on ecosystem services and, finally, acting as a knowledge brokerage between the different actors and society to advance in the reduction of human impact in the environment

There are several actors from different groups with converging concerns in this aspect, but projects that work in a transdisciplinary way have rarely been articulated; this work links architects, biologist and enginers with a same purpose, to minimize our effects in the ecosystemics systems and to optimize the water consumption.

The evolutionary history of the porpoise family across the speciation continuum through the lens of a comparative genomic approach: Putting conservation issues into an evolutionary framework.

The porpoise family (Phocoenidae) has seven species that inhabit mostly temperate waters and display a textbook example of anti-tropical distribution. Their evolutionary history remained poorly known, and some species face major conservation issues (e.g., critically endangered vaquita and Yangzte finless porpoises). Here, we used a comparative genomic approach to reconstruct the evolutionary history of porpoises across the entire speciation continuum, from the intraspecific level to species divergence in relation to past climatic changes. We assembled the mitochondrial genomes and resequenced at low coverage the entire nuclear genome of 63 porpoises. Phylogenetic reconstructions suggest that, like other toothed whales, porpoises radiated during the late Miocene-Pliocene but their current intraspecific subdivisions were shaped by environmental variations during the Quaternary Glaciations. We highlighted a parallel evolution in both hemispheres associated with symmetric adaptations to different environments (coastal *versus* pelagic) exhibiting convergent patterns of coloration and genetic diversity. This result suggests that the mechanism driving diversification of the well-known species of the Northern Hemisphere may apply also to the poorly-known southern species. In contrast to previous results, our results showed that spectacled and Burmeister's porpoises share a more recent common ancestor than with the vaquita. The vaquita diverged from southern species during the Pliocene but has low diversity, possibly due to long-term small population size, population bottleneck(s), or small founding population in the Gulf of California. We also observed divergent lineages within Dall's, spectacled and North Pacific harbor porpoises, suggesting a richer evolutionary history than previously thought. Genetic inferences of demographic trends from mitochondrial and nuclear genomes for each species and sub-species shed light on the dynamics of population size fluctuations and subdivisions. These results provide a new perspective on the divergence, adaptation and speciation processes of the porpoises. We will discuss how this knowledge can provide an evolutionary context for their conservation.

Blubber stratification of Tursiops australis and implications for using remote biopsies

Remote blubber biopsies can provide vital information on the life history, genetics, health biomarkers, toxicant levels, and diet of free ranging marine mammals in a minimally invasive manner. However, for a number of marine mammals the blubber layer does not have uniform composition with the level of stratification differing between species. Knowledge of any stratification that exists within a study species is crucial in the interpretation of blubber biopsy analysis. *Tursiops australis* is a newly described dolphin species, with two genetically distinct and isolated populations in Victoria, Australia. Due to the recent description in 2011, limited research has been undertaken on this species, however stable isotope analysis suggests the diet of these two populations differ. We identify the degree of blubber fatty acid stratification in the newly described *T. australis*. Whole blubber layer samples have been collected from stranded individuals, sub sampled into vertical layers and fatty acid methyl ester (FAME) analysis conducted to determine the level of stratification. This

provides the base knowledge of fatty acid distribution within the species and provides context to the use biopsies of free ranging individuals to assess the diet within each population.

Global dataset of killer whale genomes reveal a complex history of recurrent admixture and vicariance.

Reconstruction of the demographic and evolutionary history of populations assuming a consensus tree-like relationship can mask more complex scenarios, which are prevalent in nature. An emerging genomic toolset, which has been most comprehensively harnessed in the reconstruction of human evolutionary history, enables molecular ecologists to elucidate complex population histories. Killer whales have limited extrinsic barriers to dispersal and have radiated globally, and are therefore a good candidate model for the application of such tools. Here, we analyse a global dataset of killer whale genomes in a rare attempt to elucidate global population structure in a non-human species. We identify a pattern of genetic homogenisation at lower latitudes and the greatest differentiation at high latitudes, even between currently sympatric lineages. The processes underlying the major axis of structure include high drift at the edge of species' range, likely associated with founder effects and allelic surfing during post-glacial range expansion. Divergence between Antarctic and non-Antarctic lineages is further driven by ancestry segments with up to four-fold older coalescence time than the genome-wide average; relicts of a previous vicariance during an earlier glacial cycle. Our study further underpins that episodic gene flow is ubiquitous in natural populations, and can occur across great distances and after substantial periods of isolation between populations. Thus, understanding the evolutionary history of a species requires comprehensive geographic sampling and genome-wide data to sample the variation in ancestry within individuals.

Leopard seal migration phenology responds to long-term variation in sea ice extent

The phenology of migration is poorly understood in pinnipeds with large distribution range and relatively low abundance such as the leopard seal. Yet, it is important to understand how long term environmental variation and change is affecting their populations, local communities, and the wider ecosystem. In the Scotia Sea (southwest Atlantic), migrating seals reach the South Georgia archipelago –over 1000 km North from the pack-ice in a straight line– between February and November, and have stopover periods ranging between one day and a few months, when seals predate on locally abundant prey including other seals, seabirds, fish and crustaceans. Here, using photoidentification of 402 individuals between 2005 and 2018, we show that at Bird Island, northwest South Georgia, leopard seals migrating from the pack-ice arrive earlier, stay longer and their numbers fluctuate significantly with trends consistent with long-term variation in the sea ice environment. Our study period encompassed a temporary absence of warming in the Antarctic Peninsula and increased sea-ice extent in the Weddell Sea, which negatively correlated with the arrival of individuals and their total numbers, and positively correlated with mean stopover times. Using mark-recapture models of seasonal abundance combined with bioenergetics models and a diet analysis we found that the highest predation impact of leopard seals was on gentoo penguins (between 4 and 30% of the estimated Bird Island population), and even in years with low total numbers of seals, predation could be high because of increased stopover times. These results indicate that long-term changes in the sea-ice extent can determine the migration phenology of the leopard seal, with consequences for the prey populations they exploit at their winter destinations.

Managing anthropogenic risks to marine mammals in a changing climate: Dynamic humpback whale models to reduce entanglement risk along the U.S. West Coast.

Along the U.S. West Coast, reports of entangled of humpback whales, *Megaptera novaeangliae*, have historically been rare, but since 2014 there has been a dramatic increase, peaking at 48 confirmed reports during 2016. Causes of this increase are complex and primarily driven by unusually persistent warm ocean conditions, which in turn affected forage species distribution, timing and intensity of fishing effort, and the distribution of foraging humpback whales. Combined with increasing humpback whale populations, these factors exacerbated the spatiotemporal overlap between whales and fixed-gear fisheries, especially the California Dungeness crab fishery. A multi-stakeholder working group tasked with reducing whale entanglements has developed an ecosystem-based process for mitigating entanglement risk before and during the Nov-July crab fishing season. The assessments are based on monitoring ocean conditions, krill and anchovy abundance, observed or predicted whale distributions, and expected fishing dynamics, taking into account the impacts of harmful algal blooms and crab market pricing. To support these risk assessments, we have developed a fine-scale (3x3 km), year-round model of humpback whale density within shelf/slope habitats where whales and the crab fishery overlap. The habitat-based model integrates 2005-2014 summer/fall shipboard line-transect survey data with bathymetry and dynamic ocean habitat variables from a data-assimilative ocean circulation model and high-resolution sea surface temperature data. Independent ecosystem and marine mammal survey data from regional ship and aerial surveys were used to validate model predictions, using quantitative metrics including area-under-the-curve and true skill statistic, as well as visual inspection of predictions vs. sightings. Bi-weekly and monthly model predictions successfully captured observed interannual and seasonal patterns in humpback whale distributions, providing a dynamic tool for assessing and mitigating whale entanglement risk. Such tools are becoming increasingly important as climate-driven changes to marine ecosystems alter the nature and

extent of human interactions with marine mammals.

Short-finned pilot whale population and social structure off Cape Hatteras, North Carolina, USA.

Short-finned pilot whales (*Globicephala macrorhynchus*) are a highly social species which typically live in stable matrilineal groups but mate outside the group. Off Cape Hatteras, North Carolina, short-finned pilot whales are often found in large aggregations of several hundred animals. The study site runs along the continental shelf break, and previous research has indicated that this is an important foraging area for the population. In addition to its importance as foraging habitat, we used genetic data to investigate Cape Hatteras as a breeding site for short-finned pilot whales. We used RAD-sequencing to develop a panel of nuclear markers from 43 biopsy samples, including 18 pairs of individuals biopsied in the same group. After filtering, we retained 9610 high-quality single nucleotide polymorphisms for analysis. We used these markers to estimate an effective population size of 2671 (CI 2183-3440) individuals utilizing the Cape Hatteras region, with no evidence of population structure between seasons. In addition, we calculated and compared relatedness among individuals biopsied in the same or different groups. All female pairs sampled in the same group were close relatives (n = 5), while 78% of mixed-sex pairs sampled in the same group were unrelated (n = 9) as well as all male pairs biopsied together (n = 4). Female pairs were more likely to be related than male or mixed-sex pairs, but we found no evidence for sex-biased dispersal (mAIc; t = -0.936, p = 0.355), suggesting that potential male dispersal is social rather than geographical. This could indicate that males may be temporarily leaving their family units to seek out mating opportunities, and that Hatteras may be an important area for breeding as well as foraging.

Are there enough Chinook salmon for Southern Resident Killer Whales?

Fortune, Sarah[1]; Sato, Mei[2]; Trites, Andrew W.[3]

Southern Resident Killer Whales show signs of poor body condition, which suggests they are unable to obtain enough of their preferred prey (Chinook salmon). However, it's unknown whether this apparent energy deficit is due to reduced abundance and quality of salmon from overfishing or environmental change, or reduced salmon accessibility by killer whales due to vessel traffic and acoustic disturbance. We sought to test the hypothesis that the availability and/or abundance of Chinook salmon is insufficient to support a healthy population of Southern Resident Killer Whales. To determine whether food limitation is driving the poor health and recovery of the Southern Residents, we conducted a co-located, fine-scale, predator-prey study to compare the availability and abundance of Chinook salmon using multi-frequency echosounders and simultaneous recordings of foraging behaviour of Southern and Northern Resident Killer Whales (a contrastingly healthy population). Knowing the vertical distribution and abundance of salmon encountered by actively foraging killer whales is critical for evaluating how prey may be limiting the foraging success of these salmon specialists. The results of our study provide important insight into the mechanisms driving the apparently poor health and recovery of Southern Resident Killer Whales and ultimately help determine how to best manage this endangered species.

Deep diving pilot whales make cheap, but powerful, echolocation clicks with extremely small volumes of air.

Echolocating toothed whales produce powerful clicks pneumatically to detect prey in the deep sea where this long-range sensory channel makes them formidable top predators. However, air supplies for sound production shrink with depth following Boyle's law so that the available air volume for sound production at 1000 meters is 1% of the volume inhaled at the surface. This leads us to hypothesize that deep-diving whales must use very

small air volumes per echolocation click at depth and recycle the used air to facilitate continuous sensory flow in foraging dives. Here we test these hypotheses by analysing click-induced acoustic resonances in the nasal air sacs, recorded by sound and movement recording tags (DTAGs). Harnessing a fish swim bladder model to interpret these resonances, we are able to estimate the volume of air used per click as a function of depth. We then use the estimated air volume per click to infer the metabolic cost of clicking. Using 27000 clicks from 102 dives of 23 tagged pilot whales (*Globicephala macrorhynchus*) at Tenerife, we show that click production requires only 50 µL of air/click at 500 m depth increasing linearly to 100 µL at 1000 m. With such small air volumes, the metabolic cost of sound production is estimated to be on the order of 40 J per dive which is a negligible fraction (<0.1%) of the energy budget of a foraging dive. Nonetheless, step changes in the acoustic resonances indicate that whales make frequent pauses in echolocation to recycle air between nasal sacs. Thus, economic use of air and periodic recycling of very limited air volumes enable pilot whales, and likely other toothed whales, to echolocate cheaply and almost continuously throughout foraging dives providing them with a strong sensory advantage in diverse aquatic habitats.

Bearded seals adjust calling behavior to compensate for ambient noise in the Alaskan.

In anticipation of dramatically reduced Arctic sea ice, planning is underway for a wide variety of offshore anthropogenic activities. One of the most poignant threats associated with industrialization is the increase in anthropogenic noise. This is particularly true for Arctic phocids that breed underwater and use sound to facilitate mate selection. Male bearded seals *(Erignathus barbatus)* produce elaborate underwater vocalizations believed to attract mates and defend territories; this species may be negatively impacted by increased anthropogenic noise as calls fail to reach intended receivers and energetic costs associated with increased calling effort are incurred. In order to assess species' resilience to anthropogenic perturbations, it is essential to first document behavioral responses to naturally occurring phenomena. Using multi-element time-aligned hydrophone arrays, we investigated whether bearded seals in the Alaskan Beaufort Sea employed a Lombard Effect (increased calling amplitude) in response to changes in noise levels from natural sources. Bearded seals exhibited a linear increase in call source levels associated with ambient noise; noise explained 36% of the variance in source levels. For every 1 dB increase in ambient noise, call source levels increased by 0.57 dB re 1 µPa (95% C.I. 0.4 - 0.7) indicating that seals were capable of adjusting their behavior, but did not compensate exactly for elevated noise. A broad range of ambient noise levels were observed (78 - 107 $dB_{RMS\ 10\text{-}900\ Hz}$); the highest noise levels were dominated by calling bearded seals, and to a lesser extent bowhead whale calls. While overlapping conspecific calls occurred, there was evidence that seal calls were temporally stratified. This in combination with the observed Lombard Effect may be an effective strategy to contend with periodic sounds from biological sources; however, this strategy may not be effectively applied to continuous noise sources, like vessels or marine construction.

Insulin and blubber deposition in rehabilitating harbor seal pups (Phoca vitulina).

mfowler3@springfieldcollege.edu

Seals and sea lions (pinnipeds) go through naturally occurring stages of nutrient restriction alternating with rapid weight gain. Recent work has focused on how pinnipeds manage fuel stores during periods of fasting, whereas the physiological management of weight gain has been less well-studied. Pinnipeds undergoing rehabilitation were used in a controlled setting to investigate the relationship of an important metabolic hormone, insulin, to mass gain and lipid deposition. Over two seasons, 16 rehabilitating harbor seals pups were monitored as they were fed a steady caloric intake. Plasma insulin levels, mass gain and blubber deposition were measured over the 8 week rehabilitation period. Plasma insulin levels were low, but increased significantly across the sampling period and were positively related to blubber deposition and overall mass gain. These results indicate that despite low circulating levels, insulin may play a lipogenic role in seals and that insulin sensitivity may be an important labile physiological variable affecting lipid metabolism during different life history phases. Quantifying insulin sensitivity in blubber as well as additional mediators of lipogenesis such as adiponectin during rapid lipid accumulation will further elucidate the mechanisms

by which pinnipeds modulate the relationship between insulin and lipid metabolism.

Modeling bottlenose and striped dolphins' distribution in relation to their prey's biomass in the Mediterranean Sea

Species distribution models (SDMs) provide a useful analytical framework to study the environmental and anthropogenic factors that influence species distribution patterns, returning information that can help to define their geographical ranges and clarify which areas constitute important/sensitive habitat for their survival. For cetaceans, it has been recently shown that SDMs can be significantly improved by analyzing the species' distribution in relation to their prey, to try to account for the biotic interactions of these species with other community members on which they depend. We show here how identify areas with high probability of occurrence for two species of delphinids, one characterized by predominantly coastal habits (the bottlenose dolphin, *Tursiops truncatus*), the other pelagic (the striped dolphin, *Stenella coeruleoalba*) by modelling species' spatial location information in conjunction with their main preys. We used 1) dolphins' presence-only pooled records gathered over a 12-year period (2008-2019) by different research groups in the central Tyrrhenian Sea and systematically derived from shared photos/videos by boaters/maritime operators on social media, and 2) data on distribution and biomass of some fish and cephalopod species targeted by bottlenose and striped dolphins resulting from MEDITS survey program (International bottom trawl survey in the Mediterranean). This information has been used to model bottlenose and striped dolphins' distribution in combination with different environmental parameters, anthropogenic factors and biological cues as covariates. Log-Gaussian Cox point process models were fitted relating the dolphins' presence records to the biomass of their preys and covariates, also accounting for spatial correlation. As expected, the estimated intensity functions differed between the two species, and clear-cut relation patterns emerged especially for bottlenose dolphin. This approach could facilitate the prediction of the species' geographic distributions and the spatial identification of possible trophic interactions among species, together with the associated environmental setting, to assist management and conservation strategies.

Echo-devo: Ontogeny and evolution of the sound generating structures in dolphins (Odontoceti: Delphinida).

The ontogeny of the main structures involved in sound generation and modulation in dolphins was investigated through the comparison of the soft nasal structures between fetal, perinatal, neonate and adult specimens of three families (Pontoporiidae, Phocoenidae and Delphinidae). Fetal samples were sectioned at 10 µ in saggital and coronal view, and stained. Existing CT and MRI-scan series were combined with new data to better represent the ontogenetic stages of the three groups. The image series were analyzed in 3D-Slicer to characterize the topographical arrangement of the tissues surrounding the nasal passage. The muscles and connective tissues surrounding the blowhole region were dissected, layer by layer, to describe and lay out the nasal soft

tissues. Morphological ontogenetic-based transformations were used to create transformational characters for phylogenetic inference. The morphogenesis of the soft nasal tissues in dolphins was remarkable for its transformation during early fetal stages: the origins of the melon and the vestibular air sac were detected between Carnegie stages C16 and F22. The three groups analyzed presented distinct formation of the nasal plug and nasal plug muscles, mainly on the loss of fat pathways (or their maintenance in Pontoporiidae) and the hyperdevelopment of the nasal plug muscles in both sides (e.g. during perinatal development of Phocoenidae) or just on the left side (e.g. during postnatal development in Delphinidae). We suggest that ancestral forms of all known delphinidans might have exhibited unique soft nasal tissue morphology capable of producing highly directional sounds as known for some narrow-band high frequency species. Thus, broad-band vocalizing delphinidans, such as most delphinids, might have evolved under heterochronic events acting on the formation of the rostrum and vestibular air sacs formation, as well as on the transformation of the branches of the melon, in turn leading to a reduced directionality of the sonar beam.

Scientific tools for estimation of bycatch impacts on marine mammal populations: An ocean modeling forum working group.

The Ocean Modeling Forum at the University of Washington, Seattle, USA, has convened a Marine Mammal Bycatch Working Group in response to the US Marine Mammal Protection Act (US MMPA) Import Provisions, issued in 2016 by the U.S. National Oceanographic and Atmospheric Administration (NOAA). The rule requires nations that wish to continue exporting fish or fish products to the United States to adhere to bycatch standards comparable to those of the United States. The working group is compiling resources and developing scientific tools to help nations comply with the rule, with a special emphasis on data-poor fisheries. The project draws from case studies in Chile and Iceland, and uses management strategy evaluation tools to simulate how fisheries management might perform with sparse or biased data, while still meeting standards that are comparable in effectiveness to US MMPA objectives. The working group has four planned projects. The first two will address important steps in setting and applying bycatch standards: practical tools for estimating marine mammal abundance, and assessing bycatch mortality rates. The third is an online tool to synthesize data and evaluate potential management strategies. The fourth further evaluates applicability of the potential biological removal (PBR) method, the primary U.S. bycatch standard. Our objective is to provide tools and approaches to countries that aim to demonstrate standards that are comparable in effectiveness to US standards, even in cases where data quality or quantity may fall below those of many well-monitored US fisheries. Our objective in presenting the Marine Mammal Bycatch Working Group program at the World Marine Mammal Science Conference is to update marine mammal scientists and managers from >60 countries on progress made, encourage beta testing of our products, and identify opportunities to collaborate on implementation in countries where such tools are needed and our assistance may be welcomed.

Temporal trends in humpback whale abundance in Hawai‘i and response to climatic drivers

In 2001, the non-profit Hawai‘i Marine Mammal Consortium initiated long-term monitoring with scan sampling methodology to study the relative abundance and distribution of humpback whales (*Megaptera novaeangliae*) in their Hawaiian breeding grounds. An average of 18 scan samples were collected annually (2001-2019) from a shore site overlooking Kawaihae Bay, Hawai‘iIsland, using methods to keep effort consistent. Each sample counted the number of groups and whales and measured each group’s position with a theodolite and reticle binoculars. Counts of whales and calves were analyzed using General Additive Models, including predictor variables of year, date, observational conditions, and observer, to establish a base model. Climatic indices were then added to the model, one at a time, and their contributions were evaluated using the Akaike Information Criteria. Numbers of whales and calves showed a clear increase from 2001-2010, but became variable and dropped sharply in the latter years of the study, including a precipitous 60% drop between 2013 and 2016 (coincidentally, the year of delisting Hawai‘ihumpbacks under the Endangered Species Act). The proportion of calves showed a

similar decrease, reaching a record low of 1.1% in 2016. Increased numbers of "skinny" whales in Hawai'i (2016-2019) and trends in Alaska feeding areas, suggested that prey scarcity could be a factor in the observed changes. The two best models included the Pacific Decadal Oscillation index (lagged 1.5 years) and the North Pacific Gyre Oscillation index (lagged 2.5 years). Both models indicated that whale and calf numbers increased when these climate indices reflected colder water in the North Pacific. These results suggest that oceanographic conditions during prior feeding seasons affect the number of whales on the Hawaiian breeding grounds. Continued long-term monitoring of whale populations is essential to documenting and understanding population level responses to global climate change.

Postmortem attractions: Humpback whales investigate the carcass of a killer whale depredated gray whale calf.

Postmortem attentiveness to members of one's own species, thanatology, has been observed in various animal taxa and includes cacophonous aggregations in crows, skull fondling by elephants, and leaf dropping/adornment of the deceased by chimps. Cetaceans have been observed to care for, attend to, be aroused by, or show interest in dead or dying individuals. This includes a female southern resident killer whale who pushed or carried her deceased calf for 17 days and 100's of miles. To date, nearly all records of postmortem attentive behavior (PAB) in cetaceans are from odontocetes and directed towards members of their own species. Among the mysticetes only one observation of PAB has been recorded in the literature. This involved two adult humpbacks displaying interest in, and being sexually aroused by, a dead adult conspecific, believed to have died participating in a competitive group. Here we report on two adult humpback whales investigating and making gentle physical contact with a dead gray whale calf depredated by killer whales. This extends the list of hypersocial behaviors exhibited by humpbacks, and provides the first report of interspecies postmortem attentive behavior (iPAB) between wild species of cetaceans.

Cetacean strandings on Boa Vista Island (Republic of Cabo Verde): 2000-2019.

Twenty-four cetacean species have been described in the waters of the Cabo Verde Islands, Northwest Africa. Boa Vista (620 km2), with a coastal perimeter of ca. 115 km, constitutes the easternmost island of the archipelago and has the largest shelf, with shallow coastal and offshore waters, and occurrence of nearshore reefs. More than 40 cetacean strandings (>800 animals) has been reported here since 2000, involving 13 species, 2 Mysticetes and 11 Odontocetes. First records of four species in Cabo Verde include: minke whale (*Balaenoptera acutorostrata*), dwarf sperm whale (*Kogia sima*), false killer whale (*Pseudorca crassidens*) and pygmy killer whale (*Feresa attenuata*). The short-finned pilot whale (*Globicephala macrorhynchus*) and the melon-headed whale (*Peponocephala electra*) account for most strandings events (ca. 31% and 19%, respectively). The mean annual number of cetacean strandings events has been 2.1, with a maximum number of 5 in 2015. Mass strandings represented ca. 40% of all events, with numbers ranging between 3 and more than 200 animals. No significant differences in number of strandings where observed between the winter (November-April) and the summer (May-October) months. Unfortunately, the lack of technical and logistic resources has made it almost impossible to investigate the potential causes behind these cetacean strandings. To develop a Cabo Verde National Stranding Network which includes; training staff, veterinarian support, capacity building, funding, outreach and education in order to better deal with these events are essential priorities.

Minimizing competition in space and time in a limited marine insular coastal habitat: Cetaceans in the Madeira archipelago.

Oceanic islands seem to be important for cetaceans, considering their usually high species diversity. Thus, to better understand cetaceans' ecology it is important to study how different, apparently competing, species share limited resources in such usually small insular habitats. From 2001 to 2017, 56 127 km of effort were carried out in Madeira archipelago inshore waters in dedicated line-transect aerial and shipboard surveys, random shipboard surveys and observers on whale-watching and fishing boats. A total of 1177 sightings of 10 cetacean species and two genera were recorded on effort. Data were combined to model the spatial distribution of relative abundance of these taxa using Generalised Additive Models (GAMs), where survey type was a factor covariate, 43 other environmental covariates were explored, and model selection was based on the lower corrected AIC score. Bottlenose dolphins were present year-round, common dolphins mostly in winter and spotted dolphins in spring/summer. Bryde's whales were present in summer/autumn and fin whales peaked in March. The deep diving species were present year-round; sperm whales intermittently throughout the year, short-finned pilot whales peaking in October and beaked whales in August. All species, including the most sighted species, had an overall limited overlap in distribution, with physiographic, productivity and oceanographic related covariates explaining the sightings distribution, but with "mixed layer depth" as a common covariate to all deep diving species. In such a small insular oceanic habitat as Madeira archipelago coastal waters, with higher productivity than the surrounding oligotrophic sea, cetacean species seem to minimize competition for resources by a differentiated temporal and spatial use of the study area, with a few more abundant species taking advantage of the available resources while the remaining species, far less abundant, tend to use these waters while in migration, intermittently throughout the year, further offshore, or opportunistically.

Macroplastic counts at sea in the southeastern Thyrrhenian Sea and northwestern Ionian Sea

Frey, Silvia; Claro, Bruno
OceanCare, Switzerland
Corresponding Author: sfrey@quickline.ch

It is evident today that plastic debris is a major threat to cetaceans and other marine life. The Mediterranean Sea has been identified as one of the worldwide "hotspots" for land- and sea-based sources of plastic and microplastics. However, information on the quantitative extent of marine plastic pollution and the temporal evolution of the abundance of floating plastics are still sparce. In the context of a long-term cetacean monitoring project along the northeastern and eastern coast of Sicily (incl. Strait of Messina), Mediterranean Sea, we started to examine the extent of the plastic pollution in the surface waters based on visual debris counts. Floating debris on the water surface has been counted continuously during line transect surveys and recorded on a standardised protocol in 20-minute intervals. Counts were assigned to 12 categories (e.g. fragments, nets, bags, and non-plastics). Density maps (plastic items/km2) have been established. Floating debris has been counted during 916.9 km, 1,233.9 km, and 1,490.4 km in 2016, 2017, and 2018, respectively. Our results confirm that floating debris is ubiquitous as almost no count interval resulted in 0 observed floating items. More than 90% of observed debris consisted of plastic fragments. Highest numbers of floating plastic items have been found in the more northern part of the study area near the Strait of Messina. Our first study results allow to identify local "hotspots" of floating plastic debris in the study area and thus add information about the habitat quality. Our sampling efforts will be continued in the future and complemented by microplastic surface sampling, as well as the analysis of the chemical composition of both floating plastic and microplastic. Moreover, our data may serve as a basis for future modelling approaches to better understand the spatial and temporal distribution of floating plastic debris in the area.

Feeling the squeeze: Antarctic minke whales balance the dual pressures of maximizing energetic gains and finding suitable habitat around the rapidly changing Antarctic Peninsula.

The Antarctic Peninsula is warming rapidly, manifesting in decreased sea ice cover and changing prey availability. Antarctic minke whales (AMW) are the smallest baleen whale species, yet are the ecosystem's largest ice-affiliated endemic krill predator, and their foraging behavior and ecology remain unknown. Consequently, we lack fundamental information regarding baleen whale foraging ecology and more specifically, how climate-driven changes affect AMWs and related ecosystem dynamics. We use motion-sensor tags combined with scientific echosounder data on prey patch shape, depth, and density to test hypotheses regarding how changes in prey availability influence AMW feeding behavior, foraging rates, and energy gain. Using novel animal-borne video on tags, we measure sea ice presence and concentration at every surfacing event to test hypotheses regarding how AMWs balance the pressures of finding suitable prey while accessing preferred sea-ice habitat. In 2018-9, we deployed 33 tags on AMWs in coastal bays resulting in >400 hours of data. Additionally, we surveyed >430 km for prey availability. Preliminary analyses reveal that AMWs have faster feeding rates than any other baleen whale species, modulated by krill depth and density. AMWs fed throughout the day on a deep and dense krill layer between 100-200m. Krill then migrated vertically at night and dispersed, and minke whales ceased foraging. During daylight hours AMWs spent 52% of their time in open water and only 15% of their time in ice cover greater than 20% suggesting that prey significantly affects fine-scale distribution. Our results 1) provide an emerging understanding of how foraging behavior and energetics scale across baleen whales, 2) help to evaluate the potential for competition with other krill predators (e.g. humpback whales) as ice-free conditions manifest, and 3) provide a foundation for determining how changing sea ice conditions affect the persistence and dynamics of minke whales in this region.

Policy approaches for more sustainable marine wildlife watching

Since its inception in 1979, the Convention on the Conservation of Migratory Species of Wild Animals (CMS) has produced many resolutions and decisions that contribute to the overall goal of conserving species with an unfavourable conservation status and their habitats. One topic of recent focus is that of marine wildlife watching, including both boat-based activities and in-water interactions. The growing popularity of recreational wildlife encounters has in some areas resulted in unsustainable pressure being put on local animal groups. This has resulted in a benign use of wildlife to turn into a potential threat. Negative effects of unregulated marine wildlife watching activities include changes in habitat use and/or displacement, changes in short-term natural behaviour, chronic stress, changes in energy expenditure with potential negative consequences on individuals and overall population health, as well as injuries and death as a consequence of collision with boats or other motorized vessels. In response to this, particularly with respect to cetaceans, much guidance has been produced, including the 2018 Online Whale Watching Handbook co-produced by the IWC and CMS. CMS has also produced guidance for other affected species groups, namely pinnipeds and sirenians, sharks and rays, marine turtles and sea birds. While to date the focus was mostly on wildlife watching from boats, current and future work is dealing particularly with effects and management of in-water interactions. This poster explores key issues to address and the policy responses to them, outlines gaps and shows the role of different actors in supporting future decision making and facilitating implementation of the agreed actions.

Double Drone Drama: Using two drones to collect simultaneous visual and underwater acoustic behavioural data from gray whales in Baja California, Mexico.

The gray whale (Eschrichtius robustus) is a coastal baleen whale species that inhabits the North Pacific Ocean. The Eastern North Pacific population breeds and calves during the winter months along the Pacific coast and in lagoons in the west coast of the Baja California Peninsula, including Laguna

San Ignacio. Gray whales produce several different call types in the lagoon, and previous studies suggest that types of sound produce depend on behavioural context. Unmanned Aerial Vehicle (UAV), or "drone", technology, provides an alternative, non-invasive and often cost-effective option for monitoring marine species, with applications to aerial surveys, monitoring, habitat use, abundance estimates, photogrammetry and biological sampling. Here we demonstrate how two drones flying simultaneously can combine visual aerial observations with close-range passive acoustic measurements to better understand the behavioural contexts of call generation. Between 27 February and 17 March, 2019 a field team in Laguna San Ignacio collected aerial visual data using a Phantom 4 Pro (DJI) and acoustic data using a SplashDrone 3+ (SwellPro) equipped with a SoundTrap 300STD (Ocean Instruments). The simultaneous drone footage and acoustic recordings provided insight into the whale's acoustic behavior. Furthermore, call-type-specific source levels can be obtained using the combined acoustic/visual dual-drone approach. For example, the source level of "bubble blast" sounds was estimated to range between 113 to 125 dB re 1 μPa. The proximity of the acoustic drone with the vocalizing whales allowed recordings of a large diversity of calls, some of which were too weak to be recorded by traditional methods. Surprisingly, we also found that surface exhalations (blows) of whales could be detected underwater to ranges of 75 m in calm conditions. This preliminary work indicates how UAVs can provide new relatively non-invasive platforms for underwater bioacoustics, and how multiple UAVs can provide a more integrated snapshot into animal vocalization context.

Population structure of two minke whales species (Balaenoptera acuturostrata and B. bonaerensis) in the southern hemisphere.

In this study, we assessed the population genetic structure of Antarctic (*Balaenoptera bonaerensis*) and common (*B. acuturostrata*) minke whales in the Southern Hemisphere (SH), with special attention to the potential connectivity between western South Atlantic (WSA) and Antarctic Peninsula (AP). Mitochondrial DNA control region sequences were obtained for 21 samples (AP n=12, North n=1, Southeast n=5, and South Brazil n=3) of Antarctic minke whale and for 10 samples (South Brazil n=9, AP=1) of common minke whale. The latter were compared to sequences previously reported on GenBank (Northeast Brazil n=8; Chile n=3; South Atlantic n=1 and South Pacific n=14 sectors of the Southern Ocean) to infer population structure at larger scale in the SH, totaling 36 sequences (320bp). Antarctic minke whales showed a high genetic diversity (H=0.994; π=0.8%), with 19 haplotypes (715bp) defined by 55 variable sites. No genetic differentiation was found between WSA and AP whales. The mtDNA sequences for common minke whales revealed a high genetic diversity (H=0.860; π=0.5%) with 12 haplotypes (one newly described) defined by 26 variable sites. South Pacific sector samples were genetically different from all other localities. Additionally, animals sampled in the Northeast were differentiated (Fst=0.23; p=0.05) from those of Southeast Brazil. Mismatch distributions and neutrality tests indicated that populations of both species are not in equilibrium and are possibly experiencing a demographic expansion. Our results showed no genetic structuring between AP and WSA for Antarctic minkes based on mtDNA analysis. Such lack of structure has been previously reported for common minkes in the SH. However, we pinpointed a possible population subdivision within the WSA for *B. acuturostrata*. Such findings are important for better understanding the population structure and the migratory connections of minke whales in the SH, and should be complemented with other molecular markers for obtaining finer-scale results.

Antimicrobial resistance determinants in free-ranging Australian pinniped pups.

The rapid emergence of antimicrobial resistance (AMR) is a major concern for wildlife and ecosystem health globally. The clinical class 1

integron is a mobile AMR determinant used as an indicator of anthropogenic pollution, being rarely present in environments less affected by humans. We previously identified a class 1 integron in an *Escherichia coli* isolate from a single Australian sea lion (*Neophoca cinerea*) pup indicating that AMR determinants are polluting marine systems. The objective of this study was to determine the distribution and prevalence of class 1 integrons in the faecal microbiome of neonatal *N. cinerea*, Australian fur seal (*Arctocephalus pusillus doriferus*) and long-nosed fur seal (*Arctocephalus forsteri*) pups from eight breeding colonies along the Southern Australian coast. A subset of faecal samples (300 of 824) and *E. coli* (*n*=682) isolated from 824 faecal samples collected from 2016-2019 were analysed for class 1 integrons using PCRs targeting the conserved integrase gene (*intI1*). Class 1 integrons were detected in 14% of faecal samples (*n*=42) and 7.4% of *E. coli* isolates (*n*=51). Positive samples were from seven of the eight colonies investigated and in all three species sampled. The highest prevalence was in *A. p. doriferus* (12.5%), followed by *N. cinerea* (5.4%) and *A. forsteri* (1.6%). DNA sequencing of the variable gene cassette region identified diverse genes conferring resistance to six antibiotic classes.

The results of this study suggest that all three species are exposed to anthropogenic pollution with the carriage of AMR determinants demonstrating the extent that resistant bacteria have polluted the marine environment. As AMR determinants are frequently associated with bacterial pathogens, their occurrence suggests that all three pinniped species are potentially vulnerable to further anthropogenic pollution and unknown health risks. The implications of AMR carriage for individual and population health are a key focus of ongoing investigations.

Behayve: Configurable iPhone app maps behaviors and tracks with real-time display, integrating with ArcMap™ and supporting focal, scan, behavior and ad libitum sampling.

Researchers from Australia's Living Ocean NGO have developed and deployed a **configurable cellphone app** that **integrates the capture of behavioral, tracking and environmental data**. Concurrent focal, scan, behavior and ad libitum sampling is supported with the ability of behaviors to have multiple roles and modifiers.

Each behavior in a custom ethogram may be illustrated with a sample image, video or audio clip for reference.

Animal **behaviors and tracks, along with associated data, are displayed on the device in real time** using a Google™ map or custom onboard map, affording immediate insight. A predictive function suggests the present position of animals, useful in relocating lost targets.

Data is gathered by manual or automated means. **Range can be captured automatically from a wireless laser rangefinder**, and **compass bearing by putting a target in the crosshairs onscreen**. **Data from ship's instruments,** such as water depth and temperature, may also feed in over a wireless connection via a serial-to-wireless adapter.

Data may be reviewed and corrected at any time and may be **synced to the cloud or a laptop**. Positions can be determined even where SatNav is unavailable, using a grid map and relative positioning.

I**ntegration with ArcMap™ GIS allows voluminous data to be effortlessly displayed** in organised form with extensive labor saving. A mixture of SatNav and grid-map observations can be seamlessly displayed. **Google Earth™ and Google My Maps™** are also supported**.** Selecting an observation on the map displays associated data.

A facility is provided to sync data between the cellphones of colleagues at different locations.

This fully autonomous app can be re-configured in the field and is suitable for non-invasive studies of marine, terrestrial and avian species even in the most challenging environments. Most recently the app has been utilised successfully in an extended humpback study and is now being offered for review and feedback.

Plasma and fecal sex steroid analysis for monitoring reproductive function in captive Risso's dolphins.

The Risso's dolphin *Grampus griseus* has a worldwide distribution in tropical and temperate waters. Despite their wide distribution, the life history of this species is poorly known. A better understanding of the reproductive biology and physiology of the species is essential for effective conservation and management of wild dolphin populations. The present study aimed to monitor gonadal function by means of plasma and fecal sex steroid analysis in five sexually mature captive Risso's dolphins (two males and three females). Blood samples were collected once per month in males and twice per month in females, and fecal samples were collected once per week in males and at 2–3-day intervals in females over a one year period. Plasma progesterone (P_4), estradiol (E_2), and testosterone (T) were quantified by fluorescence immunoassay, whereas fecal progestagen (iP), estrogen (iE), and androgen (iA) metabolites were quantified by enzyme immunoassay. Fecal steroid metabolites profiles tended to appear similar to plasma steroid profiles. T and iA levels in males showed seasonal changes, with an increase from spring to autumn. High P_4 and iP levels were detected in two females during pregnancy, and cyclic rises of P_4 and iP returned one month after neonatal death and two months after parturition, in one female. The estimated mean (± SD) these cycle length was 34.4 ± 4.6 days (n = 4). In the other female, prolonged cyclic P_4 and iP elevations with an iE peak before elevations were detected during the study period; the estimated mean cycle length was 102.3 ± 22.1 days (n = 4). This report is the first to characterize reproductive physiology in Risso's dolphins. These findings demonstrate that the two females exhibited two different types of physiological cycles, and further investigation is necessary for understanding this phenomenon, including the normal estrus cycle length in this species.

Songs of fin whales in the southern Chukchi Sea

Songs, which consist sequences of sounds produced repeatedly, have been produced by some baleen whales mainly for reproductive functions. Fin whale songs consist of regular sequences repeated 20 Hz pulses. Based on their Inter-pulse intervals (IPIs), their songs can be classified into some types. These types show geographic differences, therefore, song structure is suggested to indicate population or stock structure. After the dramatic transformation of the marine ecosystem in the Pacific Arctic and recovering from depletion by commercial whaling, the number of migrating fin whales appears to be increased in this area. However, little is known about song features and group structures in this area. In this study, we aimed to reveal the song types in the southern Chukchi Sea and to examine the group structures of fin whales in this area.

We used an Automatic Underwater Sound Monitoring System (AUSOMS; AquaSound Inc., Japan) to record fin whale songs from July 2012 to June 2015 in the southern Chukchi Sea. We selected 1-hour data every week of call detection periods and measured IPIs of the songs. Based on IPIs, song types were classified and compared with the previous research to investigate similar song types.

Songs were recorded from August to November in 2012–2014. Only one type with two IPIs (10.51±1.40 s and 19.56±3.92 s) was observed. It is suggested that only one group migrated to this area. However, this song type was different from the previously reported song types in the Bering Sea and Northern Chukchi Sea recorded in 2007–2010. Future research is needed to compare with the song of the other sea area of the same year.

Feeding ecology of narrow-ridged finless porpoises in Ise and Mikawa Bay, central Japan, using carbon and nitrogen stable isotope analysis.

Stable isotope analysis is a powerful tool for understanding food habits. We analyzed carbon and nitrogen stable isotope ratios ($\delta^{13}C$, $\delta^{15}N$) of narrow-ridged finless porpoises (*Neophocaena asiaeorientalis*) in Ise and Mikawa Bay, central Japan, to understand their food habits. A total of 199 muscle samples (94 males and 105 females) were collected from dead individuals via bycatch and stranding from 1994 to 2018. Relation of $\delta^{13}C$ and $\delta^{15}N$ with sampling month, year, area, sex and body length was analyzed by Generalized Additive Models. Akaike's Information Criterion (AIC) was used for model selection. Lowest AIC indicated the best model. For both $\delta^{13}C$ and $\delta^{15}N$, explanatory variables of the best models were sampling month, year and body length. Sex and sampling area were

not selected. Data indicated that $\delta^{13}C$ and $\delta^{15}N$ decreased over 25 years, possibly due to variations in stable isotope ratio of primary producer or sea water in the study area caused by environmental changes. In general, $\delta^{13}C$ and $\delta^{15}N$ were low in February and March. Furthermore, $\delta^{13}C$ and $\delta^{15}N$ showed high levels after birth and gradually decreased with growth until a body length of 1.1 m was reached. In addition, trends of $\delta^{13}C$ and $\delta^{15}N$ apparently changed at a body length of 1.4 m, which was regarded as length at sexual maturity. These results suggest that: 1) food habits of finless porpoises are not different for males and females; 2) finless porpoises move back and forth between the two bays; 3) food habits of finless porpoises do not differ each year; 4) feeding location and food habits change with season; 5) newborn calves wean till a body length of approximately 1.1 m is reached, and 6) food habits change at sexual maturity.

¡Hurry, up up! The hematocrit development of an oceanic top predator:The Gudalupe fur seal.

Gálvez, Casandra[1]; Elorriaga-Verplancken, Fernando R.; Field, Cara[2]; Norris, Tenaya[3]

Hematocrit (Hct) is related to diving and foraging behavior of oceanic top predators such as the Guadalupe fur seal (*Arctocephalus philippii townsendi*) (GFS), which perform the second longest foraging trips (up to 600 km) among otariid species. The aim of this study was to estimate the ontogeny of GFS Hct from the neonatal to adult stage of free-ranging individuals on Guadalupe Island during 2016 and 2017. Blood was collected (EDTA tube) from the gluteal vein, and using a capillary tube, was processed on an automated analyzer. The median and standard deviation for age classes were calculated, and ANOVA and Tukey test were performed to identify potential differences between weight, age class and sex. Neonates exhibited the lowest Hct values (40.7 ± 3.7%; n= 50) followed by weaners (45.4 ± 5.6%; n= 58) and juveniles (44.9 ± 3.1%; n= 25) with the highest Hct observed in adults (48.1 ± 6.2%; n= 21; only samples from females were collected). Hct% was not related to weight and sex ($p > 0.05$) between age classes. Significant differences were observed only between neonates and adults. Our results demonstrate that, from early growth stages, GFS develop efficient and suitable oxygen stores to carry out long trips regardless of sex. Thus, these potential movement capacities could be linked to a recent high dispersal GFSs that eventually ended up in strandings of emaciated weaners and juveniles along the California Coast, including southern areas in Mexico. Knowledge of variation in Hct among age groups is vital for our understanding of the ecology and biology of the species. It is also an important parameter of health assessment, particularly relevant as warming ocean waters affect prey availability which in turn affects foraging ecology, nutrition, and survival.

Humpback whale (Megaptera novaeangliae) reproductive success takes a dive in Alaska during and after the North Pacific marine heatwave.

Gabriele, Christine; Neilson, Janet
Glacier Bay National Park, Gustavus, AK
Corresponding Author: chris_gabriele@nps.gov

Consistent long-term population monitoring by National Park Service biologists in Glacier Bay and Icy Strait, southeastern Alaska has used individual-identification to document the number of different humpback whales and the number of calves in June-August annually since 1985. After many years of considerable reproductive success, these whales experienced a sudden, sharp decline in productivity and juvenile survival beginning in 2014, following the onset of the marine heatwave that dominated the northeastern Pacific Ocean from late 2013-2016. In 2014-2018, humpback whale calving rates in the study area were much lower than historic levels. The crude birth rate (defined as the number of calves divided by the total number of whales) was significantly lower in 2014-2018 (mean = 2.8%) than in 1985-2013 (mean = 9.3%). At the same time, we documented elevated calf mortality rates (36%-100% per year) with 7 of 23 calves in 2014-2018 no longer with their mother and presumed dead by fall, compared to only 8 of 270 calves missing over all previous summers (1985-2013). None of the 22 calves born in 2014-2017 have returned as juveniles or been documented elsewhere in southeastern Alaska, suggesting a decline in juvenile survival as well. Observations of low numbers of whales and calves elsewhere in southeastern Alaska since at least 2016 indicate that these declines are not unique to the Glacier Bay area. Unusually warm waters during the heatwave have been implicated in a wide variety of cascading marine ecosystem effects. Our findings suggest that poor maternal body condition and offspring survival resulted from widespread, significant, and lasting changes to whales' forage fish and zooplankton prey base that began during

the heatwave. Applying rigorous long-term monitoring efforts to whale populations in a variety of habitats would greatly benefit scientific understanding of current and future effects of climate change on marine food webs.

Long-term prey selection of polar bears in a region of rapid ecological change in the eastern Canadian Arctic

Declining sea ice will negatively affect polar bears (*Ursus maritimus*) via habitat degradation and reduced foraging opportunities. However, diversity and availability of prey, and regional environmental conditions may influence the rate and severity of the impacts of sea ice loss. We investigated spatiotemporal changes in polar bear diet over 18 years in Foxe Basin and tested the hypothesis that polar bear scavenging on bowhead whale (*Balaena mysticetus*) carcasses has increased over time, mediated by increased subsistence harvest and killer whale (*Orcinus orca*) predation. We analyzed adipose tissue from 358 polar bears harvested from 2010 - 2017 and archived fatty acid data from 109 polar bears harvested from 1999 - 2003. Individual diets were characterized using quantitative fatty acid signature analysis. Polar bear diet varied spatially across 3 regions within the subpopulation: Hudson Strait, northern Foxe Basin, and southern Foxe Basin. Ringed seal (*Pusa hispida*) and bearded seal (*Erignathus barbatus*) were the primary prey in all 3 regions, followed by harp seal (*Pagophilus groenlandicus*) in Hudson Strait, harbour seal (*Phoca vitulina*) in southern Foxe Basin, and walrus (*Odobenus rosmarus*) in northern Foxe Basin. Bowhead whale was found in similar proportions across all 3 regions within Foxe Basin. We also found bowhead whale consumption and frequency of occurrence in polar bear diets has increased over time across the subpopulation. Bowhead whale was present in 42% of bears from 1999 - 2003 and 97% of bears from 2014 - 2017. Our results suggest that scavenging on bowhead whale carcasses has become increasingly common, and polar bears in Foxe Basin may be shifting to alternative prey in response to environmental variability. Increasing abundance of killer whales in Foxe Basin may be indirectly benefitting polar bears via the provision of bowhead whale carcasses and potentially helping mitigate the demographic effects of declining habitat, at least in the near term.

20 years of coastal dolphin population surveys in the eastern Mediterranean

In the Eastern Mediterranean Sea, few studies have been preformed on cetacean populations. Although a handful of research cruises have been executed- no long term ecological research has been conducted, with the exception of the Israeli coast (196 km). In 1998, IMMRAC (Israeli Marine Mammal Rescue and Assistance Center) began its near-shore monitoring program for coastal dolphins. Between the years 1998 – 2018 ; 782 ship-board surveys covered a total of 18,802 NM and 247 dolphin sightings were recorded. Surveys were carried out year round, with totaled-surveys-per-month ranging between 49-83, and totaled-sightings-per-month ranging between 14-27. The majority of effort concentrated on the central and Northern regions of the country's coastline, though in recent years, regular surveys begun in the South as well. Search patterns were mostly random- covering areas between the depths of 30-60 meters, though when nearing a trawler or fish farm- course is changed to search their surroundings, as dolphins are often associated with the two, due to the availability of food around them. Data recording methods have evolved over the years- starting with handwritten notes and culminating into a versatile phone app- DELPHIS, that enables all researchers to conveniently collect data during any outing to sea. Over these last 20 years changes in species presence and distribution have been observed: *Tursiops truncatus* - had been present along the entire coastline- has become scarce in the north

since 2013, while *Delphinus delphis* – that had appeared absent from Israel's coast, has been observed in the South from 2009 onwards. The changes observed in dolphin distribution may reflect small-scale environmental changes or anthropogenic affects, but could also reflect larger basin-wide changes in the Eastern Mediterranean region where knowledge is lacking. To better assess the variation in distribution, further research is underway- modelling environmental variables that shape dolphin habitat preferences.

Investigating the seasonal effect of disturbance on the energetics and population dynamics of a marine predator

Gallagher, Cara[1]; Grimm, Volker; Kyhn, Line[2]; Nabe-Nielsen, Jacob[3]

For marine species that depend on sound to navigate, forage, and communicate, anthropogenic noise can affect population dynamics and conservation status. However, predicting the impacts of noise on a population requires an understanding of how disturbances affect the physiology, energetics, and fitness of individuals. Here we present a mechanistic, spatially realistic individual-based energetic modeling framework for simulating the effects of nonlethal disturbances on marine populations. We use the model to evaluate the effect of anthropogenic noise from seismic surveys on a marine species that has been noted to have exceptionally high metabolic costs, the harbor porpoise, *Phocoena phocoena*. This model serves as a novel approach to evaluate the threat of disturbance both seasonally and spatially to identify not only where but also when a disturbance may most endanger a population, allowing for better informed marine management and spatial planning.

Influence of environmental factors on the spatial distribution of two harbour porpoise subpopulations in the Baltic Sea

The harbour porpoise (*Phocoena phocoena*) is a highly mobile cetacean found in coastal waters across the Northern hemisphere with different subpopulations in European waters. Since the SAMBAH project the continued existence of the critically endangered Baltic Proper (BP) porpoise subpopulation east of the Darß Sill and south of the Limhamn Sill is no longer in doubt. This subpopulation differs genetically, morphologically and ecologically from the subpopulation of the Belt Sea (BS). Porpoises furthermore inhabit water basins that vary broadly in salinity, temperature, and food availability potentially driving differentiation among (sub-)populations. To study the habitat use of porpoises, we deployed C-PODs in the German Baltic Sea for up to nine years on up to 15 positions nearly continuously. We calculated porpoise positive days and hours to provide unbiased estimates of local occurrence rates. These data are modelled in dependence of abiotic environmental variables assumed to be good indicators of lower trophic level species distribution and thus potentially good proxies of top predators' distribution such as distance from the shore, slope, depth, sea surface temperature and salinity. This habitat modelling serves as the basis to determine which population was recorded on the hydrophones. We reproduce an approach presented by Gallus et al. 2012 using a proxy station for the occurrence of the BS subpopulation by selecting a reference position in western German Waters under the hypothesis that porpoises from the BP show differences in habitat use, especially in winter times. Studying the spatial distribution of these cetaceans can provide crucial data essential for the design of efficient conservation strategies.

Complex social Interactions of sperm whales (Physeter macrocephalus) in the Strait of Gibraltar: The sighting of a marguerite formation with the probable presence of a calf.

The sub-population of sperm whale (*Physeter macrocephalus)* resident in the Mediterranean Sea shows a spatial distribution dependent on various factors. Particularly, spring and autumn movements are observed between the West basin and the Strait of Gibraltar, normally attributed to adult and subadult males in a foraging behaviour. In this

study, we describe a complex sperm whale behaviour observed in the Strait of Gibraltar on September 25th, 2017. The sighting consisted in a gathering of at least 10 individuals performing a marguerite formation, a typical defensive behaviour in order to protect an individual of the group. In fact, a considerably small individual was observed in this formation, surrounded by pilot whales and bottlenose dolphins. Therefore, it is highly probable that the formation was taking place to protect a calf or a juvenile. During the sighting, photos of the individuals were taken and further compared to the photo-ID Turmares Tarifa catalogue of the Strait of Gibraltar. The results did not match with any of the individuals in the catalogue. We presume new individuals may have approached the area, and the possible presence of a young individual could mean the presence of females. The occurrence of females with youngsters, if repeated, could potentially represent a new use of the area by sperm whales, and would enhance the importance of the Strait of Gibraltar in the conservation of the species.

"Small delphinids" identification: From scientific confusion to conservation issues.

Gannier, Odile; Gannier, Alexandre
GREC, Antibes, France
Corresponding Author: odile.gannier@gmail.com

Taxonomic confusion can lead to misestimation of population and to lack of accurate data guaranteeing a reliable conservation status assessment. Small delphinids have been confused since ancient times, and unfortunately it is still the case for other reasons. Ancient scientists as Aristoteles only distinguished 'dolphins' from fishes or from whales. Renaissance scholars already stated differences between several vernacular names for the presumed same animals, whereas several similar species could be confused under the same name, as 'dolphin' and 'porpoise'. For example, the striped dolphin (*Stenella coeruleoalba*) presumably inhabits the Mediterranean Sea since centuries without being specifically described, as a proper name (and precise associated identification criteria) was missing until the middle of the 19th century (before Gray and Gervais). This situation led to misidentifications and confusion with the so called "common dolphin", *Delphinus delphis*, considered as the only common dolphin in the area or used as a generic name. Finally, the name "*delphinus coeruleoalbus*" was retroactively given after Meyen, who described and sketched this animal off Brazil (1833), during a German expedition on the *Prinzess Louise*. Consequently, the striped dolphin Mediterranean presence was certainly underestimated. But, whereas the difference seems now clearly established, the status of the common dolphin remains uncertain in the Mediterranean Sea: geographical repartition, abundance trends remain in question. This taxonomic confusion is still observed and can lead to an incorrect assessment of present species conservation status. Moreover, the latest method for abundance estimation, by aerial survey, is likely to reduce knowledge instead of increasing, because both dolphins are often processed under one single appellation, "small delphinids". In case of fisheries bycatch issues, such as in the Bay of Biscay, the conservation status of each species is regrettably again unsure, because 'safe' bycatch thresholds are expressed as a fraction of population estimates (for example 1%).

This must be the place: Habitat preferences of pelagic bottlenose dolphins in the Northeast Atlantic.

Understanding spatio-temporal variations of habitat use is fundamental when designing appropriate conservation schemes for cetacean populations. In the Northeast Atlantic, pelagic bottlenose dolphins (*Tursiops truncatus*) are genetically and socially distinct from coastal populations, but their habitat preferences are unknown.

To investigate how the presence of these pelagic dolphins relates to environmental parameters, we developed generalised additive models (GAMs) using data from aerial surveys of the Irish EEZ over two summers and two winters. Binomial GAMs were trained on the two later seasons. Models were first run across the entire study area, and then including an interaction term with habitat type, dividing the region into continental shelf, slope, and abyssal waters. Their goodness of fit and predictive capacity were tested on concurrent data and on observations from the first two survey seasons.

Sea surface and bottom temperature, mixed layer depth, primary productivity, seabed aspect and rugosity all played a significant role in bottlenose dolphin distribution, as did proximity to the

coastline and various depth contours. Most covariates were only significant in one season. Notably, including the interaction term altered the effect of most variables on dolphin presence, with some predictors only appearing significant in shelf or slope waters and the shape of the relationships changing between habitats. Higher probability of dolphin occurrence was predicted near the southwest coast in summer and throughout most of the continental shelf and slope in winter. Predictions were less accurate for the first two seasons, possibly reflecting variability in habitat use over longer periods than those investigated here.

This baseline study of pelagic bottlenose dolphin habitat use in the Northeast Atlantic increases our understanding of how their distribution relates to environmental factors. Our results highlight that this population's habitat preferences are season- and habitat-specific, which will help inform marine spatial planning.

Spatio-temporal and inter-individual variations in trophic ecology of the manatee in the Mexican Caribbean: Carbon (δ13C) and nitrogen (δ15N) isotopic composition from bone-collagen over the last 30 years.

The Endangered Antillean manatee (*Trichechus manatus manatus*) inhabits marine, estuarine and freshwater environments, feeding on a wide variety of aquatic and semi-aquatic plants, having an important role in the trophic cycle of these ecosystems. Preliminary studies have revealed the diet of Antillean manatees in the Mexican Caribbean by analyzing stomach contents and feces. However, studies on manatee trophic ecology that allow to infer spatio-temporal variations in the diet of the species have not been carried out in the area. A total of 68 bone-collagen samples, collected between 1986 and 2017 in Quintana Roo, were analyzed isotopically ($\delta^{13}C$ and $\delta^{15}N$). Mean (± SD) carbon ($\delta^{13}C$) isotopic composition was -9.44 ± 2.62, ranged between -17.95 ‰ and -3.38 ‰; and mean nitrogen ($\delta^{15}N$) isotopic composition was 6.03 ± 1.57, ranged between 2.21 ‰ and 9.97 ‰. No significant differences in $\delta^{15}N$ and $\delta^{13}C$ were found among decades, sex and age class ($p > 0.05$). However, significant differences were found among locations ($p < 0.05$) in $\delta^{13}C$, but not for $\delta^{15}N$ ($p > 0.05$). Our results of stable isotope analysis in bone-collagen, show manatee feeding behavior in the Mexican Caribbean, specifically the use of seagrasses in compared to freshwater and/or brackish vegetation; also suggest that in despite of the habitat modification in the region over the last 30 years, the feeding habitats of this manatee population have remained without significant changes.

Clear evidence worldwide shows that most of our oceans and seas are highly polluted with marine litter, particularly plastics and fishing gear, among other types of toxic products. Iceland is home to more than 20 different species of cetaceans, including endangered blue whales (Balaenoptera musculus), fin whales (Balaenoptera physalus) and even rare hybrids. Some of the largest and most threatened colonies of seabirds such as the Atlantic puffin (Fratercula artica) can still be spotted here. While wildlife watching is now one of the most attractive touristic activities, whaling and hunting of threated species including seals still occurs. During the week-long pilot project expedition April 2019 we conducted floating plastic surveys (>1 mm) with a Low-tech Aquatic Debris Instrument (LADI) manta trawl. Plastics were present in all the study areas (n=6) including cod spawning areas and strategic whale feeding grounds. Fishing lines and fibers were the most abundant particles. Furthermore, fishing gear was also present on beaches (n=2), remote nesting colonies and even entangling bird´s bodies. Pure science seems to be not enough to make a rapid change in a fast changing marine environment. Ocean Missions wants to inspire and engage people to take straight action towards ocean conservation supporting

scientific efforts by a combination of science, education and adventures sailing in the fragile Arctic and Sub Arctic regions

First evidence of OPFRs presence in fin whales.

The fin whale, *Balaenoptera physalus* (Linnaeus, 1758), is a cosmopolitan cetacean. It is found in most of the world oceans, where it performs annual migrations between low-latitude breeding areas and high-latitude feeding areas. During these long-range migrations, fin whales cross water masses that may be contaminated by different types of pollutants, including the ever-increasing marine litter. Physical adverse effects of marine litter on cetaceans are well known and include entanglement, suffocation, and obstruction of the digestive system. However, chemical effects related with the ingestion of marine litter, and particularly of plastic, are still under assessment, and have been mostly associated with the toxicity of plastic additives and plasticizers. Among the compounds involved in the production of plastic, organophosphate flame retardants (OPFRs) might cause adverse reproductive, endocrine and systemic effects in long-term exposed animals. In this study, we analyzed OPFRs concentrations in the muscle of North Atlantic fin whales and in samples of its main prey, the krill *Meganyctiphanes norvegica*. 19 OPFR compounds were measured in 20 samples of fin whales and 10 samples of krill collected in 2015 in Iceland. 7 and 5 out of 19 OPFR compounds were detected in fin whale and krill samples, respectively. IPPP (Isopropylated Triphenyl Phosphate), TNBP (tri-n-butyl phosphate) and TPPO (Triphenylphosphine oxide) were the most abundant compounds in both types of samples. Mean ∑OPFR (the sum of all OPFR compounds measured) concentration, expressed on a lipid weight basis, was 985 (SD=2,239) $ng g^{-1}$ in fin whale muscle, and 949 (SD= 1,090) $ng g^{-1}$in krill. These results do not suggest a biomagnification of OPFRs, but provide a first evidence of their presence in fin whale tissues.

The high productivity of waters off Iceland makes this area an important summer feeding ground for baleen whales. The blue whale (*Balaenoptera musculus*), the fin whale (*Balaenoptera physalus*), the sei whale (*Balaenoptera borealis*), the common minke whale (*Balaenoptera acutorostrata*) and the humpback whale (*Megaptera novaeangliae*) are frequent visitors in the region. Coexistence in the same habitat of species with similar ecological requirements often entails spatial or trophic segregation to avoid competitive exclusion. With the aim of studying how these species share habitat and trophic resources, we analyzed the $\delta^{13}C$, $\delta^{15}N$ and $\delta^{34}S$ values in 90 skin samples obtained from them. Preliminary results evidenced substantial niche partitioning between most of the species. The only exceptions were fin and blue whales, whose isotope ratios overlapped highly. Minke and humpback whales showed relatively higher $\delta^{15}N$ values, probably reflecting a larger contribution of fish in their diet. However, these two species presented dissimilar $\delta^{13}C$ values, the minke whales being more enriched in ^{13}C than humpback whales, thus suggesting some degree of allopatry. In contrast, sei whales had lower $\delta^{15}N$ and higher $\delta^{13}C$ values than blue and fin whales. Overall, our results support limited interspecific competition between the species, with the only possible exception of blue and fin whales, that appear to share ecological resources.

The long, spiralled tusk of the narwhal (*Monodon monoceros*) is unique not only because of its exceptional form and structure, but because the tusk potentially contains information about the life history and environment of its owner.

The narwhal tusk itself provides a chronological framework. It is built of dentine layers – one for each year in the whale's life – containing major and trace elements incorporated during growth. The resulting elemental composition, and any variations in it, has the potential to serve as an environmental and area specific record. As narwhals are long-lived, with tusks that grows continuously throughout their lifespan, the tusk can provide unique habitat information in time and geographical space using elemental analyses.

Narwhal tusks from Greenland, spanning a time period of ~75 years, from the 1940's to 2018, have been collected with the purpose of constructing profiles including age, elements, isotopes, Carbon-14 and hormones. This on-going study investigates the elements in each tusk layer using two methods: X-ray fluorescence spectrometry (XRF) and Laser Ablation Inductively Coupled Plasma Mass Spectrometry (LA-ICP-MS). Our hypothesis is that the elemental profiles of whole tusks can uncover the location of the whales at a specific time (summer/winter grounds and migration routes), and thereby population structure, and the environmental changes these areas underwent during the lifetime of the whales, hereunder the influence from climatic changes that have occurred during this period.

Tusks have successfully been mapped using XRF and elemental profiles are constructed using LA-ICP-MS. Preliminary results show a clear variation of some elements, e.g. Strontium and Zink, through the layers. We are currently working towards identifying the most likely cause of these variations, and correlating them within a chronological framework that includes independent temperature records from narwhal specific areas. The results of this work will be presented at the meeting.

Spatial and temporal distribution of humpback whales (Megaptera novaeangliae) in the Babuyan Marine Corridor, northern Luzon, Philippines.

Corresponding Author: timjgard@gmail.com

Humpback whales wintering in the northern Philippines belong to the western North Pacific subpopulation, now recognized as a distinct population segment. The numbers for this subpopulation are low and in the Philippines threats are apparent in the breeding ground. We are presenting the spatial and temporal distribution of humpback whales in the Babuyan Marine Corridor breeding ground from 2001 to 2019. Surveys were conducted during the season from February to May. Based on our analysis of 1,078 sightings, mother-calf (MC) pairs generally preferred shallower waters while all other group types occurred in a wider range of depth. In particular, competitive groups (CG) were found, on average, at waters >200m deep. This habitat preference coincides with other literature on humpback whale breeding grounds. Based on departure date and sighting role type proportion analysis, different group types also showed patterns of arrival and departure times wherein MCs leave the latest while CGs leave much earlier. This pattern appears to be shifting progressively earlier in the season, as the median and average proportion of MC sightings have increased over time, and CGs have not been sighted since the 2015 season. These results suggest that recent surveys are observing later stages of the breeding season's departure pattern than earlier survey years, particularly since 2016, at least around one island. Therefore, our data suggest that humpback whales in the Babuyan Marine Corridor segregate themselves spatially and temporally according to role type, and that while temporal distribution patterns appear to remain relatively consistent in terms of departure order, the actual departure dates of different role types are shifting earlier, possibly in response to warming sea temperatures as a result of El Nino events. Understanding patterns of spatial and temporal distribution is important in the planning for the protection of breeding grounds of this threatened subpopulation.

When revolutions fail: Understanding the underlying mechanisms of humpback whale song revolutions through investigating failures.

Male humpback whales (*Megaptera novaeangliae*) sing a long, stereotyped, and culturally transmitted song display. Multiple humpback whale song revolutions (where a song introduced from a neighboring population rapidly and completely replaces the existing song) have spread across the South Pacific region from the east coast of Australia to French Polynesia. This has occurred repeatedly in each of the five western and central South Pacific populations until reaching French Polynesia, where the song revolutions periodically failed. Here, we investigate how undocumented population substructure, aberrant singers, and/or potential bidirectional introductions may contribute to revolution failure. Song unit sequences were extracted from over 2,000 phrases recorded across French Polynesia (Society, Gambier, Tuamotu and Austral archipelagos) from 2009-2015, to allow fine-scale analysis of composition and sequencing to understand subpopulation structure. Two decades of theme sequences in French Polynesia (1998-2015) were also analyzed to understand the overall song progression in the central Pacific. Clustering of song phrases using the Levenshtein distance indicated potential subpopulation structure across the region. Structure resulting in reduced residency times in migratory locations may contribute to song revolution failure. Understanding the mechanisms driving song revolutions and the factors that may disrupt this phenomenon will have wide-reaching implications for our understanding of song learning, song evolution and cultural transmission in non-human animals.

Searching for humpback whales two centuries post-whaling: What is left in the Chesterfield-Bellona archipelago?

Humpback whales (**Megaptera novaeangliae**) were severely depleted by commercial whaling throughout the 19th and early 20th centuries. Understanding key factors of their recovery is a crucial step for their conservation worldwide. In Oceania, the Chesterfield-Bellona archipelago was one of the primary humpback whale whaling sites of the 19th century, however, given its remoteness, it has remained almost unaffected by anthropogenic activities since then. In this study, we report on the first large-scale multidisciplinary dedicated surveys conducted in the Chesterfield-Bellona breeding area to assess the current status of humpback whales in this region two centuries post-whaling. Surveys were conducted in 2016 and 2017, totaling 24 days of effort and 57 groups were encountered. From these groups 13 whales were identified with photo-ID, 16 with genotyping and 22 with both methods. A total of six whales were equipped with satellite tracking devices. The density of humpback whales was relatively low (0.041 whales/km surveyed on average), with the highest concentrations found in the inner shallow waters of the reef complex and the neighbouring off-shore shallow banks. Surprisingly for a breeding area, the sex ratio was very skewed towards females (1M:2.8F). A large proportion of the groups encountered included a mother and calf (45%), especially in the most sheltered waters south of the Chesterfield plateau. Photo-ID and genetic comparisons suggest a strong connectivity with the New Caledonian South Lagoon breeding area to the east, but no connectivity has been detected to-date with the Australian Great Barrier Reef breeding population to the west. Satellite-tracking of three females (including one with calf) suggest use of the South East Australian migratory corridor at least during south-bound migration This study revealed that humpback whales are still inhabiting the Chesterfield-Bellona archipelago two centuries post-whaling, potentially playing a connecting role across breeding grounds of the western South Pacific.

The trophic ecology and habitat of the Gulf of Mexico Bryde's whale

The Gulf of Mexico Bryde's Whale (GoMex Whale, *Balanoptera edeni*) primarily occupies a discrete habitat near the shelf-break in the Northeastern Gulf of Mexico. This small, genetically isolated population has recently been listed as Endangered under the US Endangered Species Act, and it is important to characterize essential habitat requirements to aid in recovery planning and conservation. We examine the feeding behaviors and trophic ecology of the GoMex whale to better understand the physical and biological features of its limited habitat. Large vessel survey data demonstrate that GoMex whales occur within a restricted depth range between 178-408m and are observed most frequently near the 200m isobath. Data from telemetry tags indicate that during daylight hours, the whales dive to depths between 200-280m and execute feeding lunges near the bottom. Multi-frequency scientific echosounder data show a concentrated layer of organisms near the bottom during daylight hours with the highest acoustic backscatter occurring in the 185-220m depth range. In areas where whales are observed, these potential prey form dense patches which extend for horizontal distances ranging from 0.9 to 3.7 km and vertically from 5-10m above the sea floor extending 20-30m upward into the water column. The multi-frequency response of these aggregations along with the observed schooling behavior are most consistent with dense patches of small pelagic fishes. Mesoscale circulation patterns contribute to the high concentration of prey as there is persistent along-shelf flow of water near the shelf edge along with an inner-shelf convergence zone that may entrain highly productive shelf water. We characterize spatial and temporal variation in the structure of these prey patches within the GoMex whale habitat and demonstrate correlations between current fields, prey patches, and whale occurrence. Ongoing surveys that include trawl collections of potential prey will identify these key trophic resources of the GoMex whale.

The evolution of emergency response approach to the management of large-scale marine mammal mortality events

During the last three decades, sixteen Unusual Mortality Events (UME) have been formally declared along the northeast coast of the United States. An UME is defined under the Marine Mammal Protection Act as *"a stranding that is unexpected; involves a significant die-off of any marine mammal population; and demands immediate response."* Responses to these events encompass approximately 4,000 pinnipeds, 1,800 small cetaceans, and 300 large whales. Investigation of UMEs requires significant amount of resources to manage events and research causative factors. From 2013-2015, an UME was declared for common bottlenose dolphins *(Tursiops truncatus)* spanning the eastern seaboard from New York through Florida. Due to the expansive response area, number of response organizations, and jurisdictions of multiple government agencies, a common emergency response framework based upon the Incident Command System was implemented to manage the complexity of the event. Subsequently, in the same region four additional UMEs have been declared since 2016 for humpback whale (*Megaptera novaeangliae),* North Atlantic right whale (*Eubalaena glacialis*), minke whale (*Balaenoptera acutorostrata*), and harbor seal (*Phoca vitulina*) and gray seal (*Halichoerus grypus*). Resources from stranding response organizations and government agencies (financial, but also logistic and personnel) are required to respond to the increased number of stranded animals among all four simultaneous and ongoing events. Emergency response frameworks have been refined for the most recent events based on a comprehensive after action review and lessons learned. The emergency response framework, including disease surveillance, testing, analyses and research plans, for the recently declared UMEs will be summarized, and recommendations for management of future events responding to increased levels of live animal strandings and mortalities will be provided.

Further insight into fin whale subpopulation structure in the eastern North Atlantic.

Highly migratory marine species pose a challenge for the identification of management units due to the absence of clear oceanographic barriers. The North Atlantic fin whale was subject to intense whaling operations during the 20th century and since then has recovered with varying degrees of success between locations. Subpopulation structure has been investigated through several methodologies since the 1960s but it is still the subject of an ongoing scientific debate. Here we measured stable isotopes of carbon, nitrogen, and oxygen in skin samples from 151 fin whales collected in Iceland, Galicia (NW Spain), the Azores archipelago and the Strait of Gibraltar. In Gibraltar and Galicia, samples were collected all year long from three age classes (calf, juvenile, adult), while samples from the Azores and Iceland consisted in only adult whales sampled between April and September. We used univariate and trivariate analysis of variance and niche region analysis via tridimensional ellipses to investigate possible movement patterns. We found differences in stable isotope ratios between areas, seasons and age classes. Our findings indicate that individuals sampled in Gibraltar, Galicia, Iceland and the Azores may share a common feeding ground in the Northeast Atlantic at different times during the year and that fin whales from the Strait of Gibraltar use this common feeding ground in the summer but exploit Mediterranean resources during the winter months. This further supports the existence of a limited but current exchange of individuals between these two basins though the Strait of Gibraltar.

Underwater acoustic technologies have provided a useful method for monitoring marine mammal's distribution and habitat use. However, surveys are affected by bias in detection probability. The relation between site specific conditions and the probability of detecting cetaceans has been modeled through Generalized Additive Models (GAM). These models are useful to analyze big datasets that usually contain a surplus of zeros. However, when data is sparse, they tend to over fit easily. Artificial Neural Networks (ANN) are more adaptable to such problems. We propose their use to model bottlenose dolphins (*Tursiops truncatus*) presence in a Mexican coastal lagoon. Two hydrophones were placed at the entrance and the end of a 6 km long channel that connects the lagoon (Ensenada de La Paz) to the adjacent bay (Bahía de La Paz, Baja California Sur). The relationship between dolphin presence (indicated by recorded whistles) and oceanographic and physical variables was modeled with GAMs and ANN. The GAM incorporates six variables and describes 36.0 % of the data. The presence of animals varied mostly as a function of oceanographic variables (tidal height and tidal flow) and lunar forcing (6.5 % and 5.1 %). A three-layer feed-forward network trained through scaled conjugate gradient backpropagation was tested. The network considered nine input variables and predicted 90.4 % of the encounters of bottlenose dolphins correctly, in a balanced set. The most

influent variables might be related to productivity variability due to hydrographic and seasonal conditions, and food accessibility affected by tidal height and direction. Our results highlight the suitability of using ANN to model detection availability for studies of abundance and distribution of dolphins in coastal habitats, essential for conservation purposes.

Uncovering past declines, recent bottlenecks, and historical selection in endangered monk seals

The Hawaiian monk seal and Mediterranean monk seal are among the world's most endangered marine mammal species, and the only tropical phocid seals. Both species currently have fewer than 1500 individuals each, and their populations have not grown substantially despite extensive conservation efforts in recent decades. In order to find out if the populations of monk seals were much larger in the past, we performed whole genome sequencing on multiple individuals from each species. We analyzed this sequence data using both coalescent modelling and the site frequency spectrum to estimate historical population sizes and the timing of changes in population size. We compared the timing of these trends with the arrival and expansion of human populations in the Hawaiian Islands and the Mediterranean region, as well as with climatic changes. Through this analysis, we found evidence that the populations of both of these endangered species suffered recent and historical declines, suggesting that the populations may have already been vulnerable before any interaction with humans. In addition, we identified genes that showed signs of historical positive selection in these species and explored their relationship with the monk seals' ecological and biological traits. Combined, this work helped shed light on how both historical climate change and interactions with humans have affected the population sizes of endangered monk seals, while also identifying candidate genes that help to explain how phocid seals may have adapted to warmer waters. This research was carried out in collaboration with research teams at Yale University, AMNH, NOAA-PIFSC, MOm, and the University of Barcelona. This new understanding of monk seal population history will be used to inform future conservation efforts by establishing historical baselines for monk seal population recovery.

Stable isotope analysis as a tool to investigate foraging and group dynamics in bottlenose dolphins

Bottlenose dolphins (*Tursiops truncatus*) are social animals with a network of relationships and varied foraging techniques. A population of approximately 300 dolphins resides near Cedar Key, Florida, most of which are permanent residents. Previous long-term research on this population has documented role specialization, which is unusual in animals that cooperatively hunt. We used stable isotopes of carbon and nitrogen to examine additional questions about the foraging behavior of these dolphins, as these markers are integrated through the diet and reflect foraging habits over an extended time period. Skin biopsy samples were collected from 63 dolphins in 2010. The objectives of our study were to examine potential drivers of this variation including sex, foraging techniques, habitat use, and group dynamics. We found considerable variation in isotopic values among the samples. We found that female dolphins had lower carbon isotopic values than males (2 sample t-test, male mean -17.5, female mean -16.6, p-value = 0.008251). Nitrogen isotope values did not differ significantly with sex. We did not find differences in isotopic values by foraging technique. Ongoing analyses include examining if isotope values vary by group membership and home range size. Stable isotope data can provide more information about the foraging habits of the bottlenose dolphin population in Cedar Key beyond observations from sightings.

Stable isotopic patterns of epidermis structural layers are good indicators for gestation and lactation stages.

Metabolic needs involved in reproduction are difficult to investigate in free-ranging animals, especially in cetaceans. In this contest, advances in stable isotope approaches allow insights into animal physiology from body tissues collected remotely. Specifically, we hypothesize that the isotopic composition of epidermis structural layers provides $\delta^{13}C$ and $\delta^{15}N$ time series information that

can be used to trace gestation and lactation. We propose that the outermost stratum reflects old metabolic status, while the innermost the most recent ones. To test our assumption, we collected skin biopsies from gray whale lactating females and offspring in Ojo de Liebre breeding lagoon, Mexico, in 2011, 2018 and 2019. Although trends in $\delta^{13}C$ values were not constant between epidermis layers among specimens, $\delta^{15}N$ values differ among skin strata of all organisms. $\delta^{15}N$ values particularly in calves always decreased from the outer to the inner skin strata, most likely due to the assimilation of ^{15}N depleted maternal milk compared to placental blood. We used the nitrogen isotope fractionation of the sampled mother-calf pairs to build a model that predicts calf age and estimates $\delta^{15}N$ values when one of the two couple members is not sampled. Changes in nutritional and ecological conditions can be inferred from the year-to-year differences found between mothers' skin $\delta^{13}C$ and $\delta^{15}N$ patterns. Reproduction status actively affects isotopic patterns and their evaluation appears fundamental to correctly interpret the results of feeding and migratory studies.

Drivers of unique social partitioning in a dolphin social network

Cetaceans are known for their complex social structure. This structure may lead to behavioural diversity not only among populations, but also within a single population, with different subsets of a population exhibiting different types of behaviour. Understanding the mechanisms of these patterns is interesting biologically, but may also help conservation efforts, because not all segments of a population necessarily respond to, or interact with, human activities in the same way, or at the same time. Such differences may provide insight into the impacts of human activities on wildlife, but also into the evolution of novel behaviours, social learning, adaptation to perturbations in the environment and resilience to anthropogenic stressors. Here, we studied the social network of a resident bottlenose dolphin population over 16 years and found it highly structured into distinct social clusters of mixed sexes. Unexpectedly, the two largest social clusters overlapped spatially, but not temporally, as they used the same area at different times of day and essentially time-shared the same area. Such diel temporal partitioning does not appear to have been documented in any mammals previously. To undertand this temporal and social partitioning, we further investigated several potential drivers of it, including differences in fisheries-related behaviour, diet based on stable isotopes, pollutant levels, and genetic factors. The two clusters differed in ways they interacted with fisheries, as one regularly interacted with trawlers, while the other did not, but this did not explain the temporal partitioning. Stable isotopes indicated differences in diet, particularly differences in trophic level. There were no differences in pollutant loads, with most dolphins exceeding toxicity thresholds, and evidence of maternal offloading of pollutants. Genetic analyses are currently ongoing. This study demonstrates how different segments of animal populations can behave differently, interact differently with human activities and in turn respond differently to anthropogenic impacts.

Quality over quantity: Social bond strength and partner fidelity determine reproductive success in male bottlenose dolphins.

Reproductive success varies both within and between sexes in most animal species. During the past decade, it has been shown that inter-individual differences in sociality can affect fitness. Most studies have focused on females, while the effects of sociality on male reproductive success are less known. This is, nevertheless, of particular interest since differences in the number of offspring sired can be particularly pronounced in males. Male bottlenose dolphins (*Tursiops aduncus*) in Shark Bay form multi-level nested alliances for the purposes of gaining access to females, these alliances being characterised by strong social bonds lasting up to several decades. Second-order alliances are the core male social unit, within which

subsets of two to three males form 1st-order alliances to consort oestrus females. First-order alliances may differ in stability and composition. Within 2nd-order alliances, social bond strengths vary, with some individuals preferring or avoiding certain other alliance members, whereas other males have no preferences among their alliance partners. We use a combination of genomic and individual-level data on 58 members of seven 2nd-order alliances to investigate whether a male's social network position, home range size, relatedness and age-similarity to alliance partners influence reproductive success. We found compelling evidence that the node strength of social bonds ($p < 0.001$), as well as 1st-order alliance stability ($p = 0.016$), were significant predictors of an individual's number of consortships, a reliable proxy for number of paternities. Individual home range size, relatedness and age similarity to alliance partners, as well as the coefficient of variation in bond strength (used to measure differentiation of social bonds to alliance partners), do not influence access to females. Our results highlight that social bonds, in particular the quality thereof, influence fitness in allied males, thereby adding to our understanding of the conundrum of male cooperation between non-kin.

Clan specific coda playbacks to Caribbean sperm whales.

Cultural identity creates population structure among both humans and animals by defining social segregation between 'Us' and 'Them'. Sperm whales have a high order social structure which socially segregates hundreds of animals into distinct clans based on vocal dialect. While social communication appears to structure sperm whale society, the functions of these whales' communication signals are still completely speculative; and therefore, how groups of whales recognize each other remains completely unknown. In order to address this knowledge gap, we conducted controlled playbacks of clan-specific coda types with a paired design (Same clan coda vs Different clan coda) to well-known units of sperm whales from both of the sympatric EC1 (1+1+3 coda type is predominant) and EC2 (5R3 coda type is dominant) clans off the island of Dominica. Specifically, we tested the hypothesis that sperm whales cue into coda types for cultural group recognition and respond differently to codas specific to their clan. We completed a total of 7 full playback series. In 4 of those cases, the focal animal was instrumented with a DTag3 sound and movement tag. In all but one playback, the animals did not produce a vocal response to any of the stimuli. In the exception, the focal tagged whale produced a series of characteristic 4D codas in response to the 'same-clan' stimuli. This is particularly interesting as the 4D coda type has been suggested to contain unit level identity cues based on previous analysis. Additionally, generalized linear models indicate that cluster sizes are larger post the entire playback sequence but not necessarily after playback of specific stimuli. This study will serve as the foundation of playbacks experiments like those which have driven the study of birdsong into one of the most productive areas of behavioural ecology.

Ecotourism and cetaceans monitoring in the Pelagie Islands (Strait of Sicily)

Research ecotourism has a great potential as platform of opportunity for the collection of data on whale or dolphin distribution, habitat use, and long-term photo-identification studies at a frequency that is rarely feasible through directed research. In 2018 Mar.Eco Osservatorio della Natura Association set up a cetaceans monitoring project called "Cetaceans of the islands" in Pelagie Islands, that represent a high biodiversity area for cetaceans in the Mediterranean Sea, and it is supported by tourists participating financing. It aims to provide detailed knowledge of the spatial-temporal distribution and abundance of cetacean species occuring in the surveyed area. In this work are shown the prelinimary results of the monitoring activity carried out during summer 2018.

A total of 51 vessel-based surveys were performed randomly with 125 h of sampling effort and 897 km² covered in the study area. For each sighting, we reported group size, young specimens and associated any species in order to estimate abundance, distribution and use of habitat. The dorsal fin photo-id method was adopted.

A total of 44 sightings of *T. truncatus* were collected, 1 of *Delphinus delphis*, 3 of *Grampus*

griseus, 1 *Stenella coeruleoalba*; 235 individuals were estimated. For *T. truncatus* sigthting frequency is 0.47, the encounter rate is 0.05.

This study is a contribution to assist the regional efforts with scientific knowledge regarding the cetaceans frequentation of the IMMA area of Lampedusa and to foster tourists active participation to environmental and conservation actions throughout the educational element.

30 years of Kogia spp. strandings in South Australia: Distribution, diet and pathology investigations.

Pygmy and Dwarf Sperm whales, *Kogia* spp., are widely distributed in temperate and tropical waters, yet are among the least understood of cetaceans found in Australian waters. Since 1989, 36 Kogia spp. strandings were documented from the South Australian coast but they were not evenly distributed, with stranding occurring more frequently in the Great Australian Bight. Twenty-eight (15 juveniles, 13 adults) of these form the basis of this study. Post-mortem examinations were conducted on 16 *K. breviceps* and 2 *K. sima,* with meaningful histopathology for 6 animals. Circumstance of death was, 5 live stranded, 1 probable entanglement, 2 possible boat strikes and 10 unknown circumstance. Twelve whales had a robust body condition, two were emaciated and for the remainder, body condition could not be determined due to decomposition. Nematodes and cestodes were recorded in 12 animals. Severe subcutaneous haemorrhaging was found in 12 animals, mostly around head and neck region. Four animals had bone fractures on ribs and vertebrae but the circumstance of death could not be attributed to boat strike. Histopathology results showed mild to moderate interstitial pneumonia in 3 juveniles and mild myocardial degeneration with passive hepatic congestion and pulmonary congestion an adult animal. This heart pathology appeared to have a little similarity with pathology information from other areas of Australia. Eighteen *K. breviceps* stomachs were examined, 13 had hard-part remains of prey (primarily cephalopod beaks and crustacean remains), five stomachs contained nematodes. *Kogia sima* (n=2) stomach contents included cephalopod beaks and nematodes. Dietary information can assist in determining habitat use, foraging behaviour, preferred prey and in assessing direct or indirect interactions with fishery operations. Our study will provide critical baseline information for these species, as well as fill some of the gaps in knowledge for Australian cetaceans.

Sociality and reproductive success of female bottlenose dolphins (Tursiops truncatus) in the St. Johns River, Florida.

Gibson, Quincy[1]; Brightwell, Kristy[2]; MacVicar, Alexandra[3]; Mason, Andrea[3]

The relationship between sociality and reproductive success (RS) varies among social mammals; high sociality is associated with both positive and negative reproductive effects. Within dolphins, the relationship between female sociality and RS is unclear and complicated by the use of different measures across studies. Thus, we tested this relationship using multiple measures of sociality and RS for bottlenose dolphins in the St. Johns River (SJR), FL. Data were collected via boat-based photo-identification surveys (Mar. 2011–Aug. 2017) and the data set was restricted to females with 5+ sightings (N=87) with calves first sighted as YOYs (newborns; N=179). Sociality measures included each female's number of associates, mean non-zero half-weight index (HWI), maximum non-zero HWI, and mean group size. To account for sample size differences among females, a ratio (number of associates to number of sightings) was calculated. Number of associates and HWIs were calculated using SOCPROG v.2.8. Inter-birth intervals were calculated for subsequent YOYs. RS was quantified as the proportion of calves born during the study that survived through years one (Y1) and three (Y3). Sample sizes varied for each RS measure based on available sighting data. Females' number of associates ranged from 22-212 (mean=129.53±5.25), maximum HWIs from 0.12-0.48 (mean=0.24±0.01), and average group size ranged from 5.80-20.33 (mean=12.46±0.31). Mean inter-birth interval (N=56) was 3.03 years. Overall, 76.52% of calves survived to Y1, whereas 50.63% of calves survived to Y3. On average, females had 1.13±0.07 calves survive to Y1 and 0.62±0.07 calves survive to Y3. Calf survival to Y1 was positively correlated with number of associates ($r=0.23$, $p<0.05$) and negatively correlated with mean HWI ($r=-0.21$, $p<0.05$). Calf survival to Y3 was negatively correlated with maximum HWIs ($r=-0.26$, $p<0.05$) and associates/sightings ratio ($r=-0.12$, $p<0.05$). This pattern may be explained by SJR dolphins' large group sizes, which provide protection for vulnerable calves.

Deep sea prey layer in Cuvier's beaked whale foraging habitat modulated by ocean dynamics

Cuvier's beaked whale *(Ziphius cavirostris*) is a species of management concern in the Southern California Bight (SCB) due to their sensitivity to navy sonar and the presence of a naval test range in the region. A key component of impact mitigation for pelagic predators such as Cuvier's beaked whale is linking the abundance and distribution of both the predator and their prey to ocean dynamics. However, very few studies have attempted simultaneous measurements of both beaked whales and their prey, in part because of the limited depth range of ship-board active acoustic instruments. The aim of this study was to obtain long-term concurrent measurements of Cuvier's beaked whale echolocation activity, the deep sea prey field, and oceanographic parameters in order to improve our understanding of beaked whale foraging habitat. From March to July 2018, we deployed a mooring with a combination of passive and active acoustic instruments as well as a bottom-mounted Acoustic Doppler Current Profiler (ADCP) in the SCB at Tanner Basin (32° 39.5'N and 119° 28.6'W). Long-term acoustic recordings show that Tanner Basin is an area of intense Cuvier's beaked whale echolocation activity and thus a likely foraging hotspot. Here we report on the 4-month time series of simultaneous prey field measurements and Cuvier's beaked whale echolocation detections. We found a deep scattering layer located between 1040 and 1130 m deep, consistent with Cuvier's beaked whale foraging depth in the SCB. Fluctuations in the backscatter intensity of this scattering layer occurred over multiple temporal scales, most prominently at tidal frequencies, but with large, low-frequency fluctuations over weekly time scales. These fluctuations in the prey field are linked to both the flows interacting with the topography of Tanner Basin and overlying mesoscale flows. It appears that Tanner Basin may focus the Cuvier's beaked whale prey, creating the foraging hotspot.

Spatio-temporal distribution and habitat preferences of cetaceans in the Continental Economic Exclusive Zone of Portugal.

Cetaceans are key species in marine ecosystems and the knowledge on their distribution patterns is fundamental for the conservation and management of the ocean. In the Portuguese continental waters, 24 species of cetaceans are known, however data on their occurrence are fragmented and scarce. Hence, this work aimed at assessing habitat preferences and the spatio-temporal patterns of distribution for cetacean species in the Portuguese Continental Economic Exclusive Zone. Cetacean occurrence data was collected during summer months (July to October), from 2012 to 2017, within CETUS Project, a monitoring program using platforms of opportunity. About 43258 km were surveyed resulting in 19 cetacean species identified. A total of 962 sightings (686 on-effort) was recorded, totaling an encounter rate of 1,58 sightings per 100 Km. *Delphinus delphis* was the most frequently sighted species followed by *Stenella coeruleoalba*, *Tursiops truncatus* and *Balaenoptera acutorostrata*. Assessment of the preferences for depth, distance to the coast, latitude and longitude was conducted for the most frequently sighted species. Baleen whales' species shared similar latitudes, longitudes and distances to the coast, however, they showed significant differences in depth. Sperm and beaked whales were found in very similar habitats and showed preference for southern latitudes, a fact possibly related to the location of a steep seamount, the Gorringe. The spotted dolphin had preferences for southern latitudes and deep waters. Bottlenose and common dolphins were recorded in habitats significantly different from the other species. Based on the results, priorities for future research were defined: year-round surveys to assess/confirm the degree of occurrence and seasonality of the species, and dedicated surveys in the coastal waters of the North of Portugal and in the Gorringe seamount which seem to be suitable areas for several species.

Pulling the plug on rorqual breathing - and pushing it in for protection at depth.

The upper respiratory tract of rorquals must be protected against water incursion, particularly when breathing, and against the risk of barotrauma at depth, where air-filled spaces including bony nasal cavities experience high ambient ocean pressures (P_{amb}). The blowhole opening is actively controlled by two types of nasolabial muscles: superficial muscles that form the blowhole margins and paired tubular plug muscles that attach on the rostrum and deep on the nasal septum. The superficial and plug muscles have vastly different morphologies and positions on the skull; we propose they serve different functions. We hypothesize first, that the nasal plug muscles occlude the nasal cavities when not breathing, and second, that they facilitate pressure equilibration between nasal cavities and P_{amb} at depth. We tested these hypotheses by observing rostrum and blowhole morphology with drones and animal cameras. We dissected adult and fetal fin whales to assess tissue morphology and physically manipulate the plugs. Muscle morphology in-situ was obtained from an MRI scan of a minke whale fetus. We found each nasal plug had three histologically distinct regions: a muscular rostral region, a predominantly fatty mid-section at the blowhole, and an elastic tendon that attached the plug caudally, deep within the nasal cavity. We propose muscle activation while surfacing pulls the fatty section rostrally, opening the nasal cavities to air, while the elastic tendons snap the plugs back into place to seal the nasal cavities after breathing. At depth, we propose P_{amb} pushes the fatty region further into the nasal cavities, and calculate this could reduce the air volume of the nasal cavities by half. Such movement would equilibrate nasal cavity pressures with P_{amb} between lung collapse depth (~100-150m) and lower feeding depths (~200-300m). We conclude adaptations of nasal plug structure may provide a crucial mechanism to adjust nasal cavity volume to P_{amb}.

Modernizing Canada's approach to North Atlantic Right Whale management: Lessons learned and future challenges.

Gilchrist, Brett
Fisheries and Oceans Canada, Ottawa, Ontario, Canada
Corresponding Author: brett.gilchrist@dfo-mpo.gc.ca

Since 2016, the Government of Canada has made significant new investments through the Oceans Protection Plan, the Whales Initiative and the Nature Legacy, to advance the recovery of aquatic at-risk species, with a particular focus on endangered whales including the North Atlantic Right Whale (NARW). We present a case study analyzing the evolution of the Department of Fisheries and Oceans' adaptive management approach to mitigating key threats to this species, including fisheries interactions and vessel disturbance. These include both harm-reduction and preventative measures, such as static and dynamic closures in fisheries to reduce the risk of fishing gear entanglement for NARW, minimum vessel approach distances for cetaceans including NARW under the amended *Marine Mammal Regulations*, mandatory reporting of lost gear and marine mammal interactions in fisheries, and key investments to support gear innovation. Since significant targeted actions were taken following the NARW Unusual Mortality Event of 2017, there are some early signs of success, including no reported NARW deaths in Canadian fisheries waters in 2018. Key challenges to modernizing whale management include addressing regulatory hurdles, obtaining industry buy-in for measures, managing stakeholder expectations, and navigating scientific uncertainty. As the Department moves forward implementing an iterative harm-prevention approach to whale management, engaging Indigenous partners, stakeholders and the international community will be critical to the continued evolution of science-informed management measures that will help to achieve transboundary species recovery. The Department will build on this NARW management regime by improving existing measures and evaluating new approaches to support the recovery of these endangered whale species while considering socio-economic impacts to industry and coastal communities.

Prevalence of fishery-related scarring on the mouthlines of common bottlenose dolphins (Tursiops truncatus) around the main Hawaiian Islands

Fisheries interactions pose a serious threat to the conservation of many species of marine mammals. It is often difficult to directly observe and record these interactions, and many fisheries lack observer programs. Around the main Hawaiian Islands, multiple species of cetaceans have been documented interacting with both recreational and commercial fisheries, including common bottlenose dolphins, which have been observed depredating bait or catch from hook and line fisheries. To better assess non-lethal interactions between bottlenose dolphins and fisheries, photographs from a long-term (1987-2018) photo-ID catalog were examined for wounds or scarring that may have resulted from hooking or entanglement with fishing gear. The sample included known males and females and all age groups. Assessments included individuals from all four island-associated stocks among the main Hawaiian Islands. Photographs were examined showing mouthlines where hookings are most likely to occur. Individuals with mouthline scarring were also assessed for injuries on the leading edge of the dorsal fin and the head and/or peduncle, which may be damaged when individuals are hooked and struggle against gear. In total, photographs of 610 individually identified bottlenose dolphins were examined. Mouthline injuries consistent with fishery interactions were only found on adults. Analyses restricted to adults with ≥50% of the mouthline visible (n=432) revealed 14 (3.2%) with injuries consistent with fishery interactions, including 13 with mouthline injuries and one with a dorsal fin injury. Some individuals had additional evidence of line wraps on the head or peduncle. Individuals with such injuries were found from all four insular stocks, but were most prevalent from the Hawai‘i Island stock. These results provide evidence that non-lethal injuries from fisheries do occur in bottlenose dolphin populations around the main Hawaiian Islands. Additional research is needed to assess the significance of these results on a stock-by-stock basis in Hawai‘i.

Seals from space: Identifying change in Antarctic ecosystems via the monitoring of ice-seals and sea ice habitats by very high-resolution satellite and UAV imagery.

Gill, Prem[1]; Fretwell, Peter[2]; Rees, Gareth[3]; Staniland, Iain[2]
(1) British Antarctic Survey, Scott Polar Research Institute - University of Cambridge, Cambridge, United Kingdom
(2) British Antarctic Survey, Cambridge, United Kingdom

Corresponding Author: psg32@cam.ac.uk

Antarctic pack-ice seals (APIS) are long-lived, upper trophic level predators and amongst the largest consumers of Antarctic krill. Therefore, the monitoring of APIS populations can indicate changes in the Antarctic ecosystem. However, APIS inhabit the inaccessible sea ice zone, making traditional surveys (plane/boat) logistically difficult. Because of these challenges, reliable population estimates and habitat information for ice-seals are lacking. To overcome these limitations, *very high-resolution (VHR) satellite* and *unmanned aerial vehicle (UAV)* imagery will be used to detect/discriminate ice seal species for counts at local scales and identify habitat hotspots at broad regional scales. This involves identifying species classification parameters; extracting sea ice characteristics; constructing *habitat models* to explain population dynamics and predict responses to environmental change.

Satellite surveys have been conducted on breeding seals to test various classification techniques due to their increased haul-out duration. The accuracy of each technique will be assessed using thermal/optical data sourced from ground-truthing UAV surveys to exclude artefacts and determine count variance. Resulting insights into the distribution and habitat preference of seal colonies will inform the automated detection of *habitat hotspots* for present and future sea-ice conditions under a range of climate scenarios, the development of a penguin-seal-fisheries competition index and the first robust pan-Antarctic ice-seal population estimates. Shifts in habitat extent/competition determined from these data will inform IUCN red list assessments. Given that sea ice volume is predicted to decline significantly by the end of the century, the monitoring of ice-seals and their habitat via VHR imagery is pivotal to *polar marine conservation*. Here, we present details of the satellite/aerial surveys conducted on breeding ice seals, and the on-going development of *machine learning algorithms* to provide the first VHR sea ice classification techniques. We will also discuss the capacity for dynamic conservation management provided by an automated system for near real-time habitat mapping.

Winter distribution of endangered belugas in Cook Inlet, Alaska

Cook Inlet belugas (CIB) were listed as endangered in 2008 with a recovery plan finalized in 2016. The CIB is also one of NOAA's Species in the Spotlight; an effort to save the most highly at-risk marine species. In 2018, NOAA and the Bureau of Ocean Energy Management (BOEM), undertook a multi-year project to document the winter distribution of CIB using aerial surveys. Long-term NOAA surveys show the summer range of CIB has contracted to areas of upper Cook Inlet (UCI). However, CIB winter distribution is not nearly as well documented. The last winter surveys and satellite-tagging studies occurred in 2002. With concerns that CIB may be adversely affected by increasing development in lower Cook Inlet (LCI) a broader picture of distribution is needed. In 2018, we began winter shoreline surveys and sawtooth transects throughout Cook Inlet. Survey sightings showed belugas in both UCI and LCI. A relatively ice-free November 2018 survey recorded belugas only in UCI. Notable LCI beluga sightings occurred in Tuxedni Bay March 2018 and 2019. Previous studies have also documented beluga presence in Tuxedni in March where whales may be taking advantage of spring herring runs. March sightings near Kalgin Island (LCI) may also coincide with a herring run. Belugas were also observed in the Kenai River (LCI) in March. Historically Kenai has been an important foraging location year round but a dramatic increase in human activity may be contributing to belugas utilizing the river only during the 'off" season. Although our initial results show belugas utilizing LCI in the winter, their winter range still appears more contracted compared to the range in the 1970s,. Additionally, CIB are now remaining in UCI waters year round. Winter range information is important to take into consideration as oil and gas exploration expands in this increasingly ice-free and accessible environment.

Current review of Pacific blue whale (Balaenoptera musculus) populations
Gilpatrick, Jim[1]; Lynn, Morgan[2]; Perryman, Wayne[2]

Blue whales in the eastern North Pacific (ENP) migrate in summer/fall from Mexican and Central American waters to coastal feeding areas off of the west coast of North America (from Baja California to the Gulf of Alaska). An aerial photogrammetric analysis of ENP blue whales indicates that they are similar in total length (TL), tail length and rostral length to the pygmy blue whale (*Balaenoptera musculus brevicauda*) described from the Indian Ocean. Blue whales taken in fisheries along the Aleutian Islands were likely a separate Central No. Pacific population (based on TL data and acoustics) while blues taken in the Sea of Japan comprised a Western No.Pacific population that is likely extirpated.

A recent publication concluded that blue whales found during winter and early spring in the Gulf of California are morphologically different from the described ENP blue whales. This was based on tail lengths derived proportionally (as no TL data were available). The paper suggests, based on a recent genetics study, that Gulf of California blue whales may in fact be migrants from the southern hemisphere.

In response to this publication, in this presentation, morphometric data for ENP blue whales (derived from aerial photogrammetry and fishery data) were stratified geographically and graphically presented. Results indicate that ENP blue whales sampled at different latitudes along the Pacific are similar in external morphology (albeit sample size was small for some locations such as the Costa Rican Dome). Furthermore, the likelihood of a blue whale population in the Gulf of California that is separate from the ENP population will be discussed based on current and historical information. The relationship between eastern South Pacific (ESP) and ENP blue whales will also be discussed.

Revisiting Natura 2000 network from a Systematic Conservation Planning perspective: The endangered Mediterranean common dolphin subpopulation as a case study.

Several European conventions and agreements propose the establishment of marine protected areas (MPA) for cetacean as one of the available tools to preserve populations and their habitats. This area-based protection has been mainly driven by the

implementation of the Natura 2000 network of MPAs under the Habitat Directive (92/43/EEC). Only bottlenose dolphins and harbour porpoise are listed as cetaceans species that deserve the establishment of special areas of conservation. Nevertheless, other species such as the Mediterranean common dolphins should benefit of area-based protection to face their main threats. Here, we evaluate if the Natura 2000 network is protecting the common dolphins in the Alboran Sea through a systematic conservation approach. Furthermore, we use this endangered species as a case scenario to understand how the addition of fisheries information may influence the conservation planning output. Overall, our results suggest that the current MPA network largely overlap with the "core areas" for this population protecting 22% of its abundance. However some important gaps in conservation planning are detected at the western side of their distribution. Further, offshore areas are also systematically selected as important areas for common dolphin conservation when fishing effort is included as a cost for conservation. This is because fishing effort at such offshore areas is very low compared to that within main "core areas" for dolphins distribution, so they are "cheaper" to protect. However, these areas represent the marginal distribution of the species and their protection may have undesirable ecological consequences such as the conservation of potentially low quality individuals while harmful interactions would continue in the main "core areas". Owing to the spatial congruence between dolphins and fisheries' distribution, effective conservation actions will certainly have costs on this essential supporting service. Then conservation decision-makers must achieve a trade-off between cetacean conservation and fisheries.

Inferring animal social networks with imperfect detection.

Social network analysis provides a powerful tool for understanding social organisation of animals. However, in free-ranging populations, it is almost impossible to monitor exhaustively the individuals of a population and to track their associations. Ignoring the issue of imperfect and possibly heterogeneous individual detection can lead to substantial bias in standard network measures. Here, we develop capture-recapture models to analyse network data while accounting for imperfect and heterogeneous detection. We carry out a simulation study to validate our approach. In addition, we show how the visualisation of networks and the calculation of standard metrics can account for detection probabilities. The method is illustrated with data from a population of Commerson's dolphin (*Cephalorhynchus commersonii*) in Patagonia Argentina. Our approach provides a step towards a general statistical framework for the analysis of social networks of wild animal populations.

Environmental factors driving short-beaked common dolphin coastal distribution and habitat suitability in NW Spain.

Giralt Paradell, Oriol[1]; Díaz López, Bruno[1]; Methion, Séverine[2]

Marine ecosystems, especially those located in coastal areas are heavily affected by human activities. Research conducted in these areas should be aimed at improving the conservation of threatened species and habitats. Environmental factors have been used to understand species distribution and the latter has proven to be a fundamental tool to promote effective conservation measures and management plans. The present work explores the use of species distribution models like the Environmental Niche Factor Analysis (ENFA) to assess the habitat suitability of common dolphins (*Delphinus delphis*) in Northwest Spain, and its application to the development of effective conservation and management measures. Although recent studies on the distribution of the species in Atlantic waters show that the Northwest Iberian Peninsula is an important area for common dolphins, there is a lack of information on the ecological niche and the spatial distribution of the species in coastal areas. Presence-only data was linked to ecogeographical variables (EGV) to assess the potential distribution of the species. Data were collected during 273 days at sea, covering a total distance of 9 417 km between March 2014 and October 2017 with a total of 91 common dolphin encounters. The study reveals that tide level and sea surface salinity are the main EGVs driving common dolphin distribution in coastal areas. Furthermore, the study shows that fisheries might have an

impact on the species distribution as they exert an intense pressure in areas that include the most suitable habitat for common dolphins. Findings of this study contribute to a more comprehensive understanding of common dolphin coastal distribution and highlight the importance of species distribution models in the development of effective conservation and management strategies.

Geographical variation of piebaldism in Black Sea bottlenose dolphins

Natural elements of anomalous white hair or skin coloration are observed in many animals. These elements can be either small patches lacking pigmentation (piebaldism) or fully depigmented body surface. Such cases are relatively rare among cetaceans. Here we present the first report on one fully white and several piebald bottlenose dolphins *Tursiops truncatus* (Montagu, 1821) in the Black Sea.

In result of photo-identification of bottlenose dolphins covering all the coastal areas of the Black Sea and the Bosphorus Strait (n=751), piebald animals (n=30) have been recorded in most of areas, and a fully white dolphin has been observed in the north-eastern Black Sea between 2007 and 2013. Also, the greatest concentration of piebald dolphins was found in the north-eastern areas (Sudak, 13%, and Balaklava, 9%), significantly more than in the other areas. The lesser percentage was in the Bosphorus Strait (4%), and only few sightings have been reported from the north-western and eastern Black Sea. Cases of piebaldism were not recorded in the southern Black Sea. Therefore, there is a gradient in geographic distribution of piebaldism in the Black Sea bottlenose dolphins with the maximum in the north-eastern area. In most cases, the white patches were located on the dorsal fin: they were small, of irregular shape, often nearly symmetrical at the left and right sides. In some cases there were white patches on the dorsal side of the body or peduncle, on tail flukes. This kind of coloration can be caused by several mutations or metabolic mechanisms. Meanwhile, frequent occurrence of piebald animals in local populations can be explained by gene drift, founder effect and/or inbreeding. This could be an evidence for population divergence.

Establishing skin cell cultures in gray whales to examine their sensitivity to marine contaminants (PAHs, PFCs, PCBs, oil).

The gray whale (*Eschrichtius robustus*) often travels and feeds close to dense coastal human populations. Marine contaminants including polycyclic aromatic hydrocarbons (PAHs) (incomplete combustion products), per/poly-fluorinated compounds (PFCs) (industrial products with anti-stick and flame-retardant properties) and polychlorinated biphenyls (PCBs) (historically produced as electrical insulators), have been detected in cetacean blubber. Crude oil is released in the marine environment from both anthropogenic activities and natural sources. Little data exists on the effects of these contaminants in *E. robustus*. Our aim is to understand whether organic pollutants are cytotoxic in gray whale tissue and whether these toxicants are of concern for the species. Cell culture is invaluable in research involving protected species as it is minimally invasive and allows for multiple investigations using a single biopsy. We cultured primary fibroblasts that were propagated from skin biopsies obtained from three free-swimming eastern gray whales. Cells were maintained in DMEM/F12 media supplemented with 15% cosmic calf serum, 1% glutamax, 1% penicillin/streptomycin, and 0.1% sodium pyruvate. Cultures were incubated in a humidified atmosphere of 5% CO_2 at 37°C. Cytotoxicity was measured via MTT (methylthiazolyldiphenyl-tetrazolium bromide) and LDH (lactate dehydrogenase) assays. Toxicants selected were media accommodated fractions of crude oil and/or Corexit (an oil dispersant) or benzo[a]pyrene (B[a]P) or PCB 126 in

concentrations of 10µM, 1µM, 0.1µM, or 0.01µM or perfluorooctanoic acid (PFOA) in concentrations of 500µM, 50µM, 5µM, 0.5 µM, or 0.05µM. Exposure time points were 24h, 48h, 72h, and 96h for each toxicant. Cytotoxicity was measured colorimetrically via spectrophotometer. Cellular viability was significantly reduced after exposure to B[a]P, PCB 126, and PFOA at various concentrations and time points ($p<0.05$). Additionally, cellular viability was significantly reduced after exposure to B[a]P at environmentally relevant concentrations. Preliminary results suggest that cellular viability was reduced after exposure to Corexit. Further investigation is currently underway.

Fatty acid content of Pacific walrus (Odobemus rosmarus divergens) skeletal muscle lipids.

Godfrey, Genevieve[1]; Trumble, Stephen[2]
(1) Baylor University
(2) Baylor University, Waco, Texas
Corresponding Author: jen_godfrey@baylor.edu

Pacific walrus foraging success depends on both prey biomass and the proximity of foraging areas to haulout sites. Reduced summer sea ice availability constrains walrus habitat to secondary coastal haulout sites, which may deplete prey at those locations. Female and juvenile walruses are at an increased risk of nutritional stress, requiring shallow, densely aggregated prey to efficiently forage within their shorter aerobic dive limits, while meeting the additional energetic costs of growth and reproduction. Females nurse and forage with their calves almost continuously, giving birth to the next calf shortly after weaning the previous calf. Stored lipids are an important resource for offsetting the increased reproductive costs of lactation and pregnancy, and during periods of limited foraging. Pinnipeds preferentially metabolize polyunsaturated fatty acids (PUFA) because they require less oxygen to convert into ATP. Fatty acids were extracted and analyzed from Pacific walrus skeletal muscle samples obtained through Native subsistence harvests during spring in Alaska between 2009 – 2015 (n = 50). Muscle saturated fatty acids (SFA), at an average of 73% of total lipids, were more than twice concentrations previously noted in walrus blubber or muscle lipids analyzed in phocids. The range in SFA proportions differed between males and females, with males ranging between 33% and 88%, while females only differed between 71% and 89%. Spring walrus migration from southern to northern habitat, as well as pupping, have the potential to limit foraging in males and females and increase the reliance on stored lipids for fuel. The high proportion of SFAs in walrus skeletal muscle may indicate that the animals have exhausted the available PUFAs and MUFAs in blubber stores and have switched to mobilizing SFAs. This potentially indicates that a higher proportion of males are actively foraging during migration, while females are entirely reliant on stored lipids.

Adapting to climate change: Trends in Weddell seal abundance over two decades.

Goebel, Mike[1]; Borras-Chavez, Renato[2]

Corresponding Author: megoebel@ucsd.edu

Climate change has significantly impacted coastal marine ecosystems of Antarctica. In the last several decades, the western Antarctic Peninsula (wAP) has experienced massive ice losses, represented by glacier retreat, ice-shelf collapses and sea-ice reduction. The surrounding waters of the South Shetland Islands (SSI), a major archipelago of the wAP, are now ice-free year-round in most years. The Weddell seal (WS) has a circumpolar distribution and is an abundant predator in coastal areas of the SSI. The pagophilic nature of WS has led some to predict that loss of sea ice will adversely affect this species. Here, we examined 20 years (1997-2016) of weekly census data(November –February) for Cape Shirreff, Livingston Islandlocated in the SSI. We tested the hypothesis that the regional presence of off-shore ice and WS preference for ice results in fewer numbers hauled out on land. Contrary to predictions, there was no indication that regional offshore ice affected on-shore abundance. Furthermore, our results indicate a stable to increasing abundance of Weddell seals on land at Cape Shirreff. Despite a preference for near-shore ice, this species appears toadapt well to breeding and foraging in ice-free habitat.

Fish legacy or evolutionary novelty: Hitherto unknown bones reflect evolutionary heterochronies in cetacean skull.

Gol'din, Pavel
I.I. Schmalhausen Institute of Zoology of National Academy of Sciences of Ukraine, Kiev, Ukraine, Kiev, (select), Ukraine
Corresponding Author: pavelgoldin412@gmail.com

The cetacean skull is characterized by delayed and incomplete postnatal ossification of skull sutures. Also, there are a few additional non-typical bones and clefts appearing in the skull vault and temporal region of various cetaceans, both mysticetes and odontocetes. Some of them can be interpreted as

Wormian bones; however, others are large and not located within the cranial sutures. These ossification centers can be identified or interpreted as postparietal, tabular, lateral extrascapular, posttemporal and supratemporal bones, and, therefore, they can be classified as atavisms typically lost in mammals but existing in early reptiles, amphibians or even sarcopterygian fishes and the earliest tetrapods. Also, two ossification centers were found for the parietal bone, confirming its dual origin in amniotes. Slowing development rate well explains these phenomena, and, therefore, non-typical features of cetacean skulls, whether they are atavistic or novel, are interpreted as a result of paedomorphosis. The possible function of delayed skull ontogenetic development is the prolonged development of the braincase, temporal region and the upper jaw, as well as the skull kinetism for suction and gulp feeding.

Crimean coast of the Kerch Strait: Original evidences about cetaceans.

Goldin, Evgeny
Southern Branch of the National University of Biological Resources and Environmental Management-Crimean Agricultural and Technological University, Simferopol, Crimea, Ukraine
Corresponding Author: evgeny_goldin@mail.ru

Straits are very important in cetacean life cycle; the Kerch Strait (KS) as unique passage between Sea of Azov and Black Sea is among them. A length of KS Crimean coast between Khroni and Takyl Capes is 42.7–45.0 km. KS and adjoining area are the sites of highest fish diversity and resources concentration in the basin. Meanwhile, it is arena of rising anthropogenic pressure on marine environment, especially during last time. Cetaceans, mainly bottlenose dolphins (TT) and harbor porpoises (PP), occur in KS all year round (85.4% in summer), except of season of extremely hard ice conditions in KS and the Sea of Azov; and it is very interesting ecosystem for investigations. The analyzed materials were obtained from information of about 4000 students, local people, sailors and fishermen in 2002–18 (153 of respondents are residents of Kerch Peninsula); 200 sightings (TT – 34.0%, common dolphins (DD) – 17.9%, and PP – 48.1% of identified cases) and 75 strandings (TT – 20.5%, DD – 12.8%, and PP – 66.7% of identified cases) were reported. Crimean KS coast was divided into three sectors: North (Azov) – Yeni Kale Light House, Kerch ferry boat, Borzovka, and Kapkany; Center (Kerch) –Tuzla Spit, Kerch Bay and beaches, Arshintsevo, and El Tiygen; and South (Black Sea) – Tobechik and Takyl Cape. Some differences in cetacean taxonomic structure were distinguished: in the North and Center PP dominated in sightings/strandings – 68.2/55.6%, and 46.3/74.1%, but in the South balance between TT (50.0/33.3%) and PP (50.0/66.7%) was another. The most of sightings observed in Kerch ferry boat (10.0%), Kerch Bay (49.0%), and El Tiygen (12.0%). Strandings were discovered in Azov coastline (9.2%), Kerch Bay (58.5%), Yeni Kale Light House and El Tiygen (in 6.2%). The annual peaks of cetacean occurrence were in 2008 (23.0%), 2003 and 2012 (in 7.5%).

Phocine distemper outbreak in phocid seals off the United States east coast in 2018-2019.

An Unusual Mortality Event (UME) was declared by the National Marine Fisheries Service on August 30, 2018 due to increased numbers of harbor seal (*Phoca vitulina*) and gray seal (*Halichoerus grypus*) strandings along the U.S. coasts of Maine, New Hampshire, and Massachusetts during July and August. In January 2019 harp (*Pagophilus groenlandicus*) and hooded (*Cystophora cristata*) seals also began stranding as they migrated from Canada into U.S. waters. Strandings remained elevated and have expanded to include nine states from Maine to Virginia with over 2000 seals stranding since July 2018. Live seals had evidence of respiratory and/or neurological disease, with pneumonia present on gross necropsy examination. Histologically, seals had bronchointerstial and/or suppurative pneumonia, meningoencephalitis or encephalitis, and/or lymphoid depletion consistent with morbillivirus infection. Tissue or swab samples from ~65% of harbor and gray seals tested by polymerase chain reaction (PCR) were positive for phocine distemper virus (PDV). No harp or hooded seals have tested positive to date. Additionally, ~86% of harbor and gray seal cases tested by immunohistochemistry (IHC) were positive for PDV in lung, lymph node or brain tissue. Serum from a subset of seals tested had PDV neutralizing antibodies, with titers ranging from 1:64 to > 1:512. Virus isolation and genome sequencing of the virus from this outbreak determined the sequences to be most similar to the 1988 and 2006 PDV isolates. Naïve live seals in rehabilitation are being vaccinated with the PUREVAX® ferret distemper vaccine prior to release to ensure protection and improve survival after release. The potential impact of this outbreak on phocid seal population(s) off the US east coast is being monitored.

Assessment of sublethal cardiac injury in bottlenose dolphins (Tursiops truncatus) in the Gulf of Mexico following exposure to deepwater horizon oil-associated chemicals

Health studies conducted in the wake of the *Deepwater Horizon* (DWH) disaster represented significant progress in characterizing oil-associated effects on cetaceans; however, some critical questions remained unanswered. In 2016, an increased prevalence of systolic heart murmurs was noted in dolphins from heavily-impacted Barataria Bay, LA (BB) relative to those in Sarasota Bay, FL (SB), outside the oil spill footprint. Due to limited cardiac diagnostics in field protocols, the effects of oil on cardiac health had not been fully evaluated. To address this need, innovative field-ready techniques for cardiac evaluation were developed with U.S. Navy dolphins and then applied to live BB and SB dolphins during comprehensive health assessments in 2017 and 2018. Systematic cardiac auscultation detected fixed or dynamic murmurs in the majority of animals regardless of oil-exposure history; most murmurs (95%) were due to benign elevation of velocity of flow through one or both cardiac outflow tracts. Telemetric 6-lead electrocardiography detected arrhythmias in more BB dolphins (43%) than in SB dolphins (29%), with all animals having an underlying normal sinus arrhythmia. Arrhythmias were considered low to moderate risk for adverse cardiac events and included atrial and ventricular premature beats, sinus tachycardia, and 2nd degree atrioventricular block. Echocardiography showed the mean interventricular septal wall (IVS) thickness was less

(p=0.0031) in adult BB males (meanIVS = 0.32 cm + 0.05 SD) compared to adult SB males (meanIVS = 0.42 cm + 0.07 SD), however, whether this difference is an indication of cardiac disease or physiologic differences is not known at this time. Potential mechanisms for cardiac injury were evaluated by retrospectively examining histologic lesions in tissues of dead, stranded dolphins. On histologic evaluation, dolphins within the oil spill footprint had a higher prevalence of cardiac fibrosis than control animals stranding outside the spill area (44% vs 19%, p=0.002).

"Whales from The Hill": A platform for studying humpback whales in the northeast of Brazil.

The humpback whales from the breeding stock A are recovering and currently, the whales are observed throughout northeastern Brazil. Since 2014, monitoring studies of humpbacks have begun in Serra Grande, a region where the continental shelf is narrower in the Brazilian coast, allowing the whales to approach near the coast. Land-based visual monitoring using a total station, and passive acoustic monitoring using Oceanpods deployed on the seabed at a sampling rate up to 16 kHz were conducted between July and October in 2014, 2015 and 2018. The objective of this project is to use these platforms with unique characteristics to monitor humpback whales, evaluating habitat use and movement patterns, as well as the evolution of acoustic communication of this population. The number of individuals observed at the peak of the seasons has increased over the years, with a maximum of 21 individuals observed per hour. Most of the groups observed were in waters of less than 50 m depth. The movement patterns, as net speed (5.49±2.73 km/h) and linearity (0.81±0.18), have remained constant over the years. Singing was the predominant vocal activity, but at least 13 social calls were also detected. Ten song themes were described: four themes were maintained between 2014 and 2015, and only one between 2015 and 2018. The next steps are the description of the repertoire of social sounds of this population and the study of song evolution applying the Levenshtein Similarity Index. Intra- and inter-population song comparisons are also planned within a newly formed research network in Latin America. The continuity of these monitoring efforts in the long term will allow us to identify the population and behavioral trends of the breeding stock A, building a baseline database about humpback whales before the construction of the new Port complex in the vicinity of Serra Grande area.

Comparison in phthalates concentration in four species of whales with different feeding behaviour from Mexican Pacific

Over last decades, plastics litter have become a major problem due to its persistence and widespread distribution in the marine environment. Smaller fragments derived through environmental degradation from larger plastic can be easily incorporated in food chain, particularly microplastics (MPs), <5mm particles, that are ingested mistakenly by marine organisms and may cause long-term adverse effect as transfer and accumulate associated toxic chemicals into animal tissues. Phthalate esters (PAEs) are plasticizers that induce endocrine toxicity may have sublethal effects in hormone synthesis and, alter reproduction or other physiological and metabolic functions. The principal objective of the present study is to determine the concentration of PAEs in four whale species with economic, social and environmental importance to mexican community (*Balaenoptera physalus*, *B. musculus*, *Eschrichtius robustus* and *Megaptera novaeangliae*). To this aim, biopsies has been collectedin the whale feeding and breeding

grounds areas: San Ignacio Lagoon (gray whale: 5 males and 5 females), Los Cabos (humpback whale: 10 males) and Gulf of California (fin whale: 17 males). In addition, 8 zooplankton/MPs samples will be taken from two areas of the Gulf of California (Bahía de Kino and San Luis Gonzaga). In respect to PAEs, five diesters and their main monoester metabolites will be detected (DEHP, MEHP, DIOP, MIOP, BBzP, MBzP, DBP, MBP and DiBP, MiBP) using the GC-MS technique. Profiles of these chemical compounds in blubber will serve as plastic tracer of MPs and to assess whether the variation in feeding areas and habitats is reflected in their PAEs levels. Moreover, zooplankton/MPs samples will allow information about the ingestion/exposure to MPs and contaminated prey that affects two feeding grounds of whales in the Gulf of California.

Temporal distribution and multi-scale habitat preference analyses for Azorean blue whales

Blue whales are sighted every year around the Azores islands, which apparently provide an important seasonal foraging area. In this study we aim to characterize habitat preferences and analyse the temporal distribution of blue whales around São Miguel Island. To do so, we applied Generalized Additive Models to a seven-year opportunistic cetacean occurrence dataset (2008-2014) and remotely sensed environmental data on bathymetry, sea surface temperature, chlorophyll concentration and altimetry (MSLA). Oceanographic dynamism in the Azores has been recently studied at a regional scale. However, detailed information at a more local scale is still scarce. As our study area is well limited and relatively small, here we provide a high-resolution description of the oceanographic conditions around São Miguel Island based on the environmental variables previously cited. We emphasize its high spatio-temporal variability. In order to capture this dynamism, we used environmental data with two different spatial resolutions (low and high) and three different temporal resolutions (daily, weekly and monthly), thus accounting for both long-term oceanographic events such as the spring bloom, and shorter-term features such as eddies or fronts. Blue whales' temporal distribution was analysed for sightings recorded between 2008 and 2018, accounting for a total of 188 records. Interannual differences in the number of blue whale sightings are apparent. Our results show that blue whales have a well-defined ecological niche around the Azores. They usually cross the archipelago from March to June, every year, and habitat suitability is highest in dynamic areas (with high Eddy Kinetic Energy) characterized by convergence or aggregation zones where productivity is enhanced. Multi-scale studies are useful to understand the ecological niche and habitat requirements of highly mobile species that can easily react to short-term changes in the environment.

Female productivity and calf survivorship of bottlenose dolphins (Tursiops truncatus) in Bocas, Panama

The resident bottlenose dolphins of the Archipelago of Bocas del Toro are regularly exposed to intense interactions with dolphin-watching boats. Despite these intense interactions, the dolphins remain in the area for two reasons: the bay's safety from predators and abundance in food resources. However, ongoing studies indicate that while the preferred food source, sardines, is abundant, they provide low caloric gain. This means that the dolphins must eat regularly. Previous research has shown that Bocas dolphin foraging behavior is disrupted throughout the day by tour boats. This has created concerns about the health of the population, particularly lactating mothers and the potential effects on calf survival. In this study, we used mark-recapture data from 2004 to 2015 to infer dolphin female reproductivity and calf mortality rates. A total of 35 females were identified from 140 dolphins in the current catalog. Twenty-three of these females are regular users of Dolphin Bay. The bay is part of their home range where they regularly interact with dolphin watching boats. Each female in this population had between one and three calves during the study period, with

an average calving cycle of 62 months (SD: 21.91 months**,** Range: 24-97 months), longer than other known populations. Furthermore, calf mortality was estimated to be 0.46, which is higher than reported for other bottlenose dolphin populations. The survival rate for this population is estimated to be 0.54. Understanding female reproductive success in this local population of dolphins may provide a quantifiable measure of health and individual fitness, which are essential to protect this population.

Characterization of side scan-sonar images produced by Amazonian River dolphins (Inia geoffrensis) to reduce potential confusion during surveys of Amazonian manatees (Trichechus inunguis).

Gonzalez-Socoloske, Daniel[1]; Carvalho de Carvalho, Camila[2]; Marmontel, Miriam[3]

Side-scan sonar (SSS) has been successfully used to detect West Indian and African manatees, however confirmed sonar images of Amazonian manatees have not been obtained yet. One potential difficulty is differentiating manatee images from other large aquatic vertebrates. The Amazonian manatee shares most of its habitat with two cetaceans, the Amazonian River dolphin (ARD, *Inia* spp.) and the Tucuxi (*Sotalia fluviatilis*). In this study we characterize the sonar image produced by the ARD and make notes on behavior observed during surveys for Amazonian manatees. Boat surveys using SSS were conducted during the high (July 15-30, 2017 and March 17-21, 2019) and low (December 13-21, 2017) water seasons in Amanã Lake, Amanã Sustainable Development Reserve, Amazonas, Brazil. Sonar surveys were recorded and then analyzed with ReefMaster Sonar Viewer (v. 1.0.36). Unlike the acoustic images produced by manatees, ARD acoustic images contain sharper angles and narrower shadows. At slow speeds (1-3 km/h), the shadow resembles an ARD, with a low profile dorsal fin, a narrow beak, and a narrow tail with a fluke. At faster speeds (4-5 km/h), the acoustic image can be elongated with a wavy tail due to the ARD swimming alongside the boat. ARD in Lake Amanã repeatedly followed our boat for kilometers during several hours, swam under the boat and approached the SSS transducer, suggesting they could hear the sonar, but were not distressed by it. ARD were usually seen in small pods (1-4), however several pods would aggregate over time in relatively large numbers (10-20) around the boat. In conclusion, ARD acoustic images have unique characteristics and can be reliably distinguished from known manatee acoustic images, however due to the behavior of ARD and their propensity to approach survey boats, care must be taken when surveying for Amazonian manatees.

Environmental determinants of habitat use by Caspian seals (Pusa caspica) and implications for marine conservation planning

Here we describe a multi-year satellite telemetry study of Caspian seals spanning 2009-2017, involving 111 tag deployments, with active periods of up to 11 months. We apply state-space models to characterise tracks into 'area restricted search' (ARS, which may be indicative of foraging activity), and travelling behavioural states, and examine how environmental variables including sea surface temperature, bathymetry, bathymetry slope, distance from shore, bottom sediment type, and vessel traffic density affect the probability of ARS in summer and autumn seasons. We use General Additive Models to generate predictions for ARS habitat usage by Caspian seals across the Caspian Sea, and then evaluate overlap with human activities and the implications for potential marine protected area locations.

In the best fit models, all the environmental variables explained significant variation in ARS probability. Predicted ARS probabilities were highest in offshore areas with sloping bathymetry around the edges of the Caspian mid and southern basins, and lower in areas with water depths exceeding 400m, or with mean sea surface temperature less than 22ºC. Data from 2011 was used to generate a baseline model, and data from the 2016 deployment to validate model predictions. The original model successfully predicted ARS hot spots in the 2016 data, suggesting it adequately describes environmental factors influencing seal ARS distributions, and that there is consistency in patterns of habitat usage across years. Locations

with the highest predicted importance for ARS may be candidates for future marine protected areas to safeguard seal feeding habitat.

Human activities, including offshore industrial developments and regions with high vessel traffic density overlap with many areas with high ARS probability. Evaluating potential impacts from intensive human use of the Caspian offshore environment therefore needs to be given high priority when planning industrial activity in these zones.

Humpback whale calls detected by autonomous Wave Glider in tropical ocean basin between known Hawaii and Mexico breeding assemblies.

Humpback whale behavior and distribution have been relatively well studied in near-shore locations but far less explored in deep ocean basins, where access is limited or expensive. In recent years several autonomous robotic vehicles have been developed and tested for deep sea research including the passive acoustic monitoring of cetaceans. In this study a Wave Glider known for its success in long transits of offshore waters was fitted with a hydrophone system to record humpback whale calls. North Pacific humpback whales' summer in feeding grounds on continental shelves around the Pacific Rim from California to Japan, and, in winter, migrate southwards across deep seas to several traditional tropical breeding grounds – two of these are the Mexican mainland coast and offshore islands (Revillagigedo Islands), and the Hawaiian Islands. These Mexico and Hawaii winter assemblies have recently been assessed by US NMFS as distinct population units warranting separate management (and different protective status). However, their shared song composition indicating mixing and interchange of photo-identified whales complicates this assessment. To investigate any winter connection between these assemblies, the Wave Glider performed a 3,761.1 nm, 100-day acoustic survey from Hawaii towards Mexico (RT) circa 20° N, from 15 January to 25 April, 2018. The 2,272 hours of recordings led to over 4000 cetacean detections, including unexpected numbers of minke whales, humpback whales and unidentified odontocetes. Humpback whale calls were recorded from Hawaii to 2,184 km (1,179.3 nm) to the east, or approximately midway to Mexico. Explanations for humpback whale presence in the tropical ocean basin between Mexico and Hawaii include an undocumented migration route, an offshore assembly, or mid-season travel between assemblies.

Passive acoustic monitoring of individual movements in a bottlenose dolphin population.

Identifying individuals in a population can be crucial in conservation management strategies. Signature whistles produced by bottlenose dolphins (*Tursiops truncatus*) are an individually distinctive, dominant and stable vocal signal within their repertoire, thus providing the possibility for passive acoustic monitoring of individuals. This study focused on the population inhabiting the East Coast of Scotland. SM2M acoustic recorders were deployed in 10 different locations over the summer months of 2013, 2014 and 2015. Audio files totaling 264 hours were aurally and visually inspected. Whistle contours were given a quality index (QI) based on their visibility and signal-to-noise ratio. Whistle contours with a high QI were categorized and signature whistle types (SWTs) were determined from these categories using the SIGID bout criterion, a classification method based on the pattern of temporal production. Whistles meeting this criterion were used as templates in order to match the remaining whistles. Categories were supported during two separate visual classification tasks using 5 blind judges who were asked to match printed exemplar whistles to a subset of signature whistle templates (Fleiss Kappa statistics of $k>0.8$ and $k>0.9$). 53 unique SWTs, about one third of the estimated population size, were identified during the three-year period. The quantity and diversity of unique SWTs varied between years and among locations. Encounters were concentrated in 4 locations in all years. Preliminary mark-recapture analysis revealed individual movements both within and outside the Moray Firth SAC, and patterns of detection varied between years. One location, Stonehaven, that accounted for the majority of signature whistles in

2013 and 2015, was highlighted as being a potentially important habitat. Individual-based acoustic monitoring, using signature whistles, is a promising avenue for obtaining data complementary to visual surveys, but much work still needs to be done on whistle production and linking signatures to individuals.

Return on investment – does the inclusion of short term marks in mark-recapture studies improve abundance estimates?

Photographic mark-recapture (MR) analysis traditionally provides abundance estimates only for those individuals identifiable from long-term marks (LTM), such as nicks and notches on dorsal fins. The number of unmarked individuals is accounted for separately using two primary methods. Most commonly, the estimates are adjusted by the proportion of images with unmarked fins, which may include repeated sampling of individuals in groups to estimate the proportion of identifiable individuals. Another option, particularly for projects of short duration and smaller populations, is to identify all individuals by also including individuals with short-term marks (STM), such as tooth rakes, scars, color variation on dorsal fin or body, and associations (e.g., mom/calf pairs). We compared abundance estimates from a sample where all individuals were identifiable using LTM and STM. During 8–26 January 2018, we conducted an MR study of estuarine-resident common bottlenose dolphins (*Tursiops truncatus*) in North Carolina, USA. All photographed dolphins were individually identified (n=476), 31% (n=146) of which were identified from STM. Using only LTM dolphins with the proportional adjustment, the abundance estimate was 806 (CI=683–972, CV=0.09). Using all identified individuals (LTM and STM), meaning that no proportional adjustment was needed, the abundance estimate was higher (941, CI=828–1090, CV=0.07). In this example, the method using the proportional adjustment may underestimate abundance. Identifying all (or most) individuals, including those with STM, is more time intensive, may have false positives/negatives, and be limited in use outside of the timeframe of a study. These issues can be offset with computer-assisted matching (e.g., FinFindR) and experienced photo-identification researchers. In addition to improving estimates of population size, the ability to identify as many individuals as possible has other benefits, such as elucidating distribution and movements as determined through photo-identification.

Changes in gillnets fishery in Polish Baltic waters in the last decade in the contex of the conservation of critically endangered population of harbor porpoises Phocoena phocoena

Harbour porpoise (*Phocoena phocoena* L.,1758) is the only species of cetacean enhabiting the Baltic Sea. Due to low abundance of the Baltic population of harbor porpoises resulting from excessive bycatch among other threats, it was recognized by International Union for the Conservation of Nature (IUCN) as critically endangered in 2008. The major threat for this species in Polish Baltic waters is bycatch in gillnets which are the most popular gears used by fishery fleet below 12 meters operating in coastal zone, what is not beneficial to protecting the species. The area in Polish Baltic waters, where over 40% of total reported bycatch of harbour porpoises was reported in years 1990-1999 was the Puck Bay. For that reason the area was chosen to investigate the gillnet fishing activity posing a threat of bycatch for harbour porpoises. To precisely recognize the spatial and temporal fishing effort counting the set nets *in situ*, together with collecting the positions and types of nets were performed. Surveys were made in two periods: 2009-2010 and 2017-2018 years, what allowed to determine changes in fishing activity over the years. At the same time the data from the logbooks and monthly catch reports from fishery sector were analyzed, to identify spatial and seasonal fishing strategy in Polish Baltic waters. Research results indicated a significant reduction of number of gillnetters and the number of used gears operating both in Puck Bay and in Polish Baltic waters. The fishing data was confronted with the results of harbour porpoise bycatch and acoustic detections. The detailed knowledge of the strategy of small boat gillnet fishery which is not reflected in the state fishery statistics gives a unique opportunity to adjust the least harmful and well – targeted

measures of reducing the mortality of harbour porpoises on a local level.

Genetic variability and social structure in north-east Atlantic humpback whales (Megaptera noveangliae) off the Icelandic coast.

The variability within the genes of a species gives important information on the population dynamics, which can be useful for conservation and sustainable management of endangered populations. Although north-east Atlantic humpback whales (*Megaptera noveangliae*) are not considered endangered by the IUCN, these highly mobile and long living cetaceans face multiple challenges like climate change and pollution through waste and noise. Species with high genetic variability are considered to be less susceptible to these changes and have a higher chance of evolving adaptions. In this study 110 biopsy samples of north-east Atlantic humpback whales have been collected throughout the last two decades (98 from the south-west coast and 12 from the north-east coast). DNA was extracted from these samples and the individuals have been sexed molecularly. The mitochondrial control region will be sequenced to provide insight in haplotype variability. Furthermore, 20 microsatellite loci are going to be analysed to investigate population structure as well as relatedness between individuals to test if kin selection might be a possible trait that evolved in humpback whales that feed on the Icelandic coast. These data will give an insight about the overall genetic variability in the Icelandic humpback whale population, which is in important information regarding rapid changing environments due to climate change and other human-induced stressors.

The scale-dependence of locomotor performance has long been studied in comparative biomechanics, but how animals move in their natural environment remains poorly understood. At the upper extreme of body mass, baleen whales are among the most efficient swimmers in terms of cost of transport through a combination of low mass-specific metabolic rate and high hydrodynamic efficiency. Such high efficiency enables these ocean giants to migrate thousands of kilometers over broad geographic ranges and underlies a major component of their life history and functional ecology. However, we lack basic kinematic data for most baleen whale species. Here we combined morphometrics from aerial drone photogrammetry, whale-borne inertial sensing tag data, and hydrodynamic modeling to study the locomotion of five rorqual species (Antarctic minke, humpback, Bryde's, fin, and blue). Using fundamental kinematic parameters of oscillatory frequency and cruising speed, we quantified spatial and temporal changes in swimming performance for individual whales and compared these metrics across a wide body size range. We also directly measured the tailbeat amplitude from tag data for one humpback whale and used that measurement to estimate the hydrodynamic efficiency. Our results showed that oscillatory frequency decreases with body size ($\sim length^{-0.53}$) while cruising speed remains roughly invariant ($\sim length^{0.08}$) at 2 m s^{-1}. We also found a trend of increased tailbeat frequencies at higher

cruising speeds. Finally, we calculated a high hydrodynamic efficiency for the single humpback whale. Our results corroborate kinematic trends shown in laboratory experiments on smaller cetaceans that found decreases in the repetitive frequency of tail movements with increasing body size. Functionally, a decrease in oscillatory frequency should lead to energetic cost-savings and an enhanced ability to transit between prey patches or migrate across ocean basins. These energetic savings help explain why rorquals have evolved to occupy such an extreme body size niche.

Presence of marine debris in the stomach contents of the marine mammals stranded in the Santos Basin, southwest Brazil.

Marine debris, mainly plastic, are important threat to different habitats and marine biodiversity. Fauna can be heavily impacted thought the ingestion of residues and also by the entanglement and potential injuries, compromising their lives. In this context, the present study aims to investigate the presence of anthropogenic residues in the stomach contents of marine mammals along the coast of south and southeast of Brazil, from 2015 to 2019. The samples were collected through the records generated from the Santos Basin Beach Monitoring Project (PMP-BS), one of the monitoring programs required by Brazil's federal environmental agency, IBAMA, for the environmental licensing process of the oil production and transport by Petrobras at the Santos Basin pre-salt province. The carcasses that had been found were sent to necropsy and analysis of stomach contents, a total of 2476 stomachs were evaluated and waste was present in 91 individuals. Plastic fragments such as nylon, plastic seal, microplastics, straws and disposable cups were the recorded items in cetacean and pinniped stomachs. *Pontoporia blainvillei* was the species that had greatest interaction with marine debris, plastic was present in 63 animals showing large scale impact in this endangered species. The Franciscana Dolphin inhabits coastal zones and also interacts strongly with other anthropic activities such as fishing. Other species with a substantial number of individuals affected by plastic were *Arctocephalus australis* and *Sotalia guianensis* and a total of ten species of marine mammals showed interactions with marine debris. Therefore, it is important to investigate the occurrence of anthropogenic residues in the stomach contents of marine mammals in order to demonstrate the extent of their damage and to suggest mitigating measures supporting conservation action of marine life and tier habitat.

The quick and the dead: Novel sonar tags reveal predator-prey interactions in southern elephant seals.

Despite advances in biologging technology, obtaining in-situ observations of predator-prey interactions to assess foraging effort and success remains challenging especially for deep-diving marine predators such as the southern elephant seal (SES). Here we use a new sonar and movement tag (DTAG-4) on SES to study fine-scale interactions during individual capture attempts. The tag contains accelerometer, magnetometer and depth sensor (sampled at 200, 50, 50Hz), together with a snapshot GPS and a 1.5MHz single beam sonar

with a 6m detection range (<8mm resolution) and a 25Hz ping rate. Five tags were deployed in 2018 on post-breeding female SES (Kerguelen Islands and Peninsula Valdes) yielding 4800hrs of continuous movement recordings (12,500 dives >200m). The sonar was operated at 50% duty cycle to facilitate detection of low frequency emissions resulting from the short sonar pulses. No behavioural reactions to the onset of sonar were detected in the accelerometer or depth recordings, suggesting that such low frequency emissions are effectively inaudible. Using high-level jerk transients to detect potential prey capture attempts (PCAs), we examined sonar returns in a subset of PCAs to assess predator and prey tactics. Despite the narrow sonar beam (3.4°), clear echoes consistent with targeted prey were obtained for most PCAs. About 70% of prey were elusive with escape attempts identifiable in the sonar data as sudden changes in closing speed. Prey reacted to SES at a median distance of 0.50m (IQR 0.40-0.70m) provoking pursuits within which the SES made multiple strikes, as evidenced by continued jerk transients, to capture prey. Consequently, interactions with elusive prey were significantly longer than for unresponsive prey (PCA duration: 26.5s versus 12.4s, p-value <0.001) indicating a likely trade-off between prey nutritional value and ease of capture. These high-resolution sonar data suggest that fast reactions during hunting are critical for SES to access energetic mesopelagic organisms.

Microplastics in the digestive tracts of manatees in Tampa Bay Florida

Microplastics are of increasing concern in marine ecosystems, with potential effects on organisms including chemical leaching and physiological changes. Microplastic ingestion has been examined in carnivorous fish, marine mammals, seabirds, and plankton, little is known about effects on herbivores including West Indian Manatees (*Trichichus manatus*). As manatees graze in seagrass beds, where microplastics may accumulate, manatees may play an important role in trophic transfer of microplastics. This is the first study to examine microplastic ingestion by manatees. We selected manatee carcasses from Tampa Bay with intact digestive tracts. All manatees were necropsied using standard protocols by the Marine Mammal Pathobiology Lab which includes visual examination and manual palpation of the entire digestive tract for large plastic items. Digestive tracts were sub-sampled for smaller plastic particles by collecting 250-500 gm of material from five digestive tract segments (stomach, duodenum, cecum, distal and proximal colon). Subsamples were concentrated on 200 µm sieves and visually inspected for microplastics. Due to the high cellulose diet of manatees, it was not feasible to fully digest the gut contents. Nile Red staining along with a hot needle test and a visual examination under a compound scope was used to confirm if particles were plastic. Preliminary analysis of 10 carcasses indicated high-levels of microplastic contamination, present in all sections of the digestive tract. 80% of the manatees contained microplastics which were missed during the routine necropsies. Macroplastics were detected in 10% of the carcasses (one individual) during routine necropsy; however, we did not detect microplastics in this individual. Therefore 90% of the manatees examined contained plastics in the digestive tract. As we sub-sampled the digestive tract, it is possible this is an underestimate of plastic load in manatees. This work confirms that manatees are routinely consuming microplastics, and herbivory is an additional route for microplastic trophic transfer.

Visual cortices of cetaceans: Evidence of reduced specialization and laminar organization.

The absence of the sense of smell in toothed cetaceans, or its extreme reduction in whalebone whales, have been described in several articles. On the contrary, the development of their visual system is seldom accounted for. In fact, the value of visual acuity is debatable considering that light diminishes considerably with depth, and that most of the light spectrum is absorbed in shallow waters. We sampled and investigated the structure and cytoarchitecture of the visual cortices of several cetacean species (*Tursiops truncatus*, *Ziphius cavirostris*, *Grampus griseus*, *Globicephala melas*, *Physeter macrocephalu*s and *Balaenoptera physalus)* to evaluate their level of complexity and compare them with the sheep (*Ovis aries*), a closer terrestrial relative, and with the macaque (*Macaca nemestrina*). Our method considered the shape and size of somata in the visual cortex and allowed us

to compare layers and their variation among individuals. Our results confirmed previous reports in the literature that indicate relatively reduced thickness and overall complexity of the cetacean cortex compared to terrestrial mammals. However, we also noted subtle differences among cetacean species that could be due to factors including *i*) diving depth and habitat; *ii*) prey type; or *iii*) degree of lateralization of the eyes. The implications could be that the visual system of highly specialized mammals such as cetaceans has little left in common with what we understand of it in terrestrial mammals and shows evolutionary divergence.

Predicting and mitigating the impacts of windfarm construction on harbour porpoises

Predicting and mitigating impacts of offshore windfarm construction on marine mammals requires data on responses to different noise levels and sources from all construction activities. Policy and management to minimise these impacts have concentrated on pile-driving noise, and have assumed that received noise levels are directly, and positively, related to hammer energies. We investigated harbour porpoise behavioural responses to different activities (acoustic deterrent device (ADD) mitigation, piling noise and vessel activity) using echolocation click detectors, and characterised noise levels using acoustic recorders during the two-year construction of a North Sea windfarm. Porpoises were considered to have exhibited a behavioural response when the proportional decrease in occurrence was greater than the 1st percentile of baseline variation. Contrary to expectations, noise levels from pile driving decreased as hammer energy increased, in relation to pile penetration depth. A 15-min experimental ADD playback resulted in a 50 % probability of response within 3.9 km in the first 12 hours, with a minimum time to the first porpoise detection following ADD playbacks of 133 minutes. Harbour porpoise responses in the 24 hours after ADD mitigation and pile-driving combined decreased as the number of foundations that had been piled increased, resulting in a 50 % probability of response within 7.4 km at the first location piled, decreasing to 1.3 km by the end of foundation installation 10 months later. Distance proved as good a predictor of responses as received noise levels, presenting a more practicable variable for environmental assessments. Critically, both ADD use and vessel activity increased porpoise response levels. Our results highlight the need to consider trade-offs between efforts to reduce far-field behavioural disturbance and near-field injury through ADD use. Additionally, the current regulation of maximum hammer energy and the use of piling soft starts to minimise impacts may need to be reconsidered.

Brucella ceti infections have been increasingly reported in cetaceans, although a very limited characterization of Mediterranean *Brucella* spp. isolates has been hitherto reported and relatively few data exist about brucellosis among cetaceans in Italy.To address this gap, we studied 8 cases of *B.*

ceti infection in striped dolphins (*Stenella coeruleoalba*) stranded along the Italian coastline from 2012 to 2018, investigated thanks to the surveillance activity of the National Reference Centre for Diagnostic Activities on Dead Stranded Cetaceans (C.Re.Di.Ma.).We focused on these cases of stranding, occurred along the Apulia (N=6), Liguria (N=1) and Calabria (N=1) coastlines, through the analysis of gross and microscopic findings, the results of microbiological, biomolecular and serological investigations, as well as the detection of other relevant pathogens. The comparative genomic analysis used whole genome sequences of *B. ceti* from Italy paired with the public available complete genomes.Pathological changes consistent with *B. ceti* infection were detected in the central nervous system of 7 animals, showing non-suppurative meningoencephalitis. In 4 cases severe coinfections were detected, mostly involving *Dolphin Morbillivirus*.*B. ceti*-associated lesions' severity supports the role of this microbial agent as a primary neurotropic pathogen for striped dolphins.We classified the 8 isolates into the common sequence type 26 (ST 26). Whole genome SNP analysis showed that the strains from Italy clustered into two genetically distinct clades. The first clade comprised exclusively all the isolates from Ionian and Adriatic Seas, while the second one included the strain from the Ligurian Sea and those from the Catalonian coast. Plotting these clades onto the geographic map suggests a link between their phylogeny and topographical distribution.These results represent the first extensive characterization of *B. ceti* isolated from Italian waters reported to date and show the usefulness of WGS for the understating of the evolution of this emerging pathogen.

The response of harp seals to long-term changes in Arctic sea-ice cover

The Arctic is undergoing rapid environmental change; it is warming at twice the global average and could be ice-free as early as 2050. While these perturbations will likely result in widespread impacts, the consequences of reductions in ice cover on ecosystem function remain poorly understood. As the most abundant pinniped in the North Atlantic and a seasonal migrant between subarctic and Arctic waters, harp seals (*Pagophilus groenlandicus*) provide an excellent indicator for climate change impacts. Harp seals rely on sea-ice for breeding, and spend much of the year in association with the ice margin. In this study, we track the migration of harp seals from three breeding populations across the North Atlantic using satellite relay data loggers deployed over the last three decades. We estimate individual migration paths from satellite locations using a continuous-time state-space model, and investigate the link between harp seal migratory behaviour and summer sea-ice retreat using a space-time log-Gaussian Cox process model. We use these methods to quantify the influence of sea-ice on harp seal migratory behaviour, and then estimate the impact of changes in sea-ice under a range of future emission scenarios based on outputs from the Intergovernmental Panel on Climate Change Coupled Model Intercomparison Project. Our findings provide crucial insight into the impact of climate-change driven reductions in sea-ice cover on a key Arctic marine mammal.

Using carbon and nitrogen stable isotope signatures in vibrissae to search for clues for the cause of a California sea lion (Zalophus californianus) unusual mortality event.

From 2013-2016, an unusual mortality event (UME) was declared by National Marine Fisheries Service because increased numbers of young (6-24 month old) California sea lions (*Zalophus californianus*) stranded along the coast of California, USA. The primary factor was malnutrition; and no significant infectious disease was detected. Environmental conditions affecting prey were identified as the preliminary cause of the UME. We submitted vibrissae segments to the UC Davis Stable Isotope Facility for carbon ($\delta^{13}C$; foraging location) and nitrogen ($\delta^{15}N$; trophic level) stable isotope analysis from dead sea lions that stranded from 2008 to 2015 (before and during the UME; n=36) as well as from live sea lions sampled during health assessments (2013 to 2015; n=15). Sea lion ages ranged from 8 to 21 months (median=15 months). We hypothesized that segments of vibrissae from stranded sea lions representing pre- and post-weaning periods would have differences in $\delta^{13}C$ and $\delta^{15}N$ during anomalous years (2009, 2013, 2014, 2015) verus normal years (2008, 2011, 2012); and that there would be differences in $\delta^{13}C$ and $\delta^{15}N$ between dead-stranded and live-sampled individuals (i.e. survivors). Using generalized linear models, we detected differences in $\delta^{13}C$ and $\delta^{15}N$ values by year; however, differences were not observed during all anomalous years. Sample year was a significant predictor of $\delta^{13}C$ values in segments from pre- and post-weaning periods, and birth year was a significant predictor of $\delta^{15}N$ in segments from pre-weaning periods. There were no differences between live-sampled and dead-stranded sea lions in vibrissae segments from pre- or post-weaning periods ($p > 0.05$; Student's t-tests). Our findings suggest that young, newly independent sea lions and nursing females are capable of altering their foraging behavior. We recommend the collection of vibrissae from dead stranded otariids because they are easy to collect and store, resistant to degradation, and contain a time series of information.

Research and protected areas, the key to conservation and to raising interest in sea mammals in the local community.

In 1986, the Museo Educativo Patagonico (Atlantic Patagonia) formulated the objective of surveying areas of importance to the conservation of sea mammals, creating protected natural areas, managing them, encouraging future research and sharing findings with nearby communities in order to spark interest in the local population.

This is how the first survey came to be, counting 1198 specimens with 125 infants of Otaria flavescens in a reduced area. Nowadays, those numbers have increased to more than 18000 adults and 4600 offspring.

As a result of that research, 10 more protected areas were created, whose main aim is the conservation, research and diffusion of data on cetacean diversity and behavior.

Until 1934, registers show the presence of hundreds of whales in the Saint George Gulf. After a decade of commercial hunting, they disappeared for 70 years. In 1998, 7 individuals, were registered, and in subsequent years, whales were observed regularly. With the objective of setting the foundation for long term research (genetics, migration, identification of individuals, behavior), the museum began to register the sightings of species spotted along the coasts of Caleta Olivia. Individuals and groups of the following species were observed: Megaptera novaeangliae, Eubalaena australis, Balaenoptera musculus, Balaenoptera physalus, Balaenoptera borealis, Balaenoptera acutorostrata, Balaenoptera bonaerensis and Balaenoptera edeni.

In the past 3 years, more than 3000 specimens were descried each season, with permanent presence of whales. Not only the specimens' journey was registered, but also their feeding habits, copulation, socialization patterns, etc.

The increase in sightings of Mysticetos in the area suggests that a recolonization of areas historically inhabited by the species will take place in the future as the number of individuals gradually grows. Today the conservation area is offers the largest diversity in whales, and it houses the biggest population of Otaria flavescens in the world.

Understanding the role of acoustic cues in the formation and cohesion of super-groups of humpback whales (Megaptera novaeangliae)

Humpback whales are famous for the culturally transmitted, complex song produced by males. However, both sexes produce a repertoire of social and feeding associated calls. Humpback whales off western South Africa predictably form large 'super-groups' (>20 animals) close to shore, offering the opportunity to study feeding behaviour normally limited to the Southern Ocean. Behavioural research began in 2015 using focal group follows (2015-18), static acoustic monitoring (SAM, 2017-18) and later (2018) accelerometer tags (CATS tags) in conjunction with underwater video, to investigate vocal repertoires, production rates and possible call function at the group and individual level. Research was conducted close to Cape Town (33˚54'S, 18˚25'E), within 20 km distance from shore in < 200m water depth. We identified and visually classified >7000 calls from 20 focal follows (12 recording hrs) with humpback whales. Visual classification of the 11 most common sounds types (n = 378 sounds) was supported by Classification and Regression Trees (CART) generated from call parameters, with a test accuracy of 42%. Stereotyped calls such as the 'whup' and 'grumble' made up > 30% of the repertoire of feeding whales. Combination calls and sequences were also identified, the most clear, termed the 'ABC' combination call, was found across encounters and recordings in 2015 and 16. Production rates peaked at 44 sounds per min, with rates per individual twice as high in feeding compared to non-feeding groups. Static acoustic monitoring at three coastal locations (~ 40 m depth) detected calls in October-November across years, however detection was affected by concurrent humpback whale song. The combined acoustic data indicate structural similarity in call types and combinations over time, suggesting a functional role in feeding or group co-ordination. By monitoring the occurrence of stable calls, the presence of feeding whales can be detected using long term static acoustic monitoring.

The CALVIN Project: Middle school students embedded in ongoing research; The ultimate STEM program producing (Marine Mammal) scientists in partnership with the North Atlantic right whale recovery program.

The fifteen-year-old CALVIN Project embeds middle school students in ongoing, authentic science activities. The students call themselves the Calvineers. A high percentage of Calvineer graduates have careers in STEM fields and four are currently working in marine science fields while a number are majoring in marine science in college. The students meet once a week after school to do their own research. Students from Adams School in Castine, Maine attend three unique experiences each year where they interact with scientists from the Right Whale Consortium and the New England Aquarium who are carrying on research toward the recovery of the endangered North Atlantic right whale. Students listen to talks at conferences, talk to scientists about histories, mortalities, mitigation and research work being done. These scientists include Amy Knowlton, Scott Kraus, Stormy Mayo, Moe Brown, Michael Moore, Bill McLellen, Dan Pendleton and others from the right whale world. The Calvineers experience two whale watches guided by right whale scientists. They produce their own presentations about the endangered whales that they give to schools and organizations and have posted six award winning podcasts about current research. The Calvineers have also attended and presented at three SMM Biennial Conferences in Quebec, Tampa and Halifax. These experiences give the Calvineers a unique look into the world of science. They see that science is a complex, messy business that can be as frustrating as it is rewarding. Three Calvineers are doing research about white belly heredity, ocean acidification and plastic rope respectively. They have taken up the cause and advocate for implementation of rules reducing entanglements as well as writing Congress encouraging them to pass a bill allocating much needed funds to help save the North Atlantic right whale from extinction. The CALVIN Project is a model for successful STEM education programs at all levels.

Right whales in southern Brazil: Occurrence and photo identification in a wintering area.

The main wintering area of the southern right whale in Brazil is located in the south-central region of Santa Catarina State, along 130km of coast protected since the year 2000 by the Right Whale Environmental Protection Area (RWEPA). In this area, the Right Whale Project / Instituto Australis have been conducted aerial surveys for photoidentification and monitoring of the species. From 2001 to 2018 (except 2014), aerial surveys parallel to the coast were carried out annually in September covering the entire RWEPA. A total of 1338 whales (including 562 calves) were recorded with an annual average of 78.70 whales. The year that resulted in the lowest number of whales was 2017, with 28 whales (including 14 calves). In the year 2018, the largest number of whales were recorded, with 259 individuals (including 119 calves). There is a trend in increasing whale numbers over the years. Since the species has a tri-annual reproductive cycle, a three-year analysis of variance was performed that did not indicate a significant difference between them (Kruskall Wallis p=0,245). From the analysis of the individual photographs, a total of 838 whale were catalogued, including 174 calves. The photoidentified individuals were included in the Brazilian Right Whale Photoidentification Catalogue which contains whales photoidentified since 1987.

Inter-annual variability in the lipid and fatty acid profiles of east Australian humpback whales (Megaptera novaeangliae) in a changing Antarctic ecosystem.

Southern hemisphere (SH) humpback whales are classified as high-fidelity Antarctic krill consumers and as such are vulnerable to variations and long-term changes in krill biomass. A decline in Antarctic krill biomass, in years following low sea ice extent, has been observed and is hypothesized to have cascading effects on the feeding ecology of SH humpback whales in a changing Antarctic climate. Evidence of heterogeneous feeding patterns of Australian east coast migrating humpback whales has been observed, warranting a more comprehensive assessment of inter-annual variability in their diet. Here, we examined the lipid and fatty acid profiles of humpback whales sampled between 2008 and 2018 on the Australian east coast. The use of live-sampled blubber biopsies showed strong evidence of inter-annual variation in total lipid content, with differences of 21% among years. Fatty acid (FA) profiles varied among years, with 2017 being noticeably different from all other years. The two long chain omega-3, trophic indicator FAs for Antarctic krill, 20:5ω3 and 22:6ω3, were present in lower proportions than in other Antarctic krill consumers, and a decline in the proportion of 20:5ω3 was observed from 2008 to 2018. A distance-based linear model showed that 23.16% of the total variation in the FA profiles was explained by Southern Ocean environmental variables and climate indices, with most of the variation being explained by the Southern Oscillation Index (SOI; 9.73%). These results signify that higher trophic level- or extra-Antarctic feeding may play a more important role in the energy budget of SH humpback whales than previously expected or, alternatively, it may point to present-day changes in foraging patterns of an expanding population in a changing Antarctic sea ice ecosystem.

Occurrence of antimicrobial resistant Escherichia coli in marine animals in the North and Baltic Sea: Preliminary results.

Antimicrobial resistant bacteria are a global health threat in human and veterinary medicine, with a rapid emergence and expansion worldwide. Wildlife species can play an important role as reservoirs for these organisms. Information regarding prevalence and transmission pathways is especially lacking for marine species, which are highly vulnerable to the introduction of treated sewage in natural waters and to the enhanced horizontal transmission of resistance mechanisms naturally occurring in aquatic ecosystems. The investigation of marine and coastal animals of the North and Baltic Sea of Schleswig-Holstein, Germany and the western Baltic Sea of Denmark for antimicrobial resistant *E. coli* shall determine the current situation in these areas. Up to now, 141 rectal/cloacal and faecal swabs were collected from sea fish, coastal birds and marine mammals. The collected swabs were incubated in Mossel bouillon and the suspensions were streaked on eight different antibiotic containing MacConkey agar plates. Bacterial colonies were screened for presumptive coliform bacteria via three different selective agar plates (Gassner, MacConkey and Chromocult agar). *E. coli* species confirmation was performed by PCR assay. Confirmed isolates were tested in disk diffusion tests for their resistance against 14 antibiotics or antibiotic combinations. Resistant *E. coli* were present in 34.8 % of the samples. With 55 % positive samples, birds had the highest occurrence of resistant *E. coli*, followed by the marine mammals with 33.3 % positive samples. No *E. coli* were identified in any fish sample. The most frequent resistances detected were against streptomycin and ampicillin (all data as of April 28th 2019). The high occurrence of resistant isolates from sampled birds and marine mammals were unexpected. Further investigations will determine resistance genes and virulence factors. The obtained data might elucidate potential risk factors for the transmission of resistant bacteria or resistant determinants to livestock, companion animals and humans.

Estimating circulating concentrations of cortisol in large whales via blow sample collection with an unmanned aerial vehicle.

Monitoring physiological stress in wild animals is crucial to assess the impact of environmental stressors on individual fitness. However, measuring physiological parameters, such as the mammalian stress-related hormone cortisol, is challenging in free-ranging cetaceans. Procedures for collecting biological samples are often expensive and intrusive, e.g. collection of exhaled breath ('blow') samples usually relies on a research vessel being in close proximity to the target animal, while extending a long pole and collection device into the blow.

With advance in technology, sample collection with unmanned aerial vehicles (UAVs) represents a potential solution, being affordable and relatively unobtrusive. We present a methodology to (accurately) measure cortisol in the blow of large whales via UAV collection.

Blow samples were collected from humpback whales (*Megaptera novaeangliae*) in northern Iceland in 2018, using a DJI Phantom 4 UAV with 100 mm Petri dishes attached as a collection device. Samples were collected up to 2.2 km from the UAV pilot. Following storage at -20°C, samples were extracted from Petri dishes with an ethanol-water (50:50) wash, followed by reconstitution in water-methanol (70:30; 100 µL).

Cortisol was detected in samples following reverse-phase liquid chromatography- mass spectrometry on a C18 column and a Sciex QTRAP 6500+. Accounting for biological sample dilution by measuring the concentration of urea and three ions (sodium, potassium, chloride) in each sample, we aim to use this method to monitor the physiological stress response of humpback and blue whales (*Balaenoptera musculus*) to whale-watching encounters in Skjálfandi Bay, Iceland. Monitoring this physiological response forms part of a larger framework, including behavioural observation and body condition measurement, to assess the impact of ecotourism on cetacean populations.

The status of mediterranean monk seal (Monachus monachus) in Çandarlı Bay from 2015 to 2018, Turkey

This study was conducted to evaluate the current status of endangered Mediterranean monk seal (*Monachus monachus)* between 2015 and 2018 in Çandarlı Bay, Turkey. The study was performed by collecting monk seal sighting records of previous two years from local fishers in the area, and the asessment of the footage captured in the coastal caves by camera traps that were placed within the context of marine monitoring works of the STAR Refinery.

During the questionnaire surveys which conducted between 21 March 2017 and 21 August 2017, a total of 11 monk seal sightings were obtained from 58 coastal fishers in Aliağa, Yeni Foça, Yenişakran and Çandarlı. Out of 11 monk seal sightings, 7 of them obtained from Yeni Foça, 1 of them gathered in Aliağa, and 3 of them obtained from Yenişakran. Considering the demographic distribution of the observed individuals by fishers, it was reported that the percentage of the adult individuals had the highest ratio (73 %), while the younger individuals had the lowest (9 %). Out of 45,356 pictures taken at six coastal caves during in cave monitoring, no seal footage was obtained.

All in all, with very few sightings and no recordings of any monk seals from caves dictates the fact that the area is no longer used by the resident monk seals in Çandarlı Bay. However, possible visiting individuals around Yenifoça should not be overlooked in the future monitoring studies. The camera traps for the in cave use monitoring study was financed by STAR Refinery.

Seasons and submarine shakes: Dynamic habitat use by sperm whales in a highly productive, earthquake-struck canyon.

Flexibility in habitat use by top predators is vital for meeting their high energy requirements in a patchy and changeable marine environment. The Kaikōura Canyon (New Zealand) is a highly productive deep-sea habitat, and a year-round foraging ground for sperm whales. The number of whales visiting Kaikōura during summer has declined over the last three decades, potentially driven by oceanographic and ecological changes within the whales' habitat. Furthermore, a 7.8 magnitude earthquake triggered extensive erosion in the canyon in 2016, causing large-scale removal of benthic biomass. We investigated the drivers and seasonality of the whales' foraging distribution, and whether habitat use was influenced by the earthquake. Sperm whale locations (n=486) and diving behaviour (n=325) were recorded during boat-based surveys over three pre-earthquake and one post-earthquake year. We used species-distribution models to relate whale presences and absences to habitat variables at a fine spatial scale, including seafloor topography and in-situ water-column measurements. Habitat preferences differed substantially between summer and winter, probably reflecting temporal patterns in prey availability. In winter (33% explained variance), whale presence was correlated with depths of 500-800m and areas of low sub-surface chlorophyll; in summer (28% explained variance), whales foraged more often over depths of 1000-1300m and steep slopes, in areas with strong vertical temperature gradients. Sperm whales appeared to modify their foraging patterns in response to the earthquake. A 25% increase in the duration of surface intervals for over a year may have reflected increased effort searching for prey, while a shift in spatial distribution was probably driven by reduced prey availability in the upper canyon, where erosion was most severe. Flexibility in habitat use over seasonal cycles and after natural disturbance events highlights the dynamic foraging ecology of sperm whales. This is the first study to quantify the impact of an earthquake on a cetacean population.

Validating the use of fatty acids for quantitative diet estimation in marine mammals.

Guerrero, Alicia[1]; Rogers, Tracey[2]

Corresponding Author: aliciagv@live.cl

Fatty acids (FAs) have proven to be a useful qualitative tool to elucidate dietary patterns; however, its quantitative use in foraging studies has seen a slow growth compared to other biochemical methods such as stable isotopes. Here, we use the Bayesian tool, MixSIAR, to estimate diet of five species of marine and terrestrial mammals, based on FA data of consumers with known diets. Simulations based on real FA data derived from feeding studies allowed us to evaluate performance under different scenarios: using different subsets of FAs; using calibration coefficients (trophic fractionation) derived from other consumers and/or other sources; and when animals had been fed single or multiple diets; as well as when diets had

changed over time. In most cases, FAs correctly predicted diet preferences, even when the calibration coefficients used were derived from other species. The use of a subset of FAs produced more accurate results and reduced computational time. The use of calibration coefficients derived from other consumers does not seem to have a great impact on the predicted outcomes, however, if the calibration coefficient is derived from an animal eating a food source, which at the same time is one of the sources used in the model, it could lead to overestimation of that source. Given these results, we then applied this method to wild Antarctic seals, using blubber FAs and whisker stable isotopes to estimate diet. Both biotracers correctly identified the main components of the diet of each seal, but FAs provided a better taxonomic resolution, due to their greater power of distinction among prey species. This work promotes the use of FAs when feeding experiments are not feasible. We suggest that this Bayesian approach, formerly only applied to stable isotopes, has the potential to correctly estimate diets when applied to FA data.

Spatiotemporal trends and risks of per- and polyfluoroalkyl substances in Indo-Pacific humpback dolphins from the Pearl River Estuary, China.

Gui, Duan; Wu, Yuping
Sun Yat-Sen University
Corresponding Author: guiporpoise@gmail.com

The Indo-Pacific humpback dolphin population (*Sousa chinensis*) from the Pearl River Estuary (PRE) have suffered catastrophic declines in recent decades, primarily due to degradation of habitat quantity and quality. High levels of environmental pollutants found in the PRE humpback dolphins could potentially disrupt immune and reproduction system, making them vulnerable to disease and leading to dwindling birth rates in exposed populations. However, baseline knowledge of PFAS levels and trends in humpback dolphins from the western PRE is still lacking. Per- and polyfluoroalkyl substances (PFASs) are a group of highly persistent chemicals that have different bioaccumulation behavior in relation to lipophilic POPs. Sixteen PFAS compounds were measured in liver and kidney tissues of the PRE dolphins between 2004 and 2016. The average concentrations of PFOS, PFOA and most of the other PFASs in liver samples were respectively greater than any records previously reported in cetaceans globally. For the first time, we found a U-shaped trend for the distribution pattern of PFCAs between liver and kidney with increasing carbon chain lengths, whereas a descending trend was found for PFSAs, which may be explained by binding efficiencies of PFAS analogues to proteins. The fine-scale spatiotemporal distribution pattern of PFASs in dolphins from the estuarine region indicated that stranding location and time might be important predictors in the contaminant load in these animals. Risk assessment results showed that 46% of PFOS concentrations exceeded the Tentative critical concentration for PFOS than 35% of those in Hong Kong dolphins were above this value. Therefore, we suggested that PFOS exposure is an important understudied concern for the PRE dolphins, especially for females. Our findings contribute to the knowledge of tissue distribution and spatiotemporal trends of PFASs in the PRE dolphins, which are valuable for us to understand the PFASs exposure risk and their industrial emission in Southern China.

A critical analysis of the French marine mammal monitoring programme for MSFD first cycle, and perspectives for second cycle 2020-2026.

The Marine Strategy Framework Directive (MSFD, 2008/56/EC) aims to restore the Good Ecological Status (GES) of European marine waters through six-year action cycles. The first cycle started in 2012 with an initial evaluation of the GES and the definition of environmental targets, followed by the adoption of monitoring programmes in 2014 and of programmes of measures in 2016.

13 thematic monitoring programmes were worked out in France, among which one is dedicated to marine mammals and marine turtles, with 5 sub-programmes:

- SP1: Coastal populations of cetaceans
- SP2: Seal populations
- SP3: Marine mammals and marine turtles at sea
- SP4: Stranding of marine mammals and marine turtles
- SP5: Interactions with human activities

Each sub-programme includes different monitoring systems that gather data in order to inform GES criteria, but also to evaluate the achievement of environmental targets and the efficacy of measures.

This first monitoring programme will end in 2020 and discussions have started to update it for next cycle 2020-2026. Recommendations were made by

the European Commission in 2017, and a critical analysis was conducted in 2019 to assess the relevance of each monitoring system with regards to the revised GES criteria of EU Decision 2017/848 and to the 2018 evaluation of marine mammal GES in France.

For the second cycle, a combination of new and upgraded monitoring systems will be implemented to fill the data gaps, notably for large species and for the Mediterranean Sea, including an acoustic monitoring of coastal (SP1) and pelagic (SP3) cetaceans, aerial counting of the main seal hauling sites (SP2), observers on ferries (SP3) or bycatch surveys (SP5). In response to European and national requirements, the use of new monitoring technologies and data from citizen science will be also tested.

Energetic consequences of human disturbances and changes in krill preyscape on blue whales foraging in the Estuary and Gulf of St. Lawrence, Canada.

Blue whale survival and fitness is highly contingent on successful foraging and efficient food acquisition during intense feeding seasons. For marine air-breathing mammal, efficient foraging is constrained by oxygen acquisition at the surface and krill patches density and availability at depth. Thus factors that affect either of these components are likely to alter foraging effort and overall foraging efficiency. Here we examined the energetic consequences of a demonstrated reduction in blue whale dive and breathing times caused by vessel proximity, and of potential variations in krill preyscape as a result of selective fishery or global warming on foraging effort and energy storage capacity. Blue whale net energy gains and foraging efficiency were estimated through model simulations for different scenarios of krill density, vertical distribution, and krill species dominance ratio (2 different species), and for different degree of perturbation in foraging time and breathing time. Vessel proximity within 400 m of foraging blue whales reduced net energy gain by 15% when continuously present over a 3h period, and by more than 50% for a simulated continuous presence over a 12 hr daylight foraging period. While variations in krill species composition, density or vertical distribution, had more moderate effects on blue whale net energy gain over the range of scenarios tested in this study, they were still notable in some cases, particularly in the event of a decrease in krill density. For a species like the blue whale, which relies on a short feeding season and almost exclusively on krill for building energy reserves, changes in energy gain through altered krill preyscape or repeated human disturbances might be of special concern for the conservation and management of this endangered population.

The use of novel bio-logging technologies to investigate high mortality rates in juvenile southern elephant seals and links to dive and forage ability

High juvenile mortality rates are typical of many long-lived marine vertebrate predators. Insufficient dive and foraging ability are considered key drivers of this, which for many species need to develop rapidly as individuals quickly transition from full parental care and provisioning to complete independence. However, direct links sparse, predominantly due to the difficulties of remotely observing free-ranging marine animals that may not return to land.

In this study, we present a new method for the remote abstraction and transmission of accelerometer data collected via bio-logging technologies. Using this technique, we tracked the fine-scale behaviours and movements of 20 juvenile southern elephant seals *Mirounga leonina* during their first months at sea following weaning. Retrieved archival data from 9 individuals was used for validation. Links between survival outcome (determined via double tagging) and dive and forage ability were then investigated using a combination of Cox's proportional hazard regression and penalised shrinkage.

Abstracted transmissions included estimates of time spent in prey catch attempt behaviours and swimming effort, and reflected those from standardised processing of retrieved archives. Of the 20 individuals tracked, nine died and 11 survived. Common causes of death included increased horizontal travel speeds, decreased development in dive and forage ability, and habitat type visited.

The methods presented in this study can be used to provide novel insight toward the behaviours and movements of free-ranging marine predators from whom logger retrieval is challenging. Moreover, the factors driving early mortality can also be elucidated. For southern elephant seals, the first few months of life following independence represent a critical period for survival, when small deviations in behaviour from the norm appear sufficient to increase mortality risk. As such, this species may be particularly vulnerable to changes in climate and environment, which will have concomitant consequences on the demography and dynamics of populations.

Analysis of scars on dorsal fins caused by conspecifics indicate sex-specific differences in the behavioral patterns of lahille´s bottlenose dolphin (tursiops truncatus gephyreus)

Due to its strictly aquatic habit, free-living cetacean behaviour observation is very limited, especially in turbid waters. However, inferences about behavioral patterns of some highly social species can be made by analyzing scars on their bodies caused by conspecifics. The current work evaluated the potential sex-specific differences in aggression of bottlenose dolphin throughout the analysis of temporary and permanent marks on dorsal fin of 20 adult individuals of know sex (10 males and 10 females). We selected high-quality dorsal fin photographs obtained during photo-identification surveys of bottlenose dolphins in Patos Lagoon Estuary, southern Brazil. Temporary marks were evaluated for intensity and proportion of dorsal fin coverage, plotting the entire fin surface and calculating the scars percentage relative to the total dorsal fin area in pixels using Photoshop software. For this analysis, only photos of the left side of the dorsal fin of each individual taken during the cold season (May to October) were used. Changes in permanent marks pattern were monitored over an 8yr period according to the number of marks and tissue loss intensity (smooth, moderate or significant). A higher intensity and coverage of temporary marks on the male's dorsal fin were observed (mean=32%; DP=6%) comparing to the females (mean=16%; DP=3%) ($t=7.6393$; $p<0.001$). Overall, females presented few and smoothed to moderated permanent marks in their dorsal fins that remained constant throughout the years, while males presented much higher number of permanent marks and significant tissue loss, which amplified in length and depth over the years. The results indicate a more aggressive behavior among males, probably related to social battles for female access, which appear to be more tolerant in their social life. Our results indicate that data from natural dorsal fin marks can be used as an additional feature for sex recognition of individuals in this population using photo-identification.

Regional and seasonal distribution of stranded cetaceans in Jeju Island, Republic of Korea, from 2014 to 2018

Cetacean stranding gives us valuable information on marine mammal diversity and their ecology. However, no long-term survey of stranded cetaceans has been conducted in Jeju Island, Republic of Korea. Reports of stranded cetaceans in Jeju Island have been recorded through maritime police network. Among the collected data, the following credible information are used to investigate regional and seasonal stranding distribution: date, location, and species. From March 2014 to November 2018, 125 finless porpoises (*Neophocaena phocaenoides*) (76.2%), 28 Indo-pacific bottlenose dolphins (*Tursiops aduncus*) (17%), and 11 other cetaceans (6.7%) were stranded. Finless porpoises were mostly stranded between November and April, and they

were regionally distributed on the Northern coast of the island. On the other hand, Indo-pacific bottlenose dolphins showed seasonal variation but no significant patterns in regional distribution. Among other cetacean species, two were unidentified, and no regularity was found in both region and season. According to previous researches, finless porpoise lives in inshore of the South and Yellow Sea of Korea. There is a high probability that finless porpoises were caught by bycatch during winter fishery activities in their habitat area and drifted to the northern coast of Jeju Island. Additional research of habitat, distribution and population size is necessary to further understand this result and the ecology of the species. As a residential population, Indo-pacific bottlenose dolphin lives all around the inshore of Jeju Island, therefore, non-significant differences in regional distribution of stranding were noted. The seasonality of the standing may be explained by the higher number of visitors to the inshore area during summer to witness and report the stranding to the authority. The life history of Indo-Pacific bottlenose dolphins has not been fully explored in this study area. More detailed and extensive research of stranded Indo-pacific bottlenose dolphin can increase our understanding of the species' ecology.

Assessing the performance of open source, semi-automated pattern recognition software for harbour seal (Phoca vitulina) photo-identification data

Photo-identification (photo-ID) is a well-established, non-invasive, and cost-effective technique to collect longitudinal data of species that can be individually recognized based on natural markings. This field has been revolutionised by computer-aided software for pattern recognition, speeding up the processing of large numbers of images. Freely available algorithms exist for a wide range of species, but the choice of algorithm can have significant effects on the accuracy of the individual histories and, consequently, on derived demographic parameter estimates. We tested the performance of three open source, semi-automated pattern recognition algorithms on harbour seal photo-ID data: Wild-ID, I^3S Pattern and ExtractCompare. We also tested for the effects of database size and of data collection method (camera-lens versus camera-scope) to inform future fieldwork protocols. All algorithms generate similarity scores between pairs of images and the top 20 potential matches were inspected. The false rejection rate (FRR) of each software and the cumulative density function (CDF) for the ranks of true matches were calculated. Wild-ID had the lowest FRR (0) and ranked true matches highest (70% at rank 1). I^3S Pattern had a higher FRR (0.1) than Wild-ID and ranked true matches lower than both Wild-ID and ExtractCompare (50% at rank 1). ExtractCompare had the highest FRR (0.2) but ranked true matches higher than I^3S Pattern (60% at rank 1). Database size had a smaller effect on algorithm performance than expected, and the method of data collection by camera-lens outperformed camera-scope in every trial. Software algorithms have their own specific limitations, but ExtractCompare is currently the only pattern recognition software that accounts for orientation and torsion by using a 3-dimensional model. However, by selecting an area of the body where torsion is limited (i.e. the head), we are confident that Wild-ID outperforms both I^3S Pattern and ExtractCompare in harbour seal photo–ID data processing.

How social media is changing the way we learn about cetaceans in remote locations: Bringing 60o N sightings to the masses.

Corresponding Author: karen.hall@nature.scot

Shetland has long been an important area for cetaceans and seals due to its proximity to the European continental shelf. However, the isolated and exposed position at 60° N also makes it difficult for surveying with most data collection restricted to land based surveys by citizen scientists. The last few years have seen substantial increases in sightings around Shetland. Since 1970, there have been over 4500 cetacean sightings with 1600 (36%) in the last decade. The question arises whether this is a genuine increase or a consequence of improved communication networks. Are we simply getting better at reporting their presence around our coastal waters? Here we assess the sighting trends of five regular species: harbour porpoise, Risso's dolphin, killer whale, minke whale, and humpback whale. For the larger species, there are sighting

increases that correspond with when particular social media platforms came on stream. However, for harbour porpoise there is an opposite trend with citizen scientists only reporting unusual group sizes. A comparative analysis with effort corrected density data found that these large increases were unsupported. Sightings data were also examined to better understand site fidelity and movements. Photo ID was formerly restricted to scientists but through camera improvements and the power of social media, the quality and availability of photos has improved dramatically. Increasing social media reporting (Shetland Orca Sightings Facebook 14,000 followers and the WhatsApp group 256 users) means it is now possible to track killer whale pod movements in real time, or determine whether sightings of humpback whales or Risso's dolphins, days, or even years apart, are the same individuals. These findings show that social media can play an important role in both future conservation and public awareness of cetaceans but that data collection methods need to evolve to work with these platforms.

Anthropogenic factors important for seascape genetics in the Florida manatee.

The intersection of population genetics and landscape ecology is known as seascape genetics when assessed in marine systems. Drivers of these patterns can be difficult to determine as marine systems are diffusive and ephemeral and populations of marine organisms are often large and highly mobile. The Florida manatee presents an especially difficult case as a previous study on their population genetics revealed low levels of genetic diversity. Even so, seascape genetics has proved useful in understanding spatial distribution of genetic variation in populations with weak differentiation, low diversity, or chaotic structure. Gene movements across a seascape can be described by various distance hypotheses, including Isolation by distance, least cost path analysis and/or circuit theory (CT). The goal of the present study was to elucidate if any distance hypothesis based on abiotic (bathymetry, temperature, salinity), biotic (chlorophyll-a concentration, seagrass cover), anthropogenic (boat activity, coastal habitat disturbance), or a combination of factors could explain spatial patterns of genetic distance (GDis) in manatees. A GDis matrix was generated between all pairs of 293 individual manatees in the dataset using 20 microsatellite loci and the proportion of shared alleles (Dps). Each seascape variable was objectively parameterized using eight transformations. Mantel tests were used to select informative ecological distance hypotheses and maximum-likelihood population-effects mixed modelling (MLPE) was used to to select the model that best explained GDis based on Akaikes corrected Information Criterion (AICc). Results from the MLPE mixed modelling bootstrap (10,000 iterations) revealed that CT distance based on boat activity was selected as the top model (86.52%) followed by CT distance using coastal habitat disturbance (13.42%). The results of this study 1) add to a body of literature in seascape genetics, and 2) suggest that anthropogenic boat activity and coastal disturbance have created spatial genetic structure by disrupting gene flow.

Cetacean strandings in Iceland 1980-2018

Halldorsson, Sverrir[1]; Chosson, Valérie[2]; Gunnlaugsson, Thorvaldur[2]; Víkingsson, Gísli[2]

Since 1980, the Marine and Freshwater Research Institute (MFRI) has systematically kept records on cetacean strandings in Iceland. Such long-term stranding databases are generally regarded as an important method of collecting information on the marine environment. Information from strandings constitutes the most important source of biological/ecological data on many species of cetaceans in Icelandic and adjacent waters. Depending on circumstances (species, accessibility etc.) the MFRI and cooperating scientist have arranged for sampling and measurements of the carcasses.

Here we analyse the data on whale stranding in Iceland in the period 1980 to 2018. A total of 480 stranding events have been registered in the period consisting of 18 identified species. The total number of animals were 714 with the pilot whale accounting for the highest number of animals or 256 (including two mass strandings). The most frequent species to strand was the sperm whale (*Physeter macrocephalus*) (86 events, 98 animals) The database includes several records of two species, previously unknown for the Icelandic waters, the striped dolphin (*Stenella coeruleoalba)* and Sowerby's beaked whale (*Mesoplodon bidens*).

Both species have their main distribution south of Iceland.

The number of reported strandings has increased over time, but the reason for this is unclear and it is possible that the schematic cooperation between corresponding parts introduced in 2007 has made the reporting more efficient.

In the year 2018, 42 stranding were registered in the MFRI database, the highest number ever. The unusually high number (19) of Northern bottlenose whales (*Hyperoodon ampullatus*) and other Ziphiids (4) are noteworthy in the light of an unusually high number of strandings of these deep divers in the eastern North Atlantic that same year. The cause(s) of these events is still a matter of scientific debate and investigation.

Predicting summer fin whale distribution in the Pelagos Sanctuary to identify dynamic whale-vessel collision risk areas

Mediterranean fin whales aggregating in the Pelagos Sanctuary in summer to feed are exposed to vessel collision risk, particularly from high-speed ferries travelling through their habitat. Understanding summer fin whale distribution is key to identifying areas with potentially high collision risk. We developed predictive models to predict summer fin whale distribution using a Generalised Additive Model (GAM) and MaxEnt, and identify high risk areas along ferry routes in the Sanctuary. Data were collected in summer 2016-2017 on board ferries crossing the central area of the Sanctuary. Environmental predictors included bathymetry and mean sea surface chlorophyll concentration (*chl*) of the annual spring bloom period. We compared the predictive ability of GAM and MaxEnt based on current scientific knowledge of fin whale distribution in the Sanctuary. Collision risk was estimated as a function of the overlap between the probability of fin whale occurrence and ferry density estimated from AIS data. A total of 81 surveys were conducted in 2016-2017, resulting in 127 fin whale sightings. GAM (deviance explained=23.9%) predictions were relatively more reliable than that of MaxEnt. MaxEnt's predictive ability was likely hampered by the inability to incorporate the temporal component of data into model construction. Despite the differences, both models highlighted two recurring high collision risk areas in the summers of 2016 and 2017: in the western offshore region and the south-east region over the Bonifacio gyre. Other areas were less predictable, with risk being more widespread in 2017. Our results showed that the spring bloom *chl* is a unique predictor allowing a yearly forecast of summer fin whale distribution and demonstrated the possibility to dynamically manage whale-vessel collisions in the Sanctuary. Overcoming the modelling limitation related to MaxEnt would present an opportunity to collate data from various sources, including opportunistic sightings, to increase sample size and improve model predictions.

Estimation of population dynamics for the Antarctic blue whale using bayesian state-space models

Hamabe, Kohei; Matsuoka, Koji; Kitakado, Toshihide

hamabe.kaiyodai@gmail.com

The Antarctic blue whale was decreased its abundance by commercial whaling from 1920s to 1960s, and it has been listed as an endangered species in IUCN. Providing a valid estimate of the current abundance and increasing rate are crucial to see the extent of recovery of this population. However, due to a limited number of detections of this species during surveys, the precision of abundance estimates in each survey itself has large uncertainty. To overcome this difficulty, we propose the use of Bayesian state-space models to strengthen the separate estimates over space and time.

Sighting surveys for this species were conducted by several research programs such as IDCR-SOWER (1978/79-2003/04) and JARPA/JARPAII (1989/90-2008/09). In this study, we analyzed population abundance and dynamics of an area of south of 60 degrees South latitude between 70 degrees east to 170 degrees west longitude. Abundance estimate in Branch (2008) were used previous studies for IDCR-SOWER and those for JARPA/JARPAII were updated. Based on those abundance estimates, state-space surplus production models were estimated using a Bayesian method.

As results, the current depletion level of this species was still very low while the intrinsic rate of natural increase was estimated as slightly higher

than those for other baleen whales. Although this analysis has not accounted for any species interactions among whale species and environmental changes in the Antarctic Ocean and it is not easy to construct a whole ecosystem models, we will introduce results by possible extensions of our models to incorporate estimated population dynamics of other species as density-dependent factors beyond species.

Cognition in the wild: Dolphin communication during a role-specialized foraging tactic.

A division of labor with role specialization is defined as individuals specializing in a subtask during repetitions of a group task. This behavior is ubiquitous in humans, but there are currently only three confirmed examples found among non-human mammals; lions, mice and bottlenose dolphins. The population of bottlenose dolphins (*Tursiops truncatus*) in Cedar Key, Florida, are well known for their role-specialized foraging tactic. During "driver-barrier feeding", a "driver" dolphin herds mullet (*Mugil* spps.) towards "barrier" dolphins and as the prey are trapped they leap out of the water, where the dolphins catch them in air. However, it is currently unknown how dolphins coordinate driver-barrier behavior. By recording vocalizations with a hydrophone array during a subset of more than 300 observed instances of driver-barrier feeding by 12 different driver individuals, this study is the first to investigate how bottlenose dolphins coordinate during role-specialized behavior. Results of fine-scale audio and video analysis during a subset of ~80 driving events with highest audio quality suggests that barrier animals cue on outgoing and/or reflected echolocation signals from the driver individual. Analyses of temporal patterning of whistles before and after driving events help determine if animals may use signals to influence the behavior of others to coordinate during the behavior. The results of this study inform our understanding of the role dolphin vocalizations play in group feeding.

Marine mammal "hotspots" in the Greenland and Barents Seas as revealed by satellite tracking since 2005

Large-scale changes are currently taking place in the Arctic due to global climate change. Sea-ice declines and other environmental changes are directly impacting Arctic ecosystems and are also leading to increased levels of human activity in this region, including increases in shipping, tourism, oil and gas exploration and fishing. Identifying marine mammal "hotspots" is thus critical for safeguarding these species and their habitats. Marine mammal biotelemetry data from 528 individuals, including 12 species (20 bearded seals (*Erignathus barbatus*), 60 harbour seals (*Phoca vitulina*), 20 harp seals (*Pagophilus groenlandicus*), 20 hooded seals (*Cystophora cristata*), 73 ringed seals (*Pusa hispida*), 33 walruses (*Odobenus rosmarus*), 23 bowhead whales (*Balaena mysticetus*), 18 white whales (*Delphinapterus leucas*), 235 polar bears (*Ursus maritimus*), 10 blue whales (*Balaenoptera musculus*), six fin whales (*Balaenoptera physalus*) and 10 humpback whales (*Megaptera novaeangliae*)), tagged around Svalbard, eastern Greenland and in the Fram Strait from 2005 to 2018 were analysed to identify marine mammal hotspots and areas of high species richness in the Greenland and Barents Seas. Getis-Ord G_i* hotspots and areas of high species richness were around the Svalbard Archipelago and in the marginal ice zone of the Greenland and Barents Seas. Hotspots calculated using the number of individuals and number of locations were similar, but location-hotspots better captured foraging areas

that were used heavily by only a few individuals. Hotspots were more dynamic seasonally for species with large-scale movement patterns (e.g. harp seals, hooded seals, bowhead whales, polar bears) than for species that occupy smaller areas during their annual cycles (e.g. bearded seals, ringed seals, white whales). These analyses identify important areas for conservation and management efforts but it is important to note that conservation plans will need to be flexible due to the high intra- and inter-annual variability in the location of the marginal ice zone.

Genetic identification of North Atlantic right whale calves challenge our assumptions of growth, weaning and survival.

North Atlantic right whales, *Eubalaena glacialis*, are one of most endangered of the large whales with a current estimate of only 411 individuals. The life history parameters of this species have been tracked by an extensive photo-identification catalog since 1980. One weakness of photo-identification is that it cannot be applied to right whale calves until they are around four to five months old: the time required for their callosity pattern, the primary identifying feature, to develop. Sixty percent of the 477 calves born between 1988 and 2017 were genetically sampled as calves and 20% of those were not photographically identified. Here we use genetics to link seven of those calves to photographed sightings when they were not with their mothers- either later in their birth year or in subsequent years. Three of these were suspected to be dead (because their mothers were always alone after leaving the calving ground), but genotyping proved them to be alive. These calves may have separated from their mothers much earlier than the standard October to December separation time. One dead whale that had been classified as a calf based on its length was identified as a yearling, indicating substantial variability in physical growth rates. In three other cases, juveniles were linked back to calves from previous years that had no photo-identification information, providing information on their age and parentage. Given the wealth of information that is lost when calves cannot be linked to their mothers, genetically sampling calves on the calving ground is critical for ongoing efforts to assess and monitor trends in this species, and to test the accuracy of assumptions based on field observations. This urgency is magnified by a recent distribution shift away from known summer habitats, resulting in gaps in the photo-identification data.

Citizen science in the marine environment: A case-study estimating common dolphin densities.

Citizen science is increasingly popular and has the potential to collect extensive datasets at lower costs than traditional surveys. Ferries have been used to collect data on cetacean populations for decades, providing long-term time series allowing for monitoring of cetacean populations. We estimate common dolphin (*Delphinus delphis*) densities in north-east Atlantic and investigate the use of citizen science data to identify changes in marine mammal densities and areas of importance.

Data were collected by citizen scientists on ferries between April and October in 2006 - 2017. Common dolphin sightings data from the Bay of Biscay (n= 569), a short ferry route in the SW of Cornwall (n= 260), and English Channel (n= 75) were used to estimate detection probabilities with detection functions. Density Surface Models estimated density across ferry routes.

Overall detection probability was highest in the English Channel (0.384) and Bay of Biscay (0.348), and lowest in the SW of Cornwall (0.158). Common dolphins were estimated to occur in higher densities off Cornwall (0.400 per km^2) and the Bay of Biscay (0.319 per km^2), with low densities in the English Channel (0.025 per km^2). Densities off Cornwall appear relatively stable on the ferry route since 2006 with a slight decrease in 2017. Densities peaked in the Bay of Biscay in

2013 with lower numbers since. The general trend in the English Channel appears to be increasing densities of common dolphins over time since 2009.

This study highlights the effectiveness of citizen science data to investigate the distribution and density of cetaceans. The densities and temporal changes shown by this study are representative of those from wider-ranging robust estimates. We highlight the ability of citizen science to collect data over extensive periods of time which complements traditional surveys.

Multidecadal tooth growth chronologies allow insight into environmental influences of energy budgets and foraging movements of sperm whales from southern Australia.

In a changing climate, determining the environmental influences on energy budgets (which underpin population state) is fundamental for informing how populations may fare under future conditions. We applied novel modified dendrochronology (tree-ring science) techniques to teeth collected from deceased sperm whales (*Physeter macrocephalus*) across two sites in southern Australia (sampled across four time periods; from whaling archives and mass strandings) to establish chronologies of annual tooth growth (as a proxy for energy budgets) spanning 70 years (1935 – 2004). Generalised additive models were used to investigate relationships between tooth growth chronologies and three indices of climate phenomena associated with the El Niño-Southern Oscillation (ENSO), Indian Ocean Dipole (IOD), and Southern Annular Mode (SAM). Positive phases of the ENSO and the SAM, and negative phases of the IOD positively influenced tooth growth. The relationships varied among groups of whales, indicating that environmental drivers of relevance for the region impart differing intra-specific influences on the energy budgets of sperm whales. Correlations between chronologies and spatially explicit, seasonally averaged sea surface temperature (SST) showed that cooler SSTs also positively influenced tooth growth and identified spatial differences in foraging patterns between sample groups. These findings suggest that sperm whale groups across the southern Australian region utilise distinct foraging areas and are subject to differing regional effects of climate-driven variability. This study therefore represents an important step in understanding potential areas of foraging significance for sperm whales that inhabit southern Australian waters, and a means by which we can begin to quantify the effects of ongoing climate change on populations of this species.

Grey seals in the Northwest Atlantic: Conservation success affects growth and condition.

Hammill, Mike[1]; Sauvé, Caroline[2]

Corresponding Author: mike.hammill@DFO-MPO.GC.CA

The Canadian component of the Northwest Atlantic grey seal population (*Halichoerus grypus*) increased from around 5000 animals in 1960 to over 400 000 animals in this decade and although the population continues to increase, the rate of increase has slowed suggesting that density-dependent factors are affecting the dynamics of this population. We examined changes in growth in body length, mass and condition of grey seals measured between 1954 and 2018. Grey seal males are significantly longer (x=218 cm) and heavier (x=218 kg) than females (x=192 cm and 163 kg, respectively). Residuals from the female standard length Von Bertalanffy growth curve decreased with year of birth, at a rate of -0.12 cm·year^{-1}. Changepoint analysis on these residuals detected a significant decline in length at age from 2001 onward. Likewise, residuals from the female body mass curve decreased by -0.27 kg·year^{-1} from 1970 to 2018. Changepoint analysis identified that body mass has been lower than expected since 2006. While changes in body length were associated with changes in abundance, changes in body condition were instead associated with changes in environmental variables such as duration of ice cover and prey abundance. Age specific reproductive rates of females aged 5 and 6 years old have decreased significantly, while reproductive rates for females aged 7 years and older have shown no change. Our results show that density dependent factors are beginning to affect the dynamics of this population.

Decadal-scale changes in cetacean species-habitat relationships and distribution in summer in European Atlantic waters

In recent decades, there have been marked environmental changes in the North Atlantic that may have far reaching consequences for marine predators. Surveys to estimate cetacean abundance took place in 1994, 2005/07 and 2016 in European Atlantic waters, with the primary aim of obtaining robust information to support conservation assessments. We present new results from the 2016 summer surveys (SCANS-III and ObSERVE) on species-habitat relationships and predicted distribution and abundance for eight cetacean species to assess changes since the 1990s. In 2016, eight aircraft and three ships were used to cover an area of approximately 2.1 million km^2. Data were collected using the circle-back method for aerial and two-team tracker method for ship survey to account for animals missed on the transect line. A total of >70,000 and >10,000 km were surveyed by air and ship, respectively, generating more than 4,500 sightings of 19 cetacean species. The data were modelled as a function of a range of static (e.g. depth, slope), physical (e.g. SST, absolute dynamic topography) and biological (e.g. chlorophyll a, primary productivity) variables using Generalised Additive Models. The best models were chosen using a robust model selection protocol, and the results were compared with those from the previous surveys. Overall, for harbour porpoise, bottlenose, white-beaked, common and striped dolphins, and pilot, fin and beaked whales, the predicted distributions in 2016 were similar to those from 1994 and 2005/07, despite high variation in estimated abundance for some species (bottlenose, common and striped dolphins). This broad conclusion of relatively little change in summer distribution should be interpreted cautiously. It is important to continue collecting long-term, large-scale, high quality data sets to be able to assess how cetacean species are responding to changes in marine systems, including ocean warming.

The distribution and vocal behavior of the Atlantic white-sided dolphins (Lagenorhynchus acutus) in northern Norway

The distribution and behavior of the Atlantic white-sided dolphins (*Lagenorhynchus acutus*) are understudied in Norway. We have conducted boat surveys and underwater sound recordings in the Vestfjorden, northern Norway. 70 sightings of *L. acutus*, mainly from June to October, were recorded including Photo-ID cataloging of 55 individuals and 29 re-sightings of the catalogued individuals. Our study indicates a stronger presence of *L. acutus* than previous reported in northern Norway. The dolphin's vocalizations consisted of clicks (1-24 kHz), buzzes, calls, whistles, of which 82.91% were stereotyped whistles. Four vocalization categories (clicks, buzzes, calls and whistles,) of *L. acutus* were quantified during four surface behavioral categories (foraging, milling, socializing and traveling). We investigated if specific vocalizations of *L. acutus* were associated with specific behavioral categories and if vocal behavior changes with activity. In general clicks were the most commonly recorded vocalization (97.8-99.5%), followed by whistles (65.4-76.2% when clicks are omitted). Clicks were consistently associated with foraging (99.2%) and milling (99.5%); whistles were consistently associated with socializing (70.2%) and milling (76.2%); calls were consistently associated with traveling (32.4 %); and buzzes were absent during milling and varied (0-14.1%). Further our observations indicate a larger distribution and variety of vocalizations associated with different behaviors within this population.

Impacts of sand-dredging on the critically endangered Yangtze finless porpoise in its major inhabited lake

Han, Yi[1]; Zhigang, Mei[1]; Wang, Ding[2]

With China's rapid economic growth and the great demand of sand for construction, the intensity of sand-dredging has risen sharply in the past decade in the two biggest lakes (Dongting Lake and Poyang Lake) adjoining to the Yangtze River. As these two lakes are inhabited by almost half of the wild Yangtze finless porpoise (YFP) population, sand-dredging is posing a significant threat to the survival of this species. We examined the scale and intensity of sand-dredging activities in Dongting Lake from 2000 to 2019 and investigated their potential impacts on the YFP. We examined more than 200 qualified Landsat images from 2000 to 2019 to map the scales and calculate the intensities of sand-dredging through Google Earth Engine. We also calculated the densities of vessels waiting for sand-loading in the lake mouth area. Combining with the results of nine population surveys conducted between 2006 and 2019, our analysis showed that sand-dredging has a significant adverse impact on the population and distribution of the YFP. First, the population trend of the YFP is negatively correlated with the sand-dredging intensities. The population estimations were relatively low from 2009 to 2015 while the sand-dredging was intensified since 2009 but ceased in early 2017 due to a strict sand-dredging ban. Second, the distribution of the YFP is negatively correlated with the distribution of sand-dredging activities. The regions with intense sand-dredging activities from 2012 to 2016 have lower sighting records of the YFP. Third, the vessels in the lake mouth area have almost blocked the entire region since 2012, making the river-lake movement of the species impossible. Therefore, we stressed that the current sand-dredging ban in Dongting Lake should continue and we strongly advice to strictly regulate the vessels in the lake mouth region to restore the river-lake movement of this species.

Collaborative evaluation of a booming spinner dolphin watching industry in the Philippines, using social and dolphin behavioural surveys to inform policy development

Hanf, Daniella[1]; Vivier, Fabien[2]; Aplasca, Lorraine[3]; Ponzo, Alessandro[3]

Visitation to the small island of Panglao doubled from ~300,000 visitors in 2015 to ~600,000 visitors in 2016. An international airport with capacity for two million visitors, annually, opened in late 2018. Increasing tourist numbers has led to a proliferation in backyard built boats that facilitate an unregulated dolphin watching industry. To support local government in developing their ordinance for sustainable dolphin watching, we undertook a holistic investigation to describe the activity; understand operator and visitor perceptions; and infer dolphin habitat use and disturbance. Between February and July 2017, we collected 409 structured visitor questionnaires; 117 structured operator interviews; and partook in 10 tours, assessing them against sustainable nature-based tourism criteria. We undertook 32 boat-based surveys, recording before-during-after dolphin behaviour continuously and at five-minute intervals, as well as vessel number, spread, approach type and proximity to dolphins. Operators targeted ~150 spinner dolphins in nearshore waters early in the morning at the start of island hopping trips, with a 95% encounter rate. The predominant behavioural state was resting but events were erratic, with avoidance response and evasion increasing with increased boat number, proximity and aggressive driving. Interactions involved up to 53 boats; 20 within 20 m, another 33 within 50 m, of dolphins. Eighty per cent of boatmen indicated that they drive within 20 m of dolphins. Most enjoy working in tourism, want to make visitors happy, and don't want to cause harm to dolphins but felt pressured to be nearer when more boats were present. Visitor satisfaction and perception varied broadly but expectations were often not met and the majority were dissatisfied with high number of boats present. Conservation benefits are lacking as no visitor interpretation is provided. Decoupling dolphin watching from island hopping, using larger boats and initiating a rotation system are considerations for policy development that would achieve fewer boats.

Abundance and trends of narwhals wintering in polynyas around Greenland

Hansen, Rikke Guldborg[1]; Borchers, David[2]; Heide-Jørgensen, Mads Peter[3]
(1) Greenland Institute of Natural Resources, Copenhagen K, Denmark

Kingdom
(3) Greenland Institute of Natural Resources, Copenhagen, Denmark
Corresponding Author: rikkeguldborg@gmail.com

Polynyas are important wintering areas for marine mammals and the North Water Polynya (NOW) in Northwest Greenland is known to be the most biologically productive polynya in the Arctic. Whilst the NOW has been a reliably recurrent and high-production ecosystem for recorded history, the Northeast Water Polynya (NEW), which forms each spring over the continental shelf of Northeast Greenland, is recurring in different sizes between years. A northward coastal current interacts with a persistent shelf ice barrier under which water can flow but that retains ice floes and therefore protects the NEW area from ice advection. The Scoresby Sound Polynya Ecoregion (SSP) includes the world's largest fjord system with an associated polynya off shore in winter.

Narwhals winter in all three polynyas around Greenland and we investigated abundance and distribution of narwhals by visual aerial surveys involving double observer platforms at the wintering grounds in April 2014 (NOW) and April 2017 (NEW) and at the summering ground in August 2016 (SSP).

Narwhal density and abundance was estimated using a Hidden Markov Model (HMM) approach. This involves first estimating the parameters of a HMM for whale availability, using time-depth recorder data, and then integrating these HMMs with the aerial survey line transect data, using both perpendicular and forward distances to detected whales to estimate detection probability. Narwhals in high numbers were observed in the NOW whereas the abundance of narwhals in the NEW and SSP were low. Trend analysis show a stable population of narwhals in the NOW while no trend is possible for narwhals in the NEW. There is a long-term decline in the population that summer in the SSP.

Allied whale UME stranding analysis on the northern Maine coast

Harcourt, Julia[1]; Jones, Lindsey[2]; Longsworth, Gordon

(2) College of the Atlantic
Corresponding Author: jharcourt20@coa.edu

The goal of this study was to complete a comprehensive mapping analysis of seal stranding events documented during the Northeast Pinniped Unusual Mortality Event (UME) along the coast of Maine. Under the United States' Marine Mammal Protection Act, an UME is "a stranding that is unexpected; involves a significant die-off of any marine mammal population; and demands immediate response." Data for this study were collected by Allied Whale's Marine Mammal Stranding Response Program at College of the Atlantic. The environmental factors analyzed in ArcGIS Pro included geology, weather conditions, substrate, and coastal population. These geographic and environmental conditions were mapped to observe how each factor may affect documentation and reporting of a stranding event. Our main focus of this study was on the variance in surficial geology present at stranding locations in northern Maine. Marine mammal species habitat use patterns and human population size were compared with surficial geology and weather patterns in order to theorize where hotspots of future strandings may be found. We found that stranding events most commonly occur on favorable surfaces, either due to human overlap with marine mammals or due to the unique condition of the animal, and therefore could assist in understanding where significant numbers of future strandings occur. This study focuses on critical locations for marine mammal strandings to provide location information to prioritize close monitoring for future strandings. We have found a high preferability to ledge and mud flat environments in pinniped strandings. Approximately 50% of all pinniped strandings in 2018, most of which were associated with the UME, were found on ledges or mud flats. The remaining 50% were found on seventeen various substrates. A continuation of the study will be conducted to compare substrate preferability of pinnipeds from 2008 to 2018.

An evaluation of machine learning algorithms for detecting ice seals in images collected during aerial surveys

Hardy, Stacie[1]; Moreland, Erin[2]; Christman, Cynthia; Hou, Benjamin[3]; Boss, Yuval; Joshi, Neel; Simon, Marcel; Morris, Dan; Baer, Peter; London, Josh[1]; Boveng, Peter[1]

Corresponding Author: stacie.hardy@noaa.gov

High-resolution digital images obtained from aircraft or satellites are rapidly replacing visual sightings surveys as the basis for enumerating many marine mammal populations. Collecting images, rather than relying only on in-flight sightings, gives us a permanent record from a survey and the flexibility to use different approaches for detecting seals while eliminating elements that make visual in-flight detection

challenging (e.g., observer fatigue, camouflaging, and weather conditions). We have successfully used aerial infrared (thermal) images to detect warm-bodied Arctic seals ("hotspots") against the cold background of sea ice, and paired high-resolution color imagery to identify the hotspot to species. This method produces millions of images for surveys conducted in ice seal habitat (such as in the pack ice of the Bering or Chukchi Sea in spring) and requires the automation of the detection and identification processes for economy of labor. Through collaborations with private industry, we developed several deep learning algorithms using an annotated training imagery set and evaluated the algorithms' performance using a separate test imagery set. Here, we present an overview of each approach and an evaluation of how well these algorithms work for detecting ice seals using recall (a measure of how many of the seals were detected), precision (a measure of how many of the detections were actually seals), and F1 scores (a measure of accuracy that balances the importance of recall and precision). Preliminary testing of algorithms has yielded successful detections of ice seals, and the automated methods will reduce image processing labor by 1 to 2 orders of magnitude relative to manual inspection of the images by experienced observers.

Stealthy foraging: Dolphins can discriminate among marine species using vision alone.

Harley, Heidi E.[1]; Fellner, Wendi[2]; Odell, Kim[3]; Stamper, M. Andrew[3]

Prey capture requires stealth, however, broadband echolocation clicks may alert prey to odontocetes' interest. Using vision to identify prey would enable dolphins to remain silent, but little is known about their ability to distinguish among other ocean inhabitants visually. Will vision serve? We investigated the ability of 3 adult male bottlenose dolphins in a 5.8-million-gallon mixed-species salt water habitat to discriminate among 35 marine species of teleosts, elasmobranchs, and reptiles in a matching-to-sample task: Dolphins viewed a still photo or video sample (e.g., a permit) in one underwater window located 4 m below the surface and chose from among 3 video alternatives (e.g., a swimming look-down, permit, or palometa) in an adjacent window presented in 18-trial sessions balanced for sample identity and alternative position. Observers naïve to the presented sample identified the dolphin's choices. In later sessions, stimuli projected on the window alerted the dolphins to the opportunity to engage in these trainerless, self-initiated "foraging" sessions; if dolphins chose to participate, correct matches led to food fish appearing at the water's surface. The dolphins successfully discriminated 30 3-alternative sets (5 sessions per set; M=81.20%, SD=10.04%) and chose to participate 92.16% of the time with an average latency to response to the first sample of each session of 12.09 sec. During sessions, educators explained the science and delivered conservation messages (e.g., effects of ocean noise) to guests. Our approach provided the dolphins with choices to engage in naturalistic behaviors in the form of foraging sessions, our guests with conservation and science education, and scientists with data: Dolphins can use vision alone to discriminate both still and mobile marine species. This cognitive/perceptual capacity is necessary for dolphins to rely on vision as part of a successful foraging sequence. Vision's role in natural prey detection should not be discounted in management decisions.

Quantifying behavioural responses of minke whales to sonar activity during Navy training exercises

Data from passive acoustic monitoring (PAM) of navy training ranges can be used to test predictions of marine mammal responsiveness to naval sonar established through experimental behavioural response studies. Minke whale (*Balaenoptera acutorostrata*) vocalizations were detected, classified, localized and associated into individual tracks from data collected on bottom mounted hydrophones on the U.S. Navy's Pacific Missile Range Facility, Hawaii. Data were analyzed from before, during and after naval undersea warfare training activities in February 2014 (126 tracks) and 2017 (203 tracks). Speed and turning angles were derived for each track, and tracks were aligned with relevant contextual variables (environmental, ship and sonar-related). Firstly,

the spatial distribution of tracks was modelled using latitude, longitude, depth, year and phase (Before, During, After) as covariates. It was found that, as well as inter-annual variability across all phases, the distribution of calling whales changed in both years, with fewer tracks in the vicinity of the centre of ship activity in the During phase compared with Before. Secondly, Generalized Estimating Equations (GEE) were fit to speed and turning angle with year, phase, and time to and since the nearest sonar exposure as covariates. In both years speed increased and turning angle decreased with time since the start of the During phase. As the data are from PAM, it is unknown whether the change in spatial distribution of tracks across the range is a result of whales moving away from the range or ceasing calling, or perhaps a combination of both. The expectation from experimental studies is that minke whales will exhibit avoidance in response to naval sonar. The GEE results indicate a horizontal movement response, but to confirm whether this is an avoidance response will require combining the whale track data with the ship/source position data.

Renewals of incidental harassment authorizations under the U.S. Marine Mammal Protection Act: Process streamlining.

Harrison, Julia[1]; Wheeler, Holly[2]
(1) NOAA/NMFS
(2) National Oceanic and Atmospheric Administration, Silver Spring
Corresponding Author: jolie.harrison@noaa.gov

To provide compliance with the U.S. Marine Mammal Protection Act (MMPA), which prohibits all "take" of marine mammals including harassment unless authorized or exempt, the National Marine Fisheries Service (NMFS) issues Incidental Harassment Authorizations (IHAs) for U.S. citizens conducting activities that are expected to harass marine mammals, provided certain findings can be made and mitigation, monitoring, and reporting requirements are included. These IHAs can take five to eight months for the agency to process, and even longer in certain circumstances. NMFS has begun implementing an expedited process (with processing completed in approximately 60 days) whereby the agency may, on a case-by-case basis, issue a one-year Renewal for IHAs provided certain conditions are met and the activities covered by the proposed Renewal consist of either: 1) *another* year of identical, or nearly identical, activities as were covered by the initial IHA (or a subset of those activities) or 2) a subset of the activities covered by the initial IHA because the originally planned activities were not completed within the effective dates of the initial IHA and are planned for completion under the proposed Renewal. This expedited process is designed for application to simple, relatively low-impact projects with little to no uncertainty regarding the impacts of the activity on marine mammals, including type and amount of expected take. Here, we describe the conditions that must be met in order for an IHA Renewal to be issued, the process for Renewal issuance, and the materials that an applicant should submit when requesting an IHA Renewal.

Assessment of disturbance to Hawaiian monk seals and birds in the Northwestern Hawaiian Islands by a hexacopter UAS

Unoccupied Aircraft Systems (UAS) have great potential for Hawaiian monk seal (*Neomonachus schauinslandi)* conservation research by allowing scientists to survey seals with greater efficiency and at difficult to reach locations. UAS may also have drawbacks, including disturbance to target and non-target species which could cause stress and preclude successful research objectives. The objective of this study was to determine the extent to which an APH-22 hexacopter would disturb seals or birds in the Northwestern Hawaiian Islands. Seal behavior was recorded before and during flights at altitudes of approximately 50m, 30m, and 10m. Results showed that disturbance to seals was minimal. 81% of seals did not respond to the APH-22 above 25m. Above 40m, 12% of seals responded to the APH-22 with a raised head. Between 25 and 33m, 25% of the seals responded, with one seal flushing and subsequently returning to the beach. Between 9 and 14m, 67% of seals responded, most with a raised head. Disturbance to birds commonly found in important areas for seal surveys was recorded before, during, and after flights to determine whether UAS surveys would present risks to non-target species. Bird disturbance varied by species. Noddies (*Anous* spp.) and boobies (*Sula* spp.) most often flushed from the beach, but generally returned within minutes. Great frigatebirds (*Fregata minor*), white terns (*Gygis alba*), and several species of boobies approached the APH-22 during flight, but none made contact. This study showed minimal seal and bird disturbance from the APH-22, suggesting that this

tool can be used safely for Hawaiian monk seal conservation research. Future studies will continue to assess the impact that UAS have on target and non-target species.

Male Risso's dolphins (Grampus griseus) maintain a multi-level network of intra-alliance associations.

Corresponding Author: oceanwatch@gmail.com

Multi-level associations between male individuals have been observed in a few mammal species outside humans. In toothed whales, only male bottlenose dolphins are presently known to cooperate at more than one hierarchical level. The social structure of adult male Risso's dolphins (*Grampus griseus*) is organized in highly stable clusters, ranging from 3-12 individuals. These features offer potential for an in-depth intra-group analysis. Here we introduce a new method for data collection using a drone and social network analysis focusing on a group of thirteen wild-ranging male Risso's dolphins. This enabled us for the first time to continuously identify and record the detailed behaviour of every individual throughout the focal group follow. A total of twenty-two separate drone flights were operated in July and August 2017, during 8 distinct surveys. Synchronized surfacing behaviour was scored from drone footage for all individuals, and taken as an indicator of association stability, which was subsequently analysed focusing on relative distance over time and group-position. We recorded a total of 2,337 single breathing events, out of which 590 synchronous dyads were identified: 466 pairs (20%), 20 trios (0.9%), 6 quartets (0.3%) and 1 octet. Using social network analysis and the Dynamic Time Warping method, we detected clear synchrony partner preferences, confirming four strongly associated pairs and one persistent trio. Most pairs were found stable during a single survey but variable among surveys. A second level of association was discovered, dividing the pod in three subgroups. Interestingly, we found a correlation between lower synchrony rates and rear position for two weakly associated subgroups, whereas the third subgroup (possibly dominant males), revealed a correlation between higher synch rates and front/middle positions. Future studies will focus on drivers of Risso's dolphin male alliance formation.

Entanglement survivors; Assessing the impact of non-fatal entanglements on Scottish minke whales.

Marine mammal entanglement in fishing gear is a global problem, and a growing concern in Scottish waters. For minke whales (*Balaenoptera acutorostrata*), it has been identified as the single largest cause of death, and up to 22% of live animals show some entanglement evidence (Northridge et al. 2010). In June 2018, six organisations partnered to form the Scottish Entanglement Alliance (SEA) to better understand the scale, impact and risks of entanglement in Scottish waters from a conservation, welfare and economic perspective.

As part of this work, the Hebridean Whale and Dolphin Trust (HWDT) aims to provide an updated assessment of the proportion of minke whales that experience non-fatal entanglements. To achieve this, photo-identification data collated by HWDT between 1990 and 2018 have been analysed to assess the number of animals that show evidence of entanglement. From 485 encounters, 235 individual whales were identified, adding an additional 103 whales to the catalogue since it was last evaluated in 2008 (Northridge et al. 2010). Initial analysis indicated that 5.5% of animals showed scars potentially resulting from entanglements.

Laser photogrammetry, which positions two reference points on the animal's body to allow measurements to be taken, is also being used to classify scars from interactions with fishing gear. Preliminary analysis of the laser photogrammetry data shows that it is possible for this method to be used to measure scars, but the number of successful captures has been low, primarily due to weather conditions interrupting the laser beams reach.

The analysis of this long-term dataset allows some of the previously identified knowledge gaps to be addressed (e.g. quantifying accumulation rates of marks and scars), and will contribute to the assessment of the rate and risk of non-lethal entanglement in Scottish waters. This is crucial to

identify suitable mitigation measures, and inform management and conservation measures.

Seasonal changes in body condition for spotted, ringed, and bearded seals

As high-latitude species, Arctic seals manage considerable changes in environmental and ecological conditions annually. They depend upon sea ice for rest, predator avoidance, and to carry out key life-history processes; however, this critical substrate is declining rapidly in persistence, thickness, and extent. During times of nutritional stress and/or when energy demands exceed energy intake, seals can mobilize lipids from their insulating layer of blubber to fuel metabolic processes. Thus, blubber thickness can vary greatly throughout the year and is often used as a metric of body condition. Here, we used the traditional truncated cones method to examine fine-scale changes in blubber mass for three Arctic seal species. Subjects included 4 spotted (*Phoca largha*), 3 ringed (*Pusa hispida*), and 1 bearded (*Erignathus barbatus*) seal. Energy intake was allowed to vary naturally and seals were trained to participate in data collection. Photogrammetric and direct morphometric measurements were collected weekly at defined locations along the body. Blubber depth was measured at the same locations using a portable ultrasound machine. All measurements were averaged monthly for a minimum of 1 year and used to determine body composition. On average, spotted seals experienced a 43% annual change in blubber mass, although this value was highly influenced by one individual (range 27% - 72%). Ringed seals incurred a 19% annual change in blubber mass (range 13% - 26%), while the bearded seal exhibited a 12% change. In spotted and ringed seals, blubber mass decreased prior to and through the molt, followed by an increase post-molt; this relationship was less defined for the bearded seal. Our data suggest physiological and environmental parameters are important in driving body condition patterns in these species. Ultimately, longitudinal assessments of body condition can be used to identify critical periods when seals may be most vulnerable to disturbance or environmental change.

Risk balancing by a marine mammal: Man-made noise reduces the foraging success of seals.

Foraging theory predicts that individuals should attempt to maximise their energy gain by foraging in patches with high food densities. However, animals faced with a choice between a rewarding food patch which has a high degree of risk associated with it, and one that is both less rewarding but less dangerous, should exhibit foraging decisions that reflect both the degree of risk involved and the energetic advantage. Sounds from anthropogenic sources can affect marine mammal foraging behaviour, yet evidence of the effects on foraging success in these species is lacking. We measured the influence of anthropogenic sounds (pile driving, a tidal turbine, and a silent control) on grey seal behaviour within a simulated foraging scenario and investigated the influence of food availability and perceived risk. Seals were given access simultaneously to two underwater 'food patches' in an experimental pool where fish were delivered at controlled rates to simulate a low reward (LRFP) and a high reward (HRFP) food patch. Acoustic playbacks were made using an underwater speaker above one of the food patches (randomised during the study), and three foraging metrics (foraging duration, foraging effort allocation between the food patches, and foraging success) were measured. Foraging success was highest during silent controls and was similar regardless of speaker location (LRFP/HRFP). Under the tidal turbine and pile driving treatments, foraging success was similar to the controls when the speaker was located at the HRFP but was significantly reduced (~16-28% lower) when the speaker was located at the LRFP. Results suggest that the foraging decisions by the seals reflect a risk/profit balancing approach. In response to a perceived risk associated with the anthropogenic sounds, seals apparently showed avoidance of the sounds when the energetic rewards were low but not when the rewards were high.

Photographic capture–recapture analysis reveals a largely non-resident population of

Indo-Pacific bottlenose dolphins (Tursiops aduncus) inhabits coastal waters off the North West Cape at World Heritage listed Ningaloo Reef Marine Park, Western Australia.

Studying the demographic parameters of open populations of wide-ranging delphinids is difficult. This challenge increases when studying open populations containing a high proportion of non-resident individuals that use the study area for short periods. Failure to account for these individuals can lead to biased estimates of population demographic parameters. In this study, we used site fidelity indexes and capture-recapture models to estimate the site fidelity and abundance of an open population of bottlenose dolphins inhabiting the coastal waters off the North West Cape of Western Australia, located within the World Heritage listed Ningaloo Coast and home to the Ningaloo Marine Park. Photo-identification data was collected during boat-based surveys off the North West Cape between 2013 and 2015. A standardised site fidelity index (SSFI) estimated extremely low site fidelity (SSFI = 0.019) at the population level. Agglomerative hierarchical clustering of individual re-sight rates showed that 58% of individuals identified exhibited low levels of site fidelity, indicating that most individuals in this population are non-resident. POPAN modelling estimated a super-population size of 309 (95%CI: 261-356) individuals over the study period. A maximum likelihood transient model which considers both resident and non-resident individuals in the population, estimated a resident population of 148 (95%CI: 127-169) individuals and a super-population of 398 (95%CI: 347- 449) individuals. These models indicate that a moderately large population of bottlenose dolphins inhabits the waters off the North West Cape. The large number of both resident and non-resident bottlenose dolphins found throughout the study area suggest the coastal waters off the North West Cape are used frequently by this species. The substantial number of non-resident individuals and low site fidelity suggest, however, that bottlenose dolphins occupy a much larger area and future studies and conservation decisions should consider neighbouring waters within and outside the marine park.

Arctic marine mammal ecology and health: Finding common ground between conventional science and Indigenous Knowledge to track arctic ecosystem variability.

Hauser, Donna[1]; Moore, Sue[2]

Arctic marine mammals respond to, and thereby reflect, changes in Arctic ecosystems that are important both to practitioners of conventional science (CS) and to holders of Indigenous Knowledge (IK). Although often seen as contrasting approaches to tracking ecosystem variability, when CS and IK are combined they can provide complementary and synergistic information. Despite exceptions, ecosystem-focused CS is often spatially broad and time shallow (1000s km, decades) while IK is comparatively narrow spatially and time deep (10s km, centuries). In addition, differences in how information is gathered, stored, applied and communicated can confound information integration from these two knowledge systems. Over the past four decades, research partnerships between CS practitioners and IK holders have provided novel insights to an Alaskan Arctic marine ecosystem in rapid transition. We identify insights from some of those projects, as they relate to changes in sea ice, oceanography, and more broadly to marine mammal ecology and health. From those insights and the protocols of existing community-based programs, we suggest that the strong seasonal cycle of Arctic environmental events should be leveraged as a shared framework to provide common ground for communication when developing projects related to marine mammal health and ecology. Adopting a shared temporal framework would foster joint CS-IK thinking and support the development of novel and non-linear approaches to shared questions and concerns regarding marine mammals. The overarching goal is to extend the range and depth of a common understanding of Arctic marine mammal health and ecology during a period of rapid ecosystem alteration. The current focus on CS-IK co-production of knowledge and recent inclusion of marine mammals as essential variables in global ocean observatories makes this an opportune time to find common ground for understanding and adapting to the rapid changes now underway in Arctic marine ecosystems.

Subcellular distribution and metalloprotein detoxification of titanium, a contaminant of emerging concern, in Pontoporia blainvillei and Steno bredanensis from southeastern Brazil.

Monteiro, Fernanda; Lemos, Leila[1]; Moura, Jailson; Eocha, Rafael; Moreira, Isabel; Di Beneditto, Ana Paula M.; Kehrig, Helena; Bordon, Isabella C.; Siciliano, Salvatore[2]; Saint'Pierre, Tatiana D.; Hauser-Davis, Rachel[3]

Titanium (Ti) is a contaminant of emerging concern used in personal care products in the form of nanoparticles (TiO_2), which can bioaccumulate and biomagnify along trophic webs, eliciting deleterious effects. Ti content and detoxification data for aquatic organisms is scarce in general, while no assessments concerning marine mammals are available.Therefore, subcellular Ti distribution and detoxification were assessed in endangered *Pontoporia blainvillei* and data-deficient *Steno bredanensis* specimens from southeastern Brazil, in order to assess intracellular and, thus, bioavailable Ti contamination for the first time in both species. Kidney, muscle and liver samples were heat-extracted and insoluble (ISF), thermos-labile (TLF) and heat-stable (TSF) fractions were obtained. The TSF also contains metallothionein (MT), a metal-detoxification protein that binds to metals for subsequent excretion. MT concentrations were spectrophotometrically determined, Ti was determined by inductively coupled plasma mass spectrometry (ICP-MS) and Ti TSF detoxification was characterized by high performance liquid chromatography (HPLC) coupled to ICP-MS. Ti-metalloprotein detoxification was observed in kidney (~10%), liver (~15%) and muscle (~25%) TLF and TSF, respectively in *P. blainvillei*, while ISF Ti ranged up to 50%. All *S. bredanensis* tissues exhibited Ti detoxification, although ISF levels were high (~75%), establishing a differential Ti detoxification pathway mostly unmediated by MT. A Principal Component Analysis verified Ti-MT associations in both species, confirming TiO_2 contamination in Southeastern Brazil, since Ti binds to MT only in nanoparticle form. In addition, high oceanic TiO_2 diffusion was noted, due to oceanic currents and/or differential prey distribution, as *S. bredanensis* lives in offshore waters further from the coast than *P. blainvillei* but still presented MT-Ti correlations. Ti was associated to reduced glutathione (GSH) in both species, indicating possible Ti-GSH binding and detoxification. These findings indicate that the TSF is a valuable tool concerning Ti detoxification assessments in cetaceans, which may be applied to conservation efforts.

From phocine distemper to avian influenza: An ecological perspective on immunogenetic diversity of two sympatric pinniped species.

Gray (*Halichoerus grypus*) and harbor seals (*Phoca vitulina*) are sympatric species that inhabit the North Atlantic and have been subject to mortality events from disease outbreaks, particularly phocine distemper and avian influenza virus. Across mortality events, gray seals tend to be more immunologically robust, exhibiting a higher survival rate. This difference could be explained by various ecological factors impacting rates or direction of selection in parts of the genome related to the immune system. These factors could include haul-out site density, habitat, and degree of inter/intraspecies interaction. This research aims to compare selection for genetic diversity within the Major Histocompatibility Complex (MHC) class I among gray and harbor seals. The MHC is a group of genes that allow the immune system to recognize foreign pathogens, with class I responding to viral pathogens in particular. Possessing greater genetic diversity at this region can be tied to greater immunocompetence. Due to its duplicated nature, MHC class I diversity has been challenging to evaluate across multiple gene regions at a population scale, but recent advances in sequencing technology enable high-throughput genotyping of complete MHC regions. In this study, MHC diversity across multiple class I exons is assessed using amplicon sequencing to compare the degree of copy number variation, number of alleles and amino acid sequence diversity between species and among populations. We test the hypothesis that gray seals will exhibit greater diversity consistent with their higher survival rate during viral-induced mortality events. These analyses will be performed on tissue biopsy samples from harbor seals by-

caught in the Northeast US and live, weaned gray seal pups from three locations in the Northwest Atlantic. This research aims to address how differences in ecology drive evolutionary differences in two closely related species and investigate how sympatric species evolve in the face of natural stressors.

Persistent organic pollutant burdens in blubber of eastern North Pacific gray whales (Eschrichtius robustus) and the influence of life history parameters.

Bioaccumulation of persistent organic pollutants (POPs) in lipid-rich blubber tissues puts marine mammals at risk of developmental dysfunction, reproductive failure, and immunosuppression. Research conducted in the 1960s-1990s reported POPs in gray whales (*Eschrichtius robustus*) but contemporary data were lacking. Here, we report on baseline concentrations of contaminants in gray whale blubber across life history parameters including sex, age, and reproductive status. Blubber biopsies (n=120) were collected from free-swimming whales between 2003 and 2017 along the Pacific coast from southern Canada to Baja California, Mexico. A rare sample collection of 19 mother and calf pairs provide the first direct assessment of patterns of maternal offloading of contaminants in gray whales. POP blubber concentrations (mean ± SEM in ng/g lipid weight) were 226 ± 26 ΣPCBs, 230 ± 35 ΣDDTs, 88 ± 7 Σchlordanes, 74 ± 9 Σpolybrominated diphenyl ethers, and 74 ± 5 Σhexachlorocyclohexans. Overall mean PCB and DDT burdens were found to be lower on average than previously reported for gray whales. Statistical modeling of 20 select compounds revealed significant sex, age, and reproductive status-related POP trends. Immature whales in this study had similar POP concentrations across sexes. Adult males had higher POP burdens than immature males. Female POP burdens varied little across age-groups, with the exception of DDT metabolites and some higher chlorinated PCBs, which were higher in adult females. Significant differences in adult male versus adult female POP burdens for most compounds were attributed to maternal transfer of contaminants during reproduction. Contaminant loads of most compounds were marginally higher in mothers than in calves, further suggesting significant maternal offloading during reproduction. This study provides current POP concentrations in gray whales and enhances our understanding of POP trends across life history stages. Such information should aid in the design and interpretation of contaminant burden monitoring in this protected species.

Physical maturity in bottlenose dolphins (Tursiops truncatus) from Sarasota Bay, FL.

Physical maturity in cetaceans is defined as when growth ceases and all epiphyses are fused to the vertebral body such that the suture line is no longer visible. Many studies have shown that this is highly variable among individuals and in-depth examinations into fusion variability have been lacking. We analyzed the vertebral columns of 38 (n=22 female; n=16 male) stranded common bottlenose dolphins (*Tursiops truncatus*) known from the well-studied Gulf of Mexico, Sarasota Bay resident community. For each specimen, vertebrae were examined by anatomic region for the degree of fusion on the anterior and posterior side of each centrum and categorized as un-fused (1), fused with open suture lines (2), fused closed

with the entire suture line visible (3), fused closed with partially visible suture lines (4), and fused closed with invisible suture lines (5). An ordinal logistic regression was used to estimate a given joint's degree of fusion probability. The model had fixed effects for an individual's age, number of calves, sex, and sexual maturity and a random effect for joint. Physical and sexual maturity are not synonymous, though often linked. Our results definitively show that age and reproductive status significantly explain an individual's degree of fusion. Sex alone however, had a non-significant effect on fusing. Adult females with fewer calves had higher fusing of the vertebral epiphyses than those with more reproductive experience across multiple ages. The relationship between energetic demands of reproduction vs preconceived definitions of physical maturity is worth examining more closely. The long-term partnership between the Sarasota Dolphin Research Program and the Stranding Investigations Program at Mote Marine Laboratory offers this relationship, as well as genetic findings, to be further examined.

Some like it cold: Targeted temperature range during feeding in narwhals.

The narwhal (*Monodon monoceros*) is a high Arctic species inhabiting areas that are now experiencing increases in sea temperatures, which together with reduction in sea ice are expected to modify the niches of Arctic marine apex predators. The Scoresby Sound fjord-system in East Greenland is the summer residence for an isolated population of narwhals. The movements of 12 narwhals instrumented with FastLoc GPS transmitters were studied during summer in Scoresby Sound and during winter at their offshore wintering ground. CTD tags on additional four narwhals provided detailed information on the temperature profiles (down to 1000 m) on both the summering (284 profiles) and the wintering ground (263 profiles). Data on diving of the whales were obtained from deployments of 16 Acousonde™ recorders, and 10 satellite-linked time depth recorders deployed from 2010 through 2018. The Acousonde recorders furthermore provided information on the temperature and depth of buzzes during summer. The whales targeted depths between 300 and 500 m in summer. At these depths the preferred areas visited by the whales had temperatures ranging between 0.6 and 2.0 ºC with an average temperature at 300 m of 1.1 ºC (0.6-1.8ºC, SD=0.25). The buzzing activity during summer was focused (10% kernel probability distribution) on depths between 282 and 387 m where the temperature when buzzes occurred was within 0.5-1.0 ºC. In winter the whales targeted depths >500 m where the average temperature was 1.3 ºC (range: 0.7-1.7, SD=0.29). It is unknown if the small temperature niche of whales while feeding is because prey is concentrated at these temperatures and are easier to capture at low temperatures, or because there are restrictions in the thermoregulation of the whales. In any case, the small niche requirements emphasize the sensitivity of narwhals to habitat changes.

Diet analysis of seals in the southern North Sea based on faeces; A comparison between molecular and physical analysis.

Diet is key to understanding an animals' requirements and its role in the ecosystem. We investigated the diet composition of two seal species occurring in the southern North Sea, the harbour (*Phoca vitulina*) and grey seal (*Halichoerus grypus*), based on their faecal remains. Both species recently grew exponentially, and may play an important role as top predator. The methodology used traditionally is limited to hard parts recovered from excrements, but this method lacks the possibility to detect prey without bony structures or hard parts that did not survive digestion. Analysing fragmented DNA of consumed prey may give a better and broader insight into these seals' diet. This study compares both approaches. For this we used frozen seal faeces samples collected over several years (2011 - 2018) along the Dutch coast. For the hard-part analyses, faeces samples were washed and remaining hard parts were examined and brought to species level. For the DNA extraction, different methods were used to dissolve the faecal samples; Ethanol, water and/or freeze-drying and PBS buffer. Ethanol resulted in the fixation of particles, obscuring the analysis of hard parts. The Qiagen

Fast DNA Stool Kit was used to extract DNA. To identify prey DNA, a ~77 base pair fragment of the 16S mtDNA was used. Since not only fish DNA is targeted, but also other chordate animal species like seals, a blocking primer was added to block (most of) the seal DNA. Next Generation Sequencing was used to sequence all present faeces DNA. By comparing the hard parts with the DNA based analyses we were able to make a (more) complete analysis of the very variable diet of harbour and grey seals living in the southern North Sea, thus obtaining a first insight in their role in the ecosystem.

Risk of collisions between fin whales and marine traffic in the Garraf coastal area, Balearic sea

Ship strikes are a major non-natural source of fin whale (*Balaenoptera physalus*) mortality in the Mediterranean Sea, as has been proven in the past and possibly pose a sinister threat for the health of this understudied population, or as recent insight suggests, populations. Even though these problematics have already been a focus of a previously done research for a certain part of the Mediterranean, this study focuses on the negative relationship between the fin whale spatial distribution and the trajectory of cargo ships in front of the Garraf Coast, Balearic Sea. This study is a part of a much larger overall and ongoing multiannual research of fin whales frequenting the nutrient rich area of the Garraf coastal waters in the spring season. Using the sightings data that was acquired over the years it was possible to gain insight into the distribution pattern of the whales in the research area, as well as attain data of shipping tracks from cargo vessels that pass through the research area. In addition, local fishermen shared the location of several whale bones from carcasses that they fished out, suggesting possible collision events. By mapping fin whale distribution in the Garraf coastal area against the marine traffic data, this study proves a considerable spatial overlap within this fin whale feeding ground and the marine traffic, exposing that the discussed area is one with a high probability of ship strikes and also locates the most problematic hotspots in the area. Furthermore, the bones found in the area by the fishermen contribute to the notion that ship strikes do happen, but are largely unreported. The presented study serves as a warning and hopefully an instigator for stakeholders to take action towards mitigation policies, as well as a benchmark when those policies begin implementation.

Counting needles in a complex haystack- first abundance estimates for endemic Chilean dolphins in northern Patagonia, Chile

sonja_heinrich@hotmail.com

Southern Chile has the most complex fjord system in the world, and is home to the endemic and apparently rare Chilean dolphin (*Cephalorhynchus eutropia*). No regional or range-wide abundance estimates exit for this species, yet these are imperative to evaluate conservation status and potential effects of anthropogenic threats. Conventional distance sampling methods are not considered suitable due to logistic constraints, the dolphins' patchy distribution, extreme nearshore habitat preference and cryptic behaviour. This study used predictive species distribution modelling to identify focal areas for intensive mark-recapture surveys to estimate abundance of Chilean dolphins in northern Patagonia, where most of Chile's intensive aquaculture farming takes place. Based on the dolphins' predicted occurrence and survey safety considerations we selected eight focal areas spanning the full north-south (41^{o}-46^{o}S) and east-west (72^{o}-73^{o}S) extent of northern Patagonia. We conducted 2-3 week long intensive photo-identification surveys in the focal areas over three consecutive summers (2017-2019) and estimated abundance using closed population mark-recapture (MR) estimators. Encounter rates varied across focal areas from 2-4 Chilean dolphins per 10 km of nearshore survey effort (n=4,100 km). Resighting rates of individuals within focal areas were high (40-80%) with no resightings made between study areas. All dolphin populations were small with (preliminary) MR estimates ranging from 38 to 95 adult individuals (estimates corrected for mark rates). Seven of the 8 surveyed populations were exposed to potential bycatch in aquaculture and fishing operations. Summing population estimates from the focal areas gives 465 Chilean dolphins (95%CIs: 335-621). Assuming the surveyed habitat is representative of the non-surveyed predicted suitable habitat, Chilean dolphins in northern Patagonia seem to number at most in the low thousands. This first region-wide abundance estimate for Chilean dolphins provides a much needed ballpark figure, and the novel local population estimates are sufficiently precise to

guide relevant management and conservation initiatives.

Comparison of the timing abilities of a harbour seal (Phoca vitulina) and a South African fur seal (Arctocephalus pusillus)

Heinrich, Tamara; Hanke, Frederike; Dehnhardt, Guido
University of rostock, Rostock, Germany
Corresponding Author: tamara.heinrich@uni-rostock.de

Living in the marine environment might require a precise sense of time as for example tides control access to food as well as haul-out places. Good timing abilities thus seem to be essential for foraging decisions, but also for navigation and orientation when estimating speed of movement for example. A previous study showed, for the first time, the high sensitivity of a phocid, the harbour seal, in discriminating time intervals. In the present study, we compared the harbour seal's timing abilities with the timing abilities of an otariid, the South African fur seal. This comparison seemed essential as phocids and otariids differ tremendously in many respects including lifestyle and habitat and might thus also differ regarding their timing abilities.

The experiments were conducted under constant light conditions inside an experimental chamber. In a two-alternative-forced-choice procedure, the animal was required to discriminate between standard and longer comparison time intervals marked by a white circle on a black background that was displayed for the respective time interval on a monitor. Time difference thresholds were determined for several standard time intervals in the millisecond to second range by a staircase method.

Contrary to our expectation, the timing abilities of an otariid and a phocid are comparable, with mean Weber fractions of 0.1 for the fur seal and 0.13 for the harbour seal. Timing might thus be a fundamental cue for pinnipeds in general to be used in various contexts thereby complementing information provided by the classical sensory systems.

Estimating relative mortality from satellite tracking data: A quantitative approach on Southern elephant seals.

Satellite telemetry is a powerful tool to study animal movement especially that of cryptic and marine animals but has had limited application in demographic studies. One possibility is that tracking data can provide data on animal mortality at sea. There is always a proportion of tags that fail during the deployment but disentangling animal mortality from simple tag failure is challenging. Southern elephant seals (SES) present as a model species to disentangle these factors due to the availability of large multi-year tracking datasets, detailed demographic information (particularly survival rates) and the demonstrated knowledge that satellite tags deployments don't in themselves influence mortality. A series of survival analyses were performed on satellite tag data from 185 seals from Isles Kerguelen carrying SMRU SRDL_CTD tags between 2005-2018. Of these 76 returned to land while the remaining 107 tags failed at sea, with an overall failure rate of 43% for females and 74% for males. Several behavioural factors were tested to explain this difference, including habitat use, foraging behaviour and dive characteristics, but none were influential. We included natural mortality, based on known rates for these age classes, as an offset in models to estimate technical tag failure. We then used this failure rate to contrast animal mortality rates in years of good and poor foraging conditions (based on SAM), and found that animal mortality was higher in poor foraging years for females but not sub-adult males. This demonstrates the ability of satellites tags to estimate relative survival rates.

Habitat use and behavior of satellite tagged humpback whales off Kauai

Henderson, Elizabeth[1]; Deakos, Mark; Aschettino, Jessica[2]; Engelhaupt, Dan[2]; Alongi, Gabriela[3]; Leota, Tara[4]

A multi-year satellite tagging effort was conducted on humpback whales off the island of Kauai from 2017-2019. Nineteen whales were successfully tagged, with tag durations lasting 1.6 – 12.3 days. All seven whales tagged in 2017 transited west to the island of Niihau after being tagged; six of the

whales continued traveling northwest following islands and seamounts, while one began traveling directly north from Niihau. In 2018, four of the six tagged whales also traveled west to Niihau and on to the closest seamounts, while one animal traveled to Oahu and another animal started traveling to Oahu but then went to Niihau. Finally, in 2019 one animal traveled west to Middle Bank before turning around and returning to Niihau; one animal remained close to Niihau; one animal remained close to Kauai; and a female and primary escort from a competitive pod stayed together for at least four days while traveling to Oahu. During this field effort, the location, group size, and group behavior were recorded for all encountered humpback whales. A habitat use analysis was conducted on all encountered groups to determine if different social groups occurred in specific habitats or if they were randomly encountered in a variety of habitats. For example, mother/calf pairs were typically encountered in nearshore, shallow waters on the southwest side of Kauai, while stationary dyads were often encountered in shallow water off the west side. Variables such as Julian date, latitude and longitude, water depth, distance from shore, and the number of other animals in the area were included in a Generalized Estimating Equation of group behavior. In addition, the social role and behavior of the tagged animals were examined to determine if the habitat or social role in which the tagged whales were encountered was related to where the animals traveled once tagged.

In vivo measurements of ringed seal (Pusa hispida) lung volumes: Insights from biomedical imaging.

Pinnipeds rely on blood, muscle, and lung oxygen stores to support breath-hold diving. Defined by impressive blood volumes, hemoglobin concentrations, and myoglobin content, pinnipeds have a greater capacity to store oxygen in their blood and muscles than their terrestrial counterparts. Thus, these parameters are more commonly the focus of comparative physiological research, with lung structure and function less well studied. Deep diving pinnipeds rely heavily on blood and muscle oxygen stores while diving and collapse their lungs at depth to avoid tissue trauma and pressure related injury. More shallow diving pinnipeds may not fully collapse their lungs on routine dives, and likely rely on lung oxygen stores to a greater degree. Ringed seals (*Pusa hispida*) are among the smallest phocids. They are relatively shallow divers that exhibit short dive durations (typical dives < 100 m and < 8 min), and may rely on lung oxygen stores to a greater extent than other phocids. Currently, there are few studies aimed at understanding how respiratory control and lung oxygen storage is regulated in living marine mammals. Most studies rely on postmortem excised lungs to estimate total lung volume. In this study, we used high-resolution CT scans to provide the first in vivo measurements of total lung volume in ringed seals (n=5) ranging in age from 5 months to two years. All seals were anesthetized and intubated for scheduled veterinary procedures. Full body scans were obtained in 2.5 mm sections at a range of lung pressures (0, 30, and/or 37 mm Hg). By determining total lung volumes from 3-dimensional models of air spaces in living animals, we advance current understanding of diving lung oxygen stores. Further, these data can be combined with previously established estimates of blood and muscle oxygen stores to evaluate overall diving capacity and constraints in this species.

High-frequency masking noise decreases echolocation performance of harbour porpoises.

Vessel activity is widespread in the marine environment, emitting broadband noise with potential impacts on marine mammals. Vessel noise can extend into frequency ranges that overlap with echolocation signals of small toothed whales, thereby posing a risk for biosonar masking. Masking can decrease their ability to decode echo information, crucial for navigation and foraging. To address that potential problem, we tested whether high frequency noise at realistic vessel noise levels can mask the echolocation performance of harbour porpoises (*Phocoena phocoena)*. Two trained and free-swimming porpoises wearing a multisensor tag (DTAG) were tasked with discriminating between two targets by echolocation, mimicking the ecologically relevant scenario of a foraging toothed whale. At the same time they were exposed to third-octave band limited noise at 2 kHz (control

band, 122-128 dB re 1µPa RMS) or 125 kHz (echolocation band, 105-111 dB re 1 µPa RMS). Custom-built hydrophones were attached above each target continuously recording sound. We conducted 392 trials and show that porpoises increase median click source levels by 4-17 dB when exposed to noise within their echolocation range, suggesting a compensatory mechanism to cope with masking. Despite this, both animals were still significantly poorer at discriminating the targets during these trials, demonstrating their inability to compensate sufficiently to alleviate masking impacts. In comparison, the porpoises maintained their click source levels and performance when exposed to control noise. We conclude that relatively low levels of high-frequency noise, such as from cavitating vessel propellers, can cause masking of porpoise echolocation and that compensatory mechanisms evoked by the animals are insufficient to maintain echolocation performance. As a consequence, high frequency components of vessel noise may have negative fitness impacts on porpoises and other small toothed whales, and we therefore emphasize that high frequency vessel noise effects are included in marine management.

Impact of climate variability on the abundance of gray whale (Eschrichtius robustus) in Ojo de Liebre Lagoon, Baja California Sur, Mexico.

It has been observed at the end of the last century and during the first decade of the present that the abundance and distribution of gray whales in their wintering grounds is related with sea ice extent in their feeding grounds. Changes in the sea surface temperature (SST) have also been reported in their breeding grounds due to El Niño/a events. For that reason, the goal of the present work was assess the impact of climate variability on the population of gray whale that used Ojo de Liebre Lagoon (OLL) in the past 15 years, and evaluate the occurrence of the described patterns in the past. For that, we made correlations and regressions analysis between gray whale censuses in OLL and the environmental variability in their breeding grounds in the coast of the Baja California Peninsula and their feeding grounds in the Arctic (Bering, Beaufort and Chukchi Seas). During these 15 years, the relationship between ice extent in Bering Sea over the other Arctic grounds as well as production of calves has been observed again (*RSpearman=-0.63, p<0.05*). This relationship shows that a lesser amount of ice at the Bering Sea in the summer increases the production of calves the following winter, confirming the importance of this region as feeding ground for the pregnant females. There is also a meaningful relationship between sea ice extent at the Beaufort Sea in October, the northernmost feeding ground, and the date of the maximum peaks of abundance within OLL (*RSpearman=-0.79, p<0.05*). This relationship suggests a delay in the migration date when there is little ice in the Beaufort Sea and vice versa.

Early development of in-air and underwater sound production in harbour seals (Phoca vitulina)

Harbor seal pups are unique among phocid seals in their rapid adaptations for swimming and diving. They are known to produce both in-air and underwater calls to keep in contact with the mother during the lactation period. We studied the acoustic development of their vocalizations both in air and underwater through simultaneous hydrophone, microphone and video recordings of two seal births, one female and one male, in the outdoor facility at Fjord&Bælt, Denmark. The pups made their first in-air vocalizations 1-3 min after birth. They started to move around 13-25 min and both went into the water 39 min after birth and almost immediately started diving. Their first underwater vocalizations were heard 60-162 min after birth, or 21-123 min after first entering the water. Most sounds were heard during the first day post-partum, and for all days recorded, most sounds were produced underwater. The in-air and underwater sounds resembled one another, but also showed differences in terms of frequency content and sound intensity. The mothers only produced very infrequent sounds in air and probably never under water. This shows that harbour seals rapidly

develop their abilities to produce sounds both in air and underwater, and that they use the sounds to stay in contact with their mother. The fact that they predominantly produce underwater sounds and that they enter the water very rapidly after birth compared to other seals indicate that not only do their diving abilities develop at a very early age, but so does also their sound production and probably also their hearing abilities. This has important implications for understanding not only how sounds are used between mothers and pups during the lactation period, but also how anthropogenic noise may affect the bonds between the mother and the pup.

Multiple dietary techniques indicate little use of commercial fisheries species by gray seals (Halichoerus grypus atlantica) in U.S. waters.

The return of gray seals (*Halichoerus grypus atlantica*) to the northeast United States has prompted renewed concerns about their significance as fisheries competitors. However, there is limited understanding of their diet and foraging habits in US waters. While many diet studies continue to use prey identifications from remains in fecal samples, they are often paired with a complementary method, such as stable isotope analysis. An increasing number of studies have used DNA metabarcoding to improve taxonomic resolution and the number of taxa identified in predator diets. We used these three methods in tandem to determine gray seal diet from fecal samples collected at haulouts along Cape Cod, Massachusetts, USA to assess potential dietary overlap with commercial fisheries for targeted species. Fecal samples were collected between January 2016 and March 2017 and represent recent foraging activity in inshore waters. The fecal soft matrix was used for both DNA metabarcoding and stable isotope analysis of carbon and nitrogen. The remainder of each sample was analyzed for prey remains. A stable isotope mixing model was used to estimate the proportion of sand lance (*Ammodytes* spp.), squids and benthic fishes to gray seal diet. All three methods revealed that fishes were the main source of food for gray seals, with sand lance and flatfishes as the predominant prey types. Genetic analyses improved taxonomic resolution and doubled the number of taxa identified in seal diet. When these data were compared to a previous investigation of gray seal diet, species richness and diversity decreased over a ten-year period. Overlap between prey items consumed by seals and with commercial fisheries species was low and tended to occur infrequently. These results indicate that gray seals have a less diverse diet than the previous investigations and a reliance on non-commercial species in U.S. waters.

Construction and validation of a dolphin habitat measurement instrument (Tursiops truncatus) in the Port of Veracruz.

Opinion surveys are used for data collection in social sciences, and one of the areas where such tools are often required is biology research. The aim of this study was to create a social assessment instrument to explore the opinions of the residents of the Port of Veracruz with regard to a dolphin species (Tursiops truncatus) present in the Veracruz Reef System and its habitat. This species is considered a natural indicator of environmental health in the areas where it is distributed. The questionnaire was designed to include 13 Likert-type social impact questions, grouped into two sections: the first six items focused on general information about the species and the remaining seven assessed the respondents' perception of the danger faced by the species and its habitat. Factor analysis based on data obtained in a pilot study with 80 participants revealed a three-construct structure (knowledge of the habitat, risks for the species and conservation of the species) with all 13 items showing sufficient factor loadings and a total explained variance of 62.2%. Reliability analysis of the complete 13-item scale showed good internal consistency, with a Cronbach's alpha coefficient of 0.81. In conclusion, the instrument showed satisfactory validity and reliability for social assessment with regard to views of the state of the ecosystem of marine mammals, in this case the dolphin.

Genetic diversity of leopard seal Hydrurga leptonyx at Danco Coast, Antarctic peninsula.

The Leopard seal, Hydrurga leptonyx, has a wide distribution throughout the Antarctic circumpolar region. They have solitary habits, haul out on pack ice for long period, and individuals tend to congregate in the same area of the ice for reproduction. The leopard seal shows site fidelity to reproductive sites, which may imply restricted gene flow between groups. In order to conduct the first assessment of genetic diversity of leopard seals in waters around Danco Coast, we amplified mitochondrial DNA Control Region (mtDNA-CR, 423 bp) from DNA extracted from 13 blood samples collected in Primavera base during 2011-2012 austral summer. Our results show high haplotype diversity, represented in unique haplotype for each sample, and only haplotype shared between two samples. Network analyses confirm high diversity with some divergent haplotypes, which suggest that individuals sampled belong to one population. Due to ice dynamic as a consequence of climate change, many individuals are shifting their diet habits, showing dietary specializations which may have the potential to promote genetic differentiation in the long-term. Given the lack of leopard seals genetic studies this hypothesis cannot be tested. Research studies using mitochondrial and nuclear markers are needed to assess the genetic

Return of the fin whales: Feeding aggregations of fin whales around the Northern Antarctic Peninsula.

Fin whales *(Balaenoptera physalus)* were one of the most abundant whale species in the Southern Hemisphere before their exploitation by commercial whaling, which reduced them to 2% of their pre-whaling population size. Their recovery status today is unknown and information on distribution or abundance is lacking. Over the past years, however, opportunistic observations of high numbers of fin whales have been reported from the Northern Antarctic Peninsula area. We targeted this area with dedicated visual surveys (aerial and shipboard) during four research cruises between 2013 and 2019 to investigate the abundance and distribution of fin whales around the Antarctic Peninsula and along the Scotia Arc. Using distance sampling methods and model-based abundance estimation, we identified high densities of up to 0.114 individuals/km^2 (95 % CI 0.053–0.181). We encountered large aggregations of fin whales during all expeditions, numbering to up to 70 animals feeding together. We were able to film these aggregations by means of helicopter and drone supported camera systems, providing high resolution footage of the behavior and interaction of the fin whales. This is the first documentation of feeding aggregations of fin whales in the Southern Ocean. Furthermore, we collected acoustic data on krill distribution and abundance during feeding events, providing insights into predator-prey interactions.

Our results suggest that fin whales have returned to an area which served as a feeding ground prior to the whaling period, and that they regularly aggregate in the area in high numbers. This may serve as a first indication for population recovery. Future research into population structure and migratory origins is needed for the evaluation of

the current population status. Furthermore, our observations provide first indications for cooperative hunting behavior in fin whales when exploiting krill swarms.

Coda type variation over 30 years in Galápagos sperm whale clans.

Cultural evolution can manifest as changes in vocal repertoires over time. As long-lived, social, and vocal species, cetaceans often display social structures coupled to vocal communication, which makes them good candidates to undergo vocal evolution. A remarkable example is the sperm whale (*Physeter macrocephalus*). Their societies are segregated into clans that are defined by distinct dialects—repertoires of stereotyped patterns of clicks called codas. However, it is unknown whether and how dialects, or codas themselves, change over time. Here, we document within-coda type variation in the dialects of clans seen off the Galápagos Islands over 30 years. We assigned 10,566 codas to clans based on multivariate similarity analyses of inter-click intervals (ICIs) and used contaminated mixture modeling and principal component analysis to classify the most common codas into types. We then used general linear models to assess if the ICIs of specific coda types changed over time. We found that the Regular (1,750 codas, 5 years, 1985-1995), Short (561 codas, 4 years, 1985-2014), and Four-Plus (1,215 codas, 4 years, 1989-2014) clans exhibit within-type variation across years, but the clan with the most temporally restricted data did not (Plus-One; 788 codas, 3 years, 1985-1989). Therefore, the structure of coda types can change over time and codas also exhibit different patterns—and likely rates—of change. Changes to Regular clan codas occurred across all ICIs, while only some ICIs changed in 'irregular' clan (Short and Four-Plus) codas; this trend reflects the maintenance of codas with equal spacing between clicks within the Regular clan and the increased variation in click spacing and patterning among the two irregular clans. We suggest that these temporal changes in vocal communication stem from within-clan cultural drift, but revealing the extent to which other biological or ecological drivers are involved awaits further research.

A global analysis on the energy content of the diet of the harbour porpoise (Phocoena phocoena)

The harbour porpoise (Phocoena phocoena) is an opportunistic predator to which quantity of prey might be more important than quality. In the North Sea, prey is often small and/or of low energy content (e.g., gobies, whiting). However, harbour porpoises should probably strive to consume prey with higher energy content to maintain energy balance. In this global analysis, diet studies on stomach contents of stranded or bycaught harbor porpoises were analyzed in more detail regarding average energy contents of ingested prey. The calculated average of all these studies resulted in an energy content of 6.1 kJg-1. However, variation in energy contents in different locations was considerable. In Europe, low energy contents were found in the UK (4.9 kJ·g-1), the Netherlands (5.0 kJ·g-1) and Germany (5.0 kJ·g-1), whereas much higher values were found in the Bay of Biscay (6.3 kJg-1), Ireland (6.8 kJ·g-1) and Kattegat/Skagerrak (7.8 kJ·g-1). Studies at the east coast of the USA showed high energy contents in the Gulf of Maine (6.6 kJ·g-1) and in the Bay of Fundy (8.4 kJ·g-1). In contrast, harbour porpoises in the Salish Sea along the west coast of the USA, took mostly lean blackfin sculpin (Malacocottus kincaidi), resulting in an energy content of only 4.2 kJ·g-1. There is a lack of knowledge on the relationship between diet and fitness of harbour porpoises. Therefore, further monitoring studies that relate prey quality to harbour porpoise vital rates, such as calving rates, age at first fecundity and survival would be recommended.

Protecting the critically endangered vaquita porpoise: Update on illegal net removal efforts.

ABSTRACT

The vaquita porpoise (Phocoena sinus) is the most endangered marine mammal in the world. This cetacean is endemic to the Mexican region of the Upper Gulf of California, and its population estimated to be at less than 22 individuals. Accidental entanglement in illegal gillnets used to capture totoaba bass (Totoaba macdonaldi) fueled by a lucrative illegal trade for their swim bladders, is the leading cause of mortality for vaquitas.

Despite a ban on the use of gillnets placed by the Government of Mexico in 2015 and extensive enforcement efforts, illegal nets continue to exist within the range of the critically endangered Vaquita. Incidental by-catch mortality of other species of biological importance also occurs in the area. This includes several other species of marine mammals and endangered marine fauna.

The removal of entangling gillnets from their habitat is considered one of the most urgent and important tools for the immediate protection of this species of porpoise. Started by Sea Shepherd's Operation Milagro in collaboration with the Mexican Navy in 2015, the net retrieval efforts were expanded under the lead of the Department of the Environment (SEMARNAT) together with WWF-Mexico, Museo de la Ballena and the fisherman's organization PESCA ABC and Cooperativa Islas del Golfo. Since its formal start in 2016 more than 1100 entangling nets have been removed from the Vaquita habitat through these collaborations. Current net removal efforts are focused in the area of the Vaquita Refuge (established in 2005) where the highest density of vaquitas is estimated to occur, based in acoustic detection trends.

Linking use of ship channels by West Indian manatees (Trichechus manatus) to seasonal migration and habitat use

Most research on marine mammal occurrence in ship channels focuses on large cetaceans in offshore shipping routes, while nearshore research largely addresses small vessel strikes. Marine mammals, such as the West Indian manatee, that reside in or migrate through nearshore areas, have potential to travel through a wide range of channel types, encountering a greater diversity of vessels than previously recognized. Understanding how and when manatees use shipping channels can help evaluate risk associated with channel use, especially as manatees increasingly occupy habitats outside of their traditional Florida range. We tested the extent and conditions of ship channel use by manatees along the north-central Gulf of Mexico (nGOM) coast by combining data from satellite-tagged individuals, opportunistic citizen-sourced sightings, and environmental attributes linked to manatee movements. Manatees used both nearshore ship channels (130 and 300m wide) and open water fairways but used nearshore channels more frequently, consistent with known habitat requirements. Satellite-tagged individuals swam faster and moved more directly in all channel types, indicating use of these channels as migratory and travel corridors. Accordingly, generalized additive models revealed that manatees used channels most often during spring/early summer and fall and at temperatures coincidental with timing of typical, regional entry and exit migration. Manatees also occurred in ship channels when freshwater discharges were lower, likely because timing of peak manatee occurrence in the nGOM coincides with seasonally lower discharge. Expanded shipping activity world-wide is likely to increase interactions between marine mammals and a variety of vessel types, and these effects may be particularly impactful to migratory animals like manatees that use nearshore habitats at the interface of recreational boating and commercial shipping. By predictably linking ship channel use to migration and habitat use, our approach can aid in risk-assessment for vessel collision and other shipping related activities for migratory marine species globally.

Investigating potential gray whale individual foraging specializations within the Pacific Coast Feeding Group

Although individual niche specialization within populations has been widely documented, populations are typically managed based on the assumption that all individuals are ecologically equivalent. This approach can be problematic when

a single management strategy is not effective at protecting all individuals within a population equally due to distinct ecological patterns. We examine the presence and degree of individual foraging specialization within the Pacific Coast Feeding Group (PCFG) of gray whales feeding near Port Orford, Oregon, USA. The 264 PCFG gray whales already display a hierarchical form of foraging specialization: At a species level they are the only baleen whale to feed benthically; at a population level PCFG whales do not migrate to the Bering Sea with the other 26,000 Eastern North Pacific gray whales; at a sub-group level there is evidence of temporally and spatially restricted resource exploitation (e.g., ghost shrimp foraging in WA, USA). We tracked 96 gray whales in the nearshore habitat using a theodolite (405 hours) during the same 4 week summer period in four consecutive years (2016-2019). Behavioral classification of these tracks revealed that whales spent almost half of their time foraging (47%), while searching (28%) and travelling (15%) were less prominent. Simultaneous to data collection on whale movements, we collected zooplankton prey samples using a research kayak. Community analysis of these zooplankton samples reveal distinct spatial and temporal patterns in prey availability to whales. We link whale movement and prey data in space and time to assess individual foraging specializations of PCFG whales. With the potential resumption of the Makah tribal gray whale hunt and increased anthropogenic coastal use, increased understanding of the PCFG foraging ecology is needed. Our research will inform management decisions of this small, culturally distinct population unit by identifying resources of high importance to individuals and determining differences in their foraging.

Humpback whales in the Mariana archipelago: Local breeding habitat and links to other western north Pacific breeding and feeding grounds.

Humpback whales (*Megaptera novaeangliae*) that breed in the western North Pacific (WNP) are listed as endangered under the U.S. Endangered Species Act. Previous research in the WNP concluded that the full extent of humpback whale breeding areas is unknown. Small-boat surveys were conducted during February-March 2015-2018 off the island of Saipan in the Mariana Archipelago to collect humpback whale photos for individual identification and biopsy samples for genetic analysis. Fourteen mother-calf pairs and 27 other non-calf whales were encountered, leading to a photo-identification catalog of 43 individuals. Seven non-calves were re-sighted in multiple years, including 4 females associated with calves in one or more years. This site fidelity of reproductive females and the presence of newborn calves and competitive groups indicate that whales are using the area for breeding. Comparisons of the Mariana Archipelago humpback whale photo-identification catalog with other North Pacific humpback whale catalogs resulted in 10 matches to breeding (Japan and Philippines) and 3 matches to feeding (Russia) grounds in the WNP. DNA profiles of biopsy samples from 24 individuals (14 females, 10 males) revealed 7 mitochondrial DNA haplotypes. The mtDNA haplotype frequencies from the Mariana Archipelago showed significant differentiation from the Okinawa, Japan and Philippines breeding grounds and the greatest identity (i.e., least differentiation) with the Ogasawara, Japan, breeding ground and the Commander Islands, Russia, feeding ground. The study area off Saipan represents only a small portion (12%) of the available breeding habitat with depths <200 m (1,283 km^2) within the Mariana

Archipelago. Future surveys should include other shallow-water areas to determine how many whales are using the Mariana Archipelago and to what extent. The Mariana Archipelago should be considered as a breeding area for WNP humpback whales in ongoing research and conservation efforts for this endangered population.

Is risk-taking behaviour among dwarf minke whales learned or innate?

Inquisitive behaviours towards humans and boats have been observed in many cetacean species. Such behaviours can increase the risk of vessel strike and entanglement, and repeated interactions can result in desensitisation or habituation, which may also have indirect impacts on fitness and survival from less time spent on critical behaviours.

Dwarf minke whales (*Balaenoptera acutorostrata* subsp.) are renowned for their inquisitive behaviour. During austral winter, they regularly approach vessels and swimmers in the Great Barrier Reef, often to within a few metres, and occasionally to less than a metre. Inquisitiveness has been associated with specific life-history stages in some cetacean species, as seen in juvenile humpback whales and bottlenose dolphins. While previous research has identified several factors associated with close approaches by dwarf minke whales, such as group size and previous exposure to the stimuli, the incidence of such behaviours among demographic cohorts remains unknown.

We investigated the prevalence of close approaches by dwarf minke whales between sexes and life-history stages during 41 commercial swim-with encounters from 2017–2018. Preliminary results suggest there is no difference among sexes or size classes for close approaches; however, two individual whales were responsible for 26% of all recorded approaches closer than 3m. Similar findings have been reported for other higher-risk behaviours such as physical contact, and these patterns of occurrence suggest that the short-term desensitisation of some individuals is occurring. Our study also examines the longer-term sightings history of individual whales to assess the potential for repeat exposure over multiple years to influence risk-taking behaviour.

This detailed understanding of how anthropogenic interactions influence the risk-taking behaviour of dwarf minke whales can assist in appropriately mitigating the threats that arise from such interactions. Furthermore, this study contributes insights into the behavioural ecology of a typically elusive oceanic rorqual rarely observed outside of the Great Barrier Reef.

Using dynamic energy budget models to assess the impact of disturbance on life history and population dynamics of medium-sized cetaceans.

Hin, Vincent; Harwood, John; Roos, André M.
University of Amsterdam, Amsterdam, Netherlands
Corresponding Author: V.Hin@uva.nl

A challenge in conservation is to assess the levels of disturbance that cause significant adverse effects on wildlife populations. To address this, the Population Consequences of Disturbance (PCoD) framework provides a conceptual model that links behavioural and physiological changes in disturbed individuals to the response of the population. We use Dynamic Energy Budget (DEB) modelling to implement the PCoD framework for medium-sized cetaceans, in particular long-finned pilot whales (*Globicephala melas*). In the DEB model, life history unfolds from the balance between energy increasing processes of resource and milk feeding and energy demanding processes of lactation, gestation, metabolism and growth. With this model we assess how varying levels of disturbance affect the life history of female pilot whales, and how the impact of disturbance changes with changes in abundance and seasonal variation of their prey. Calves born to young females are most sensitive to disturbance, because young females have lower capacity to carry energy reserves, while being faced with high demands of lactation. Higher levels of disturbance also affect survival of calves born to older females, as well as degrading female survival and body condition. These results change when density-dependence operates through prey depletion by pilot whale individuals. In the density-dependent case, disturbance leads to a mortality peak among young, lactating females that have produced their first calf. However, the remaining individuals benefit from an increase in prey availability resulting from the abated top-down control. This leads to an earlier onset of reproduction, increased reproductive output later in life, and increased body condition. Although high levels of disturbance will eventually cause population to go extinct, density dependence is able to mask adverse effects of disturbance on female life history. These results call for a better understanding of density-dependent processes and advocate for caution in the management of marine mammal populations.

At-sea responses to acoustic disturbance in diving northern elephant seals: Venous blood temperature and control of perfusion.

Marine animals face environmental shifts and increased human activities in the ocean, including shipping, recreation, and seismic exploration. Disturbances may alter short-term behavior and long-term life history patterns, however many of the mechanistic details of responses remain unknown. Because the life histories of marine mammals such as seals rely on their diving abilities, physiological specializations to diving will likely define the scope of underwater response to a disturbance stressor. To characterize physiological responses and their role in buffering impacts of disturbances, we measured an integrated set of cardiovascular and activity metrics in translocated northern elephant seals exposed to experimental acoustic disturbances at-sea. Blood temperature within the extradural vein was continuously logged using an indwelling thermistor. When exposed to an experimental noise disturbance on the ascent phase of a deep dive, juvenile elephant seals exhibited an immediate dive inversion, resuming their descent. This response was accompanied by a rapid decline in venous blood temperature, which reached 31°C in the deepest and longest duration dive inversion. Declines in venous blood temperature have been previously associated with extended diving in this species. Therefore, this physiological response to disturbance may reflect either: an indirect outcome of extended dive durations following the dive inversion or; an intensification of the dive response after disturbance. The rapid decline in blood temperature suggests a short-term change in the dive response. Altered perfusion patterns, such as reduction of muscle blood flow or use of arterio-venous shunts in the flippers, would explain rapid blood temperature declines. In particular, reduced perfusion to working muscle could reduce blood temperature, as well as limit muscle oxygen uptake, and may be a key factor in fine-tuning the dive response after a disturbance. Integrated assessments that include muscle oxygenation will be a next step in advancing our mechanistic understanding of perfusion control in disturbed diving.

A spatial bycatch risk assessment for dugongs in northwestern Sri Lanka.

Marine mammal bycatch, a major threat to sustainable populations, poses a particular challenge in developing countries. Data to document bycatch and the effects of bycatch are often lacking. We have created a spatial and temporal risk bycatch risk assessment (ByRA) toolbox that makes use of existing data and creates a framework for data acquisition that provides local practitioners and scientists the tools they need to evaluate bycatch risk. ByRA calculates areas of bycatch risk based on the presence or absence of management strategies, the intensity of fishing activity by gear type, and an estimate of the spatial likelihood of interaction between fisheries and species. Our objective was to apply the ByRA toolbox to assess the spatial exposure of dugongs to incidental bycatch in the blue swimming crab (*Portunus pelagicus*) fishery in Palk Bay and the Gulf of Mannar in northwestern Sri Lanka. We traveled to Sri Lanka to meet with agency experts and local scientists. In Palk Bay and the Gulf of Mannar, we met with community leaders and traveled to fishing villages, mapping net use and fishing areas. From observations and conversations, we concluded that the exposure of dugongs to the crab nets is low, due to the placement and configuration of the nets. However, shark/ray nets commonly used by villagers, and illegal commercial trawling close to coasts are risky to dugongs, and also have a highly unsustainable bycatch of marine turtles. ByRA outputs show that the risk of bycatch is most directly associated with areas of fishing occurrence. For the dugong, most of this risk is in the Gulf of Mannar, in areas with illegal trawlers and shark/ray nets. As uncertainty is quite high in this analysis, we caution that risk could be generalized and overestimated. There is a critical need for formal surveys in this area.

First evidence of fish in the diet of long-finned pilot whales (Globicephala melas edwardii) In New Zealand waters

Knowledge of foraging ecology is important to identify overlap – and therefore potential interactions – between cetaceans and commercial fisheries. However, despite the high frequency of long-finned pilot whale (LFPW; *Globicephala melas edwardii*) strandings on the New Zealand coast, their diet remains poorly understood. To assess LFPW diet and how it may relate to commercial fisheries within New Zealand, we (1) examined stomach contents from a mass-stranding event on Farewell Spit in February 2014 (n=39), and (2) compared these to previously reported data from mass-stranding events that occurred in the same location in 2005 (n=10) and 2008 (n=11). Multivariate analyses were applied to determine temporal and sex differences in the number and size of hard part remains recovered from stomachs during post-mortem sampling. Prey items were evident in 87% (n=34) of individuals examined from the 2014 stranding event (20 females and 14 males). Five individuals (1 female and 4 males) were recorded with empty stomachs. Prey primarily comprised cephalopod remains (542 lower and 476 upper beaks), with the lower beaks belonging exclusively to arrow squid *Nototodarus* spp. Fish remains were reported in the stomachs of four males – representing the first report of fish in the stomachs of LFPWs from New Zealand waters. Although no temporal difference was evident, significantly higher numbers of *Nototodarus* beaks were recorded in the stomachs of stranded females compared to males across all years (2005, 2008 and 2014). Differences in diet observed both between sexes and across all stranding events are discussed in the context of international studies of LFPW diet. Furthermore, first evidence of fish in the diet of LFPWs in New Zealand waters is explored along with the apparent importance of commercially fished arrow squid to the diet of LFPWs in this region.

The Greenlandic harbour porpoise – a separate ecotype?

Understanding the mechanisms that drive the gradual adaptation and divergence of unique genetic and behavioural characteristics is key in marine mammal management and conservation. In this study, we combine genetic and tracking data to examine the genetic affinity, spatial distribution and habitat use, of harbour porpoises (*Phocoena phocoena*) in West Greenland relative to neighbouring porpoise populations in Canada and Iceland.

Eighteen satellite transmitters were deployed on harbour porpoises and tracked for up to 3 years during 2013-2017 off the coast of West Greenland. Additionally, tissue samples from Canadian (n=26), Greenlandic (n=30, partly from the tagged animals) and Icelandic (n=12) porpoises were used for population genomic analysis using a panel of >1000 single nucleotide polymorphisms (SNPs)

For animals with tags transmitting a full year, the tracking data revealed remarkable long-distance oceanic movements during winter combined with strong summer site fidelity, where all animals returned to the tagging area during the August breeding season. Similarly, the genetic data provided high support for the existence of two populations consisting of 1) harbour porpoises from Canada and Iceland, 2) harbour porpoises from West Greenland alone, respectively. Similar to patterns observed in other suggested North Atlantic harbour porpoise ecotypes in e.g. the Black Sea, Iberia and Mauritania, the genetic data suggests that the Greenlandic harbour porpoises split from other populations in the Atlantic through a bottleneck or founding event about 10,000 years ago associated with the Last Glacial Maximum. We hypothesise that the unique genetic and behavioural characteristics of West Greenland porpoises results from adaptations to regional climate and environment, especially the increased extent of seasonal sea ice coverage. Our findings merit a

revision of harbour porpoise management in Greenland, including implementation of hunting quotas.

Advantages of applying Bayesian framework in the analyses of ontogenetic dietary shifts in a coastal delphinid

Ontogenetic changes in foraging ecology reflect changes in individual life history, including transition from calf, that maximise growth and survival, to adulthood that maximizes reproduction. As early post-natal survivorship and recruitment plays important role in long-term viability of populations, better understanding of early-life foraging ecology helps unravelling the population dynamics, which is especially important for threatened species/populations, such as Indo-Pacific humpback dolphins (*Sousa chinensis*) that face multitude of anthropogenic pressures. Metabolically inert dentine growth layers provide an annual life history record of individual diet, facilitating studies of ontogenetic dietary shifts. Using micro-milling, we extracted high-resolution dentine material from teeth of humpback dolphins and analysed $d^{15}N$ in all extractable dentine layers (n=441) from 38 individuals (14 males, 18 females and 6 of unknown sex) that stranded in the Pearl River Delta (PRD) between 2007 to 2018.

In the traditional approach of investigating ontogenetic shifts, polynomial functions are fitted to the obtained measurements and population-level changes are determined based on changes in the fitting function. By doing so, individual variability nested within a population-level pattern is frequently undermined. In our study, we performed a hierarchical Bayesian modelling with probabilistic programming using PyMC3 package, assessing individual variability in weaning age, with partial pooling of individual change points nested within the population-level pattern and/or within the inherent differences between sexes. Our results show that humpback dolphins in the PRD wean at the age of 2.51 years (mean), with 95% highest posterior density over the age of 2.11 to 2.92 years, with males weaning ~4 months earlier than females. Given the unusually high calf mortality reported in the past 5 years in Hong Kong, a period marked by extensive coastal construction projects across eastern PRD, our results provide new valuable insights directly applicable in assessing the population long-term viability.

Ontogenetic changes in trace element ratios track lifetime freshwater exposure in bottlenose dolphins (Tursiops truncatus).

Prolonged freshwater exposure can have harmful effects on bottlenose dolphins (*Tursiops truncatus*), ranging from skin lesions and electrolyte abnormalities to organ failure and death. Determining if a dolphin has been exposed to freshwater for prolonged periods of time can be difficult without costly and labor-intensive direct observation. We tested the feasibility of reconstructing long-term freshwater exposure in bottlenose dolphins using trace element ratios in teeth, which are comprised of annual growth layer groups (GLGs) that assimilate elements reflective of environmental conditions throughout life. Teeth were collected from dolphin carcasses that stranded along the Alabama, USA, coastline between 2011 and 2019. These years encompassed a range of precipitation and freshwater discharge in this freshwater-dominated system. Individuals from multiple size- and age-classes were analyzed using laser ablation-inductively coupled plasma-mass spectrometry (LA-ICP-MS). There were differences in elemental composition between enamel and lifetime GLGs. Ontogenetic shifts were seen in some elemental ratios (Zn:Ca, Ba:Ca, Pb:Ca) between prenatal and postnatal GLGs, including interannual variation (spikes in Ba:Ca) in postnatal GLGs consistent with seasonal freshwater inputs to the system. Zn:Ca and Ba:Ca were tightly coupled in postnatal dentin while Pb:Ca and Ba:Ca showed similar trends throughout development. These data suggest Alabama resident bottlenose dolphins experience interannual variation in environmental conditions, particularly seasonal pulses of low-salinity that are traceable using elemental ratios in teeth. These results support the potential for trace elements in teeth to be used for assessment and historical tracing of habitat variation, including freshwater and associated

contaminant exposure in bottlenose dolphins throughout their lifetime.

Skin disorders in Risso's dolphins off the west coast of the UK; A photographic assessment.
Hodgins, Nicola[1]; Eisfeld-Pierantonio, Sonja[2]

Corresponding Author: nicola.hodgins@whales.org

Risso's dolphins (*Grampus griseus*) are known for their heavily scarred appearance, which is primarily the result of social interactions with conspecifics. Scarification also results from interactions with other species of delphinid, prey species and anthropogenically induced stressors, such as fishing gear and boats. Another reason for extensive scarring on individual dolphins may be as a result of various epidermal diseases and parasites. Skin diseases have been extensively studied in various species of odontocete, however very little is known about the various cutaneous disorders affecting free-ranging Risso's dolphins. Some studies have shown that the presence, epidemiological pattern and severity of skin disorders can reflect the general health of the population being studied and provide more information as to the level of various environmental and anthropogenic stressors.

Images of individual Risso's dolphins' dorsal fins, heads and bodies taken during photo-identification surveys off the west coast of Scotland and Bardsey Island in Wales between 1997 and 2018 are being used to assess the presence and prevalence of skin disorders, including lesions and epidermal diseases. There is evidence of potential fishery related injuries and collisions with vessels. Interestingly, initial analysis has shown there to be a significant number of individuals with strange 'cow teeth' shaped scars, similar to but startingly different from, bites of the cookie cutter shark which has not been reported in UK waters although suitable habitat exists. However, lampreys are present in UK waters and a similarity with their wound pattern cannot be denied although a detailed comparison has yet to be done. We are only aware of a few similar such wounds having been documented elsewhere and are keen to understand more about the prevalence of skin patterns, lesions or wounds which might be symptomatic of disease, predator-prey interactions or human-induced trauma.

Using drones, artificial intelligence and geospatial techniques to revolutionise dugong and seagrass protection globally.

Dugongs are an effective barometer for seagrass health; monitoring dugongs facilitates the conservation of this 'Vulnerable' species and the protection of their seagrass habitat that supports the livelihoods of many coastal communities in the dugongs' range. Aerial surveys are the most efficacious method for monitoring dugongs, but traditional manned surveys are prohibitively expensive, dangerous, and require significant expertise. Only 4 of the 46 countries in the dugong's range (90% of which are least-developed or developing) have conducted regular surveys. Our collaborative global efforts, led by the UNEP/CMS Dugong MOU, to conserve dugongs and their critical habitat require user-friendly, affordable and scalable conservation tools. Drones are a cheap and safe alternative, but significant expertise are still required to develop robust survey designs, and extract, interpret and analyse data from drone images. We are developing a suite of tools to assist non-experts to conduct drone surveys. These include small-scale survey designs suited to off-the-shelf drones; and image processing software (Dugong Detector) with integrated geospatial software (OceanMapper). Dugong Detector includes manual and automated (machine learning) processing capabilities for (a) recording details about fauna sightings, (b) classifying visibility conditions experienced during the survey (sea state, turbidity and glare), and (c) classifying visible benthic flora (seagrass/algae). OceanMapper plots these data using the drone's telemetry data. The automated extraction of both sighting and environmental data from the images will produce comparable and standardised data globally. We have trained local researchers in Vanuatu and Philippines to use our tools, and will implement ongoing monitoring strategies for four other developing countries over the next four years. Each country has different levels of local expertise, knowledge of dugong status and spatial coverage requirements. We discuss these challenges, the benefits and limitations of our survey tools, and the degree to which we can ultimately make aerial surveys accessible to non-experts.

Automated seal counts using aerial images and machine learning techniques

During the breeding and moulting seasons, a predictable proportion of grey seals *Halichoerus grypus* and harbour seals *Phoca vitulina* haul out on land in the Wadden Sea. These seasonal aggregations provide excellent opportunities to make accurate population size estimates. Traditionally, hauled out seals are manually counted, either directly during aerial surveys or from images collected during the survey. In this study we provide an alternative approach, using machine learning techniques (i.e. computer vision) to identify and count seals from aerial survey images.

A Convolutional Neural Network (CNN), pretrained on a large benchmark dataset, was trained using manually annotated aerial images of seals. By using a pretrained CNN, the time to train the network was significantly reduced and training could be done on a single GPU. Resulting seal counts from the CNN were cross validated with manual counts.

The method presented in this study dramatically reduces the time required to process aerial images, while also eliminating the potential effect of observer bias. By using the same architecture and parameter values, the method can easily be employed elsewhere. This process is known as transfer learning and requires only a relatively small set of additional annotated training images and little time to (re)train the network for other regions and/or seal species.

Dig this! – acoustics of detection and localization of a buried target by a bottlenose dolphin (Tursiops aduncus)

In the wild dolphins are known to be able to detect fish buried in sand to at least 25 cm depth through echolocation. To investigate how a dolphin might do that, and what the underlying acoustics might be, we designed an experiment in which a dolphin was trained to detect and locate a hard-foam target buried in a large sand container (1.2m x 1.1m x 0.6m) that had been placed on the bottom of the pool at 3.5m depth. The dolphin was blindfolded with a set of eyecups during the experiment to ensure that only echolocation cues could be used to detect the target. The target was slowly submerged into the sand over the course of 36 sessions. Nine different locations for the target within the confines of the container were trained and tested. The dolphin was required to station vertically above the location of the buried target for three seconds to indicate that she had correctly identified the location. A planar hydrophone array of 16 hydrophones was placed above the open sand box at a distance of about 10 cm to record the signals that the dolphin emitted during the task. Ten seconds of high-frequency data (sampling rate of 500 kS/sec/channel) were recorded during each trial. As the target was placed deeper into the sand the performance of the dolphin dropped from 75 percent (buried half way) to 64 percent (fully buried). The preliminary analysis of the collected acoustics of the ongoing experiment shows what signals the dolphin emitted during the search for the buried target, how long she searched and how she adjusted her echolocation signals to the changing positions and depths of the target. In particular, the dolphin seemed to prefer lower frequency clicks as compared to a previous echolocation experiment.

Secretive sea monsters on the South African coast: Patterns of beaked whale strandings in space and time.

The beaked whales (Family Ziphiidae) are perhaps the least known taxon of mammals. Studies of their biology are made difficult by their offshore distribution, deep subsurface habitat, apparent rarity and shy behaviour. This is also true for the Southern African Subregion. We used data collected along the South African coast over the past 50 years by various stranding attendance programmes to infer aspects of their spatial and temporal distribution. Over 200 stranding incidences from nine species have been recorded since 1964. Five of these accounted for 90 % of records: *Mesoplodon densirostris*, *M.layardii*, *M.mirus*, *Ziphius cavirostris* and *M.grayi.* The remaing species were rarely recorded: *Hyperoodon planifrons, M.hectori, Berardius arnuxii* and *Indopacetus pacificus*. The spatial distribution was uneven, with half of strandings occurring within 12 % of the coastline. Six stranding hotspots were noted, all close to cities. The greatest number of incidences (15 % of all strandings) were recorded for St. Helena Bay. Inter-annual changes indicate a gradual increase in numbers of strandings to the mid 1980's, with a subsequent decline for all regions. 1984 was exceptional for strandings, primarily due to large numbers of *M.densirostris* found ashore. Strandings of two of the species, *M.densirostris* and *M.layardii*, were strongly seasonal. Biases in term of sex and age class were apparent for some species. While both spatial and temporal results are influenced by an uneven search effort, they may indicate that the various species of beaked whales have different habitat preferences and distributions in the subregion. This study indicates the value of long-term stranding datasets in assessing the biology of little known marine species.

Use of finite mixture models with stable isotopes to identify source habitat of stranded common bottlenose dolphins

Strandings are valuable indicators of fishery-cetacean interactions, particularly where observer programs are insufficient. When multiple stocks of a species are parapatric, the stock of stranded or bycaught animals may not be apparent. Five stocks of common bottlenose dolphin, two estuarine, two coastal and one offshore, occur in North Carolina, USA. To date, only the offshore morphotype is distinct. The estuarine stocks are small and are subject to fishery interactions that may exceed sustainable levels. Thus, at least being able to differentiate estuarine from coastal stocks is critical. Characteristic patterns of stable isotopes of carbon, nitrogen, and sulfur have the potential to predict the source habitat— estuary, coast, or offshore—of stranded dolphins. Using stable isotope measurements from skin of dolphins, we developed a finite mixture model in a Bayesian framework to classify individuals according to their source habitat. Classification accuracy was evaluated using a training data set (n=141 biopsy samples). Results were applied to additional biopsy samples ("test" subsample) (n=292) and samples from strandings (n=462). For the test subsample, the predicted stock was consistent with likely stock, determined from the location and season of sampling, for all (n=14) offshore, 92% (n=189 of 205) of coastal, and 72% (n=53 of 74) of estuarine dolphins. For strandings (n=471), the predicted stock was consistent with location of stranding (or genetics for the offshore morphotype) for 100% (n=28) of offshore, 90% (n=346 of 386) of coastal, and 56% (n=27 of 48) of estuarine strandings. The largest discrepancies occurred for predicted estuarine dolphins found on or along the coast, which is consistent with known movements of estuarine-resident dolphins into coastal waters. Stable isotopes are a powerful approach in concert with other information for identifying the source habitats of stranded and bycaught dolphins in North Carolina.

Growing pains: How the juvenile period influences adult male social position and reproductive success within multi-level dolphin alliances.

In many animal societies, fitness is affected by social factors at various organizational levels of adult social networks. However, few studies have examined whether future fitness can be predicted from juvenile sociality. Indeed, in many gregarious mammals, juveniles are understudied, yet investment in social bonds during this critical period of social development may impact adult reproductive success. In Shark Bay, Western Australia, adult male bottlenose dolphins (*Tursiops aduncus*) form multi-level alliances within a fission-fusion society. Allied males work together to herd single estrus females and these alliance relationships are crucial for each male's reproductive success. Although alliance membership does not crystallize until after sexual maturation, these cooperative partnerships start to develop before males become sexually mature. Here, we use 30 years of data to quantify the changing structure of the social networks of 31 male bottlenose dolphins from their juvenile period through to early adulthood. We quantify how early social network centrality, and social investment (as measured with activity budgets) predict a male's future centrality within the alliance network, as well as his reproductive success (as measured via consortship rate, which is highly correlated with paternities). Our results reveal significant inter-individual differences in temporal change in ego network structure, where individual males engineer their social positions as they mature. This suggests that an individual's gregariousness is a significant determinant of allied male social network position and reproductive success. These findings highlight the importance of including immature life history periods in studies of long-lived species to reveal how early social behavior affects future fitness.

Effects of vessels and their sounds on the foraging dives of endangered fish-eating killer whales (Orcinus orca)

Anthropogenic disturbance can affect recovery of endangered marine mammals especially if disturbance affects fitness-related activities. Prey availability and vessel disturbance are identified risk factors of endangered Southern Resident killer whales (SRKW) as vessels and their sounds can mask signals used for foraging and disrupt foraging behavior with implications for energy acquisition. To investigate vessel effects, we utilized suction cup-attached digital acoustic recording tags (DTAGs) to investigate sound and movement of SRKW and measure received noise levels to correlate with concurrently-collected geo-referenced vessel data. Previous work demonstrates that SRKW prey capture dives are kinematically distinct and detected with high accuracy when validated with whale acoustic data and predation observations. Here, using kinematic signatures of prey capture, we tested the probability of prey capture for all dives to depth of SRKW preferred prey (>/= 30 m) against a number of covariates including echosounder presence/absence, vessel counts, vessel distance, and vessel speed. We additionally tested several received noise level metrics (mean, median, minimum and maximum for four bandwidths in dB rms) as competing covariates. Commercial echosounder (transmitted and reflected) signals were detected 34% of total deployment time, most often occurred at 50 kHz and correlated with high frequency band noise levels. We found no effect of noise level on the probability of prey capture but flow noise limited available sample size. However, the probability of prey capture decreased as median vessel speed increased, which in turn is a significant predictor of received noise levels. We also tested effects of vessel variables and noise levels on several dive parameters. Duration increased and rate of descent decreased significantly during prey capture dives when echosounder signals were received, indicating effects of prolonged effort to capture prey when vessels emitted sonar. These results inform conservation and management efforts to preserve SRKW foraging opportunities and mitigate vessel effects.

Eco-tour boat compliance to NOAA marine mammal viewing guidelines in Naples, Florida.

Knowledge of compliance to marine mammal viewing guidelines is essential to understand the interactions and potential impacts of tour operations on cetaceans. This is particularly important in areas of thriving ecotourism, as in Naples, Florida, where in March 2019 tourism contributed an estimated $3.69 million to the economy. Our study examined the compliance of Naples eco-tours operating around bottlenose dolphins (*Tursiops truncatus*) to the U.S. NOAA Marine Mammal Viewing Guidelines, and the ways in which captains' perceptions influence this compliance. Compliance was assessed via 16 observations of 8 boat-based eco-tours during March - April 2019. Captains' perceptions of their compliance to the guidelines, as well as their opinions of the guidelines, were obtained through an online questionnaire distributed after the field observations were completed. Of the twelve NOAA viewing guidelines, tour operators violated, on average, five (42%) guidelines, with two companies violating seven (58%) guidelines. All eco-tour companies (100%) violated three of the guidelines: 1) Do not view dolphins from a distance of less than 50 yards; 6) Never pursue or follow marine wildlife; and 7) If approached by a marine mammal, put your vessel's engine in neutral; allow the animal to pass and move slowly away. The guideline with the next highest rate of non-compliance (75%) was 9) Avoid excessive vessel speed or sudden changes in speed or direction, and do not maneuver a vessel in a way that may change the animal's behavior. Within this guideline, 22% of the 64 total dolphin sightings observed involved eco-tour vessels maneuvering with the intent to induce wake riding. Possible factors affecting compliance include tour educational outreach, captain perceptions and awareness of guidelines, and number of years in business.

Creation of an atlas for the assessment of skin disorders in Canary Islands atlantic spotted dolphins (Stenella frontalis)

An oceanic form of Atlantic Spotted dolphin (*Stenella frontalis*) inhabits the temperate waters off three mid-Atlantic archipelagos of the Macaronesian region (Azores, Madeira and Canary Islands). Despite scarce information about its biology and state of conservation in the area, there is evidence that the species is threatened by anthropogenic factors, especially pollution and fisheries interactions. Skin disorders can be an indicator of free-ranging cetaceans' health status and can be assessed through the analysis of good quality photographic material. We report on the assessment of skin disorders in Atlantic Spotted dolphins in the Canary Islands through photos obtained from standard procedures during boat-based cetacean surveys carried out between September 2004 and October 2014. In first step, a visual atlas was created to facilitate assignment of the observed lesion linking to their probable etiology. Dolphins were stratified into six age classes based on relative size, morphology and coloration (presence and extent of spotting). A total of 17.318 images were recorded from more than 254 sighting events of the species in the archipelago. All images fulfilling the pre-defined quality requirements such as close-up views (flanks, back, tailstock, head and dosal fin), good focus, light, resolution, allowing the identification of dermal disorders with detail were used in the analysis. Skin disorders were divided into: 1) skin lesions of possible infectious origin, 2) abnormalities in coloration and 3) nonlethal traumas of different origins. Atlantic spotted dolphins showed 16 types of dermal disorders, including tattoo skin lesions, coloration anomalies (piebald), natural (shark predation) and anthropogenic traumas (especially related to fishing interactions). The preliminary results constitute a useful tool that facilitates future research and standardization among researchers.

Simulating collision risk between marine mammals and a tidal energy device: How varying ecological and behavioural parameters impacts our conclusions.

Marine renewable energy (MRE) development has reached the stage where small-scale arrays are being installed. For tidal MRE, the potential for marine mammals and other large marine vertebrates to collide with a device, particularly the moving parts such as rotors, remains a major concern for consenting/permitting and licencing. Efforts to predict the risk have commonly used formulaic modelling, however whilst providing a solid platform for the incorporation of ecological and behavioural data, this approach is unable to incorporate complex parameters such as varying swimming angles of an animal. Here, we further develop a simulation-based 4D collision risk model first demonstrated by Schmitt et al (2017) which showed how the 3D figure-of-eight trajectory of a tidal kite could be simulated in order to assess collision with a seal-shaped object. Building on from this work, we simulate a similar scenario using gaming software but add additional ecological parameters including: angle of animal approach, swim speed and shape. We then demonstrate how outputs can be post-processed to incorporate further behavioural data such as dive profiles. The results from these simulations provide examples of how variation in the input parameters influences collision probabilities and can lead to a reduction in estimated collision risk. This demonstrates the potential for using simulated collision risk models as a foundation, on which empirical data or expert elicitation could be used to provide more informative estimates of collision risk. In developing this framework, where parameters (including device type) can be varied with relative simplicity, simulation-based collision risk models can be adapted on a case-by-case basis and could therefore provide a more tailored estimation of collision risk for each unique development. Consequently, this work and further developments to incorporate fine-scale behaviour data, such as from sonar/tags, could be of interest to consultants, industry, regulators and their statuatory advisors.

"Pacific Scan I" and "Global Scan I", towards a long-term Marine Mammal Spatial Observatory

"Pacific Scan" and "Global Scan I", launched respectively in June 2018 and February 2019, are two studies based on recent developments in artificial intelligence to automatically detect populations of endangered baleen whales in satellite imagery.

While the number of studies using satellite imagery to estimate the number of individuals of different species (polar bears, seals, right whales, etc) is increasing, recent studies typically rely on manual counts, human visual assessment, or limited automation which makes analysis a slow and tedious process. In the context of a rapidly increasing amount of spatial big data and rapid biodiversity loss this becomes a considerable impediment to the progress in knowledge which is necessary for conservation.

This presentation introduces the developments- based on a combination of deep learning, classic computer vision techniques, supercomputing and GPU computing- which allowed for fast review, limited false detections, and for a count of marine mammals which exceeded 900 individuals, both adults and calves, with a focus on Eastern Gray Whales and on the yet unknown migration route of critically endangered Western Gray Whales towards South East Asia.

"Pacific Scan" and "Global Scan I", are the first steps towards a systematic use of satellite imagery to rapidly bridge spatial knowledge gaps (migration routes, breeding grounds, etc) for endangered or data-deficient whale species (e.g. Right Whales, Blue and Fin whales, Omura's whales,...).

Interannual variation and trends in marine mammal sighting rates over 30 years (1987-2016) in the Bay of Fundy, Canada

The Gulf of Maine (GOM), one of the fastest warming bodies of water in the world, has experienced profound environmental and biological changes over the last decade. As waters warm, marine mammals are predicted to shift their ranges. The objective of this study was to describe observed changes in marine mammal sighting rates in the Bay of Fundy, an important and highly dynamic habitat in the northern GOM and a seasonally important feeding ground for endangered North Atlantic right whales. Our analysis leverages 30 years of vessel-based surveys conducted by the New England Aquarium—with consistent data collection protocols and observation platform across all years. We analyzed annual sighting rates for all marine mammal species observed in August and September from 1987–2016. Our analysis revealed increased sighting rates of humpback whales, minke whales, gray seals, and harbor seals; and decreased sighting rates of right whales. Sighting rates for the planktivorous right whale were negatively correlated with those of the piscivorous minke whale, humpback whale, and gray seal ($p<0.05$). Sighting rates of minke whales, fin whales, and harbor porpoise were all positively correlated with each other ($p<0.05$). Grey and harbor seal sighting rates had the strongest pairwise correlation out of all species tested ($r= 0.67$, $p<0.05$). These changes in sighting rates coincide with warming waters and are likely due to shifting prey resources. Our results provide insights into how marine mammals have responded to rapid climate change and highlight the importance of consistent monitoring efforts. By assessing these trends, we hope to better understand the changes in marine mammal use of the Bay of Fundy in the context of the larger Northwest Atlantic climate narrative, which in turn will help inform long-term resource management and conservation efforts.

Participatory science and directed survey methods: A case study with delphinids in the Maui Nui region of the Hawaiian Islands.

Howe, Marian[1]; Lammers, Marc[2]; Baird, Robin[3]

Corresponding Author: merra.howe@gmail.com

Given the difficulties and costs often associated with surveying cetaceans, enlisting members of the public to collect data offers a promising alternative approach with proper project design and implementation. Furthermore, comparison of cetacean "participatory science" (aka citizen science) data with data collected during traditional scientific studies helps reveal strengths and weaknesses of a participatory science approach and may also improve the robustness of the results. With a large number of vessel operators on the water throughout the year, including dolphin-oriented tour boats, the Hawaiian Islands offer an ideal study site to employ such a dual-method comparison to enhance understanding of nearshore Hawaiian dolphin distributions relative to bathymetry. This study recruited tour and fishing vessel operators using the shallow Maui Nui basin of the Hawaiian Islands to report delphinid sightings. In addition, researchers conducted standard dolphin surveys within the same region. Water depths at locations where sightings were recorded were compared between methods for commonly-observed delphinid species. The participatory science approach was successful in generating a large sample size of sightings from five different species, and these observations occurred in similar depth ranges as those recorded during standard surveys for all species except spinner dolphins (*Stenella longirostris*) and short-finned pilot whales (*Globicephala macrorynchus*). However, both methods indicate that pilot whales occur in the deepest sectors of the study area, while common bottlenose dolphins (*Tursiops truncatus*), false killer whales (*Pseudorca crassidens*) and spinner dolphins occupy areas of shallower depths. Certain improvements are recommended for the participatory science methodology of this study, including documenting the level of effort expended by volunteers and the geographical extent of their observing effort. Ultimately, however, the findings demonstrate the potential value of participatory science and of using a multimethod approach to infer odontocete distribution trends relative to bathymetry in areas where both methods are feasible.

Predicting whale surface feeding activity due to tidal tnfluences in the Stellwagen Bank national marine sanctuary

Howes, Laura
Boston Harbor Cruises/University of Massachusetts Boston
Corresponding Author:
lhowes@bostonharborcruises.com

Predicting behaviors and distribution is a crucial aspect of understanding the ecology of species which spend the majority of their time beneath the surface. Stellwagen Bank National Marine Sanctuary (SBNMS), located in Massachusetts

Bay, is a feeding ground for numerous whale species. Understanding when surface feeding behaviors occur can help prevent fishing gear entanglements and ship strikes with whales. However, it is poorly understood how exactly whales locate their mobile prey, and so predicting when they will be at the surface is difficult. There have been few studies on tidal influences on whale feeding behavior, and none have investigated the Massachusetts Bay region. This study investigates if tidal flow influences the surface feeding patterns of baleen whales in the SBNMS. Standardized observations of surface feeding behaviors of *Megaptera novaeangliae, Balaenoptera physalus, Balaenoptera acutorostrata, Balaenoptera borealis,* and *Eubalaena glacialis* were collected from opportunistic sighting platforms via commercial whale watch vessels from March 2014 - November 2015. Tidal data was obtained from the NOAA Tides and Currents database and categorized into flows of ebb, flood, and slack. As there is no specific SBNMS tide station, Provincetown, Massachusetts station was chosen as it is the closest proximity to SBNMS. Values were tested using a chi-square goodness-of-fit test, $\alpha = 0.05$. Results show that feeding observations were not equally distributed among the three tidal flows X^2 (2, N = 1280) = 16.98, $p = 0.0002$. The highest number of feeding observations occurred during ebb tide, followed by slack tide. While this study is exploratory, it shows that tidal flow is one the many factors that can help predict whale surface feeding patterns. Determining patterns of when whales are likely to be at the surface can aid in planning of shipping routes and fishing gear placement, and ultimately help reduce injuries and mortalities.

Aerial drone photography to highlight habitat challenges of critically endangered taiwanese white dolphin

Hsu, Hsin-Ting[1]; Tsai, Chia-Yang[2]

Corresponding Author: twsousa@gmail.com

The Taiwanese white dolphin (*Sousa chinensis taiwanensis*) is Taiwan's only endemic cetacean. The population was listed as CR by the IUCN in August 2008. There are about 65 of the animals remaining, all of which reside along the coast of western Taiwan. According to a paper published in 2013 (Sloonton), a rate of death due to human causes of more than one per seven years will result in extinction.

Taiwan ended nearly forty years of martial law in 1987. With the lifting, the floodgates were opened to massive and irreversible development of the west coast such as coal and gas fired power plants, waste disposal dumps, industrial parks, petrochemical and steel plants and so on. After nearly more than thirty years of this unrelenting development Taiwan's west coast has become seriously polluted and the non human natural environment severely compromised. There is but one way to save the TWD from extinction, and that is to preserve the remaining natural habitat.

This is a video compiled from aerial drone photographed footage taken along the coast of the TWD's confirmed habitat and illustrates the current state of heavy human alteration of the sea and land. We hope this video will increase public awareness and understanding of the challenges posed by development to the survival of this population of severely endangered cetaceans having a small and very limited range. We intend to illustrate that protecting the TWD is tantamount to protecting the ocean, rivers and all the beings that rely on these habitats, as well as demonstrating the benefits that the human animal will derive.

It started with a fisher's tale: Interdisciplinary research on marine mammals, their history, and their threats in the Gulf Of Mottama, Myanmar.

Very little research has been conducted on Myanmar's coastal marine mammals, though it is probable that they, like marine mammals globally, face serious threats. Dedicated research and conservation projects, and local capacity for both, are desperately needed. At the Point B Myanmar Coastal Conservation Lab, led by young local researchers, we combined interdisciplinary research with stakeholder engagement and capacity-building for research at a never-before studied site: the Gulf of Mottama (GoM), along the central part of Myanmar's coastline. This project began in mid-2018, based on conversations with fishers alerting us to the likely presence of coastal cetaceans in the area. Local Ecological Knowledge

(LEK) interviews and boat-based surveys confirmed the presence Indo-Pacific Finless porpoises (Neophocaena phocaenoides), Irrawaddy dolphins (Orcaella brevirostris), and Indo-Pacific Humpback dolphins (Sousa chinensis). LEK interviews indicate that: there is small-scale fisheries bycatch of these species; bycaught cetaceans are often sold and consumed, for meat and medicinal purposes; their distribution has shifted and abundance declined over time; fishers generally have positive perceptions about cetaceans. This work laid a foundation for our ongoing activities, including research on population abundance and bycatch, engagement with communities through participatory research and outreach, and reporting to government entities as part of the larger, multi-sector Gulf of Mottama Project's work to link research to management. To better understand the broader context of Myanmar's coastal marine mammals, we conducted a systematic social media search for posts about marine mammal sightings and strandings, for the whole coastline. We mapped the posted marine mammal incidents to supplement the limited knowledge of marine mammal distribution and threats in the country. This project is an important example of integrating knowledge from diverse sources – from fishers' tales, to social media, to research conducted by local researchers – to fill major data gaps and guide conservation actions for Myanmar's marine mammals.

Habitat selection of Yangtze finless porpoise in the Yangtze River

Huang, Jie[1]; Zhigang, Mei[2]; Wang, Ding[1]

Corresponding Author: jhuang1990@outlook.com

Information on habitat selection of critically endangered Yangtze finless porpoise (YFP) is important for effective conservation, but this information is still poorly understood. Generalized additive models were used to assess the YFP abundance and distribution in relation to environmental factors and boat traffic in the Yangtze River. The relative abundance of YFP was conditionally dependent on low chlorophyll-a concentration, high dissolved oxygen concentration, high pH, high ORP, moderate turbidity, high fish density and low ship density(<2.5 ship/km). YFP selected the locations in the river with greater Ratio (ratio of main channel greatest width to smallest width) than area where YFP were absent. Our results indicated that the most likely reason for YFP to prefer the sections of the river with greater Ratio is the relative lower ship density in these area. Although one third of the length of distribution Range of YFP in Yangtze River were already reserves of YFP, human activities (especially boat traffic) in the reserves are still inevitable. With the economic development of the Yangtze River basin, the boat traffic is increasing rapidly. Thus, YFP abundance may decline further due to impact of increasing boat traffic. Based on our results, to design better preforming conservation measures, ship density was suggested to be controlled below 2.5 ship/km at least in the reserves of YFP.

A dynamic approach to estimate the probability of exposure of marine predators to oil exploration seismic surveys over continental shelf waters.

The ever-increasing human demand for fossil fuels has resulted in the expansion of oil exploration efforts to waters over the continental shelf. These waters are largely utilized by a complex biological community. Large baleen whales, in particular, utilize continental shelf waters as breeding and calving grounds, foraging grounds, and also as migration corridors. We developed a dynamic approach to estimate the likelihood that individuals from different populations of blue (*Balaenoptera musculus*) and humpbacks whales (*Megaptera novaeangliae*) are exposed to seismic surveys as they move over the continental shelf. Animal tracking data for the different populations were filtered and behaviors (transit and foraging) were inferred from the tracks using Hidden Markov Models. We simulated a range of conditions of exposure by having the source of noise affecting a circular area of different radii (5, 25, 50 and 100

km), moving along a gridded transect of 270 and 2,500 km^2 at a constant speed of 9 km h^{-1}, and starting the simulated surveys every week of the year. We developed a standardized index of impact (0 – low impact to 1 – high impact) determined by the cumulative foraging time that individuals are under exposure weighted by the proportion of individuals exposed to the survey. Our results showed a high variability across study sites and relatively low impact of randomly places seismic surveys (e.g. mean index of impact for 50 km radii was ca. 0.07 for both the small and large surveys), as the habitat utilization patterns of each population are highly variable, but allowed us to identify populations that are particularly susceptible to exposure from seismic surveys over shelf waters, as well as the areas where seismic surveys would have the largest impact on these species.

Assessing the seasonal foraging ecology of bowhead whales (Balaena mysticetus) using baleen thyroid hormone (T3) profiles.

Stable isotope analysis and satellite-linked dive recorders have indicated bowhead whales forage during the winter period, although the relative importance of winter foraging in their annual energy budget remains poorly understood. With growing concerns over the energetic impacts of climate-change induced shifts in prey distribution, it is becoming increasingly important to understand the foraging ecology of Arctic marine mammals. Thyroid hormone (thyroxine, T4, and triiodothyronine, T3) concentrations decrease in vertebrates experiencing a nutritional deficit, which slows metabolism and allows the organism to conserve energy. The objective of this study is to assess bowhead whale foraging ecology using T3 profiles along baleen plates, in combination with previously measured stable isotope profiles.Baleen plates were collected between 1998-2011 from 9 subsistence hunted bowhead whales across the Eastern Canadian Arctic. The plates were drilled at 2-cm increments from the base, down the entire length of the plate, with each increment representing 1-2 months of growth. T3 was extracted using methanol and measured using enzyme immunoassays. T3 concentrations ranged from 202.77-1212.52 pg/g. Autocorrelation analysis revealed no detectable periodicity for T3 and there was no correlation between T3 concentrations and stable isotope values, which did cycle seasonally. The lack of regular seasonal cycles in T3 concentrations supports year-round feeding, strengthening the hypothesis that bowhead whales do not fast during the winter. Intermittent variation in T3 concentrations could be related to short-term disruptions in feeding, potentially while traveling between foraging locations. Knowledge gained from this study will help to identify critical foraging habitat and better understand where and when caloric requirements are met.

Humpback whale mother and calf diving and vocal behaviour during the breeding season in Madagascar.

In Humpback whale, the mother-calf pair is the only stable social unit, and as in all mammal species, the social bond between the mother and her calf is very strong. Here, we investigate how this bond translates into their diving profiles, swimming and vocal behaviour. We deployed Acousonde on mothers, on calves and on both individuals during 5 successive breeding seasons in Madagascar (2013-2017). We recorded their diving activities, their accelerometry profiles as well as their vocal interactions (20 single deployments, 8 mother-calf simultaneous deployments). Simultaneous deployments showed a very high degree of synchrony, the mother initiating the dive, the calf following its mother and leaving it to breath at the surface several times during a dive. Accelerometer data showed that the swimming behaviour of calves is not as stable and well controlled than adult females. The vocal repertoire of the mother-calf pair was described and correlated with the diving profile. Such investigation allowed us to determine if these calls are emitted in a particular circumstance (surface or bottom activity, descending or ascending phase of the dive) and thus we can suggest a specific

behavioural context. On the 27 calls of the vocal repertoire we focused on 5 calls likely produced by mothers (100Hz, basses, booms, trills, and wop), and 1 call type (heek sounds) by calves. Heek sounds were produced during surface activities and mostly while descending. Basses and wops were recorded mostly during surface activities, trills during shallow dives while descending, whereas booms and 100Hz sounds were produced during diving and mostly while the ascending diving phase. Thus, these different contexts of vocal production suggest different roles or functions for these different types of social calls.

The Franciscana's phonic lips

Huggenberger, Stefan[1]; Benites Moreno, Ignacio[2]; Frainer, Guilherme[3]

In the nasal complex of toothed whales there is a valve-like structure, the Monkey Lips – Dorsal Bursae complex, which is involved in sound generation. Therefore, these lips were called phonic lips and are characterized by grooves running parallel to the general nasal air stream. These grooves on the anterior nasal passage epithelium are shimmed by the anterior dorsal bursae. This situation was found in delphinids, such as the bottlenose dolphin and the humpback dolphin, in the harbor porpoise and in physeterids. Interestingly, in the Franciscana dolphin, *Pontoporia blainvillei*, the situation is slightly different. As revealed by careful macroscopic examination of 7 heads, the position of the grooves - a series of small wrinkles oriented parallel to the air stream - representing the 'monkey lips' is more medial and slightly more distal than the position of the dorsal bursae, at at the border of the dorsal aperture of the nasofrontal air sacs. This means, the area with these characteristics (the area of the small grooves) usually called 'monkey lips' in delphinids and porpoises has a slightly different topography to the (anterior) dorsal bursa in *P. blainvillei*. Accordingly, the anterior dorsal bursae do not shim the 'monkey lips' in *P. blainvillei*. This means in turn, that the epithelial area shimmed by the anterior dorsal bursae is not characterized by grooves or wrinkles in *P. blainvillei*. Although data on the histological structures are still missing in P. blainvillei our results point to the working hypothesis that the phonic lips and the 'monkey lips' may be not homologous in this species.

Localizing and assigning whistles to individual, free-ranging dolphins using a drifting hydrophone array.

A key element in animal communication studies is the localization of vocal signals to individuals. This is often difficult to achieve for aquatic animals such as dolphins. Bottlenose dolphins (*Tursiops* spp.) communicate using frequency-modulated tonal whistles. Due to the difficulty of identifying vocalizing individuals when dolphins are not isolated, most knowledge on dolphin whistle use comes from studies with captive dolphins or temporarily restrained wild dolphins. However, the findings of such studies are not fully representative of natural behavior and allow only limited inference regarding wild populations. Previous studies on free-ranging wild dolphins have used towed hydrophone arrays with limited localization possibilities. Fixed hydrophone arrays have been used successfully, but mainly in shallow waters close to shore. Here, we propose the use of a drifting hydrophone array as a novel and accurate method of localizing whistles of free-ranging dolphins in open waters and present preliminary results on its performance. We focus on whistles of Indo-Pacific bottlenose dolphins (*T. aduncus*), a species underrepresented in studies of dolphin vocalizations.The array consisted of three hydrophones, each suspended under a free-drifting buoy and attached to an acoustic recorder within the buoy. The buoys were connected to a GPS that continuously logged their position and the recordings were synchronized acoustically. The source location of recorded whistles was then determined using pairwise differences in whistle arrival time between hydrophones. In conjunction with boat-based behavioral observations, footage from an unmanned aerial vehicle, and photo-identification using a camera equipped with a compass and inclinometer, localized whistles were then assigned to individually identified dolphins. With the ability to localize whistles and assign them to individuals, this methodology will provide us with valuable new insights on the social and behavioral context of whistle use in wild dolphins.

Mating season inferences from annual testosterone cycles in baleen of adult male

bowhead whales (Balaena mysticetus)

Baleen of mysticete whales accumulates steroid hormones as it grows, such that a single baleen plate can be used to reconstruct the individual's endocrine history over the timespan of baleen growth, 1-2 decades in bowhead whales (*Balaena mysticetus*). We analyzed testosterone and corticosterone (an adrenal stress hormone) in baleen of nine adult males from eastern Canada and Greenland to infer breeding season and frequency, and associated stress. Baleen plates of 184-314 cm length were drilled at 2 cm intervals (each interval representing ~1-2 mo), followed by extraction and assay of immunoreactive testosterone and corticosterone. Testosterone concentrations cycled along baleen of all nine males. Average periods ranged from 21 cm in the smallest whales to 14 cm in the largest whales, consistent with annual bowhead baleen growth rates and differential growth rate associated with age (slower in older individuals). Change in testosterone peak amplitude over time was significantly related to whale body length (a proxy of age), with amplitude increasing with age for smaller individuals and decreasing with age for larger individuals, a pattern suggesting influences of sexual immaturity, maturity (reproductive competition), and possible reproductive senescence. Annual testosterone peaks were strongly correlated with stable nitrogen isotope ($\delta^{15}N$) peaks in summer but with an offset of several months, consistent with elevated testosterone concentrations during spring, the purported breeding season. Corticosterone concentrations cycled synchronously with testosterone in some males, while variation was irregular in others; this pattern is consistent with known bowhead whale breeding behavior, i.e. some males are likely non-competitive while others are at peak competitiveness, such that individuals may incur differing levels of breeding-associated stress. We conclude that male bowhead whales exhibit annual testosterone cycles, and that baleen hormone analysis enables examination of reproductive seasonality, onset of sexual maturity, potential reproductive senescence, and other aspects of reproduction in male mysticetes.

Investigating an ongoing Florida manatee Unusual Mortality Event through gut microbiome metagenomics

Hunter, Maggie[1]; Iwanowicz, Deborah[2]; Givens, Carrie[3]

A dramatic reduction of seagrass due to long-term, non-toxic phytoplankton blooms in the Indian River Lagoon preceded a Florida manatee unusual mortality event (UME) in Brevard County, Florida. This UME is ongoing since 2012, and a dietary change due to little or no seagrass availability is a hypothesized contributor. To further investigate the gut microbiota and diet consumed by manatees in the area affected by the UME, a high-throughput metagenomic barcoding approach was implemented. The Illumina MiSeq next-generation platform was used to generate non-overlapping 2x300 bp paired-end DNA barcode sequences to provide comprehensive and rapid indexing of species. A targeted sequencing approach based on the bacteria 16S rRNA genes was employed to PCR amplify loci of available microbial species present in the gut. Manatee fecal material (N=20) from UME-associated animals was compared to 'control' samples (N=10) killed by boat strikes from the same area. The MiSeq runs produced millions of sequences with a minimum Phred score of 20 on trimmed reads. This represents a minimum base call accuracy of approximately 99%, providing high confidence in the quality of DNA submitted. Operational taxonomic units (OTUs), observed richness of species diversity (α-diversity), and differences between control and experimental samples (β-diversity) were assessed to determine differences in bacterial species associated with the control and UME samples. Microbiota from over 500 genera and nearly 1800 bacterial species have been identified in the gut and evidence was found for differences in the bacterial communities between the two experimental groups. Sequencing the gut microbiome can help to identify diagnostic species, such as toxic gut microbiota, and irregular community assemblages signifying a physiological change. This high-throughput approach can add to the tools used to investigate this and future UMEs in manatees.

Examining New Zealand leopard seals: The first resident population outside of Antarctica.

While leopard seals (*Hydrurga leptonyx;* LS) are mainly distributed throughout the Antarctic and subantarctic regions, some vagrants disperse northwards of the Southern Ocean, and usually comprise juvenile animals in poor body condition. To determine if this was the case for LS in New Zealand (NZ) waters, we established the New Zealand Leopard Seal Database (NZLSD), a species-specific collation of more than 2,700 specimens and sightings recorded between 1200 and 2018.Sightings date back to the 1200's and have increased over time, with peak records during the last century. LS have been reported in all seasons and regions of NZ and are predominantly comprised of adult individuals in good or excellent body condition. Juvenile LS's comprise 34% of NZ records and births have also been documented. Through the use of unique pelage patterns, we have catalogued more than 200 unique individuals. The numbers of LS sighted in NZ per annum have continued to increase over time, with the highest record being 74 in 2018. We have documented multi-year occurrence for multiple individuals, with one female showing residency in NZ waters for seven years. To understand why LS occurrence and residency continues to increase in NZ waters, we examined their diet through observing foraging behaviors and conducting and scat analysis. We processed over 100 LS scat samples and recorded the consumption of a variety prey species that included fishes, birds and other pinnipeds. One leopard seal has shown a proclivity to consume seaweed on a regular basis. Using all the data we have collated, we show that NZ's LS's are indeed resident compared to those vagrant's recorded in other regions abutting the Southern Ocean. Furthermore, considering the framework of the NZ Government's Threat Classification System, we show that LS should be reclassified from its status as 'Vagrant' to 'Resident' in NZ waters.

Variances in contour patterns of dugong chirps suggest individual signature.

Signature calls of marine mammals are useful cues to maintain group cohesion, favoring information about the sender's identity and location. These calls can be important for mothers and calves of dugongs (*Dugong dugon*) that form close cohesion during their nursing period. A previous study has shown that dugongs chirps were used to advertise the location of the sender in the context of vocal exchange (Ichikawa et al., 2011). Here we predict that identity of the sender is also embedded in the dugong chirps. In this study, vocalization contours of chirps of free ranging dugongs were classified. Frequency components of contours were fed into the X-means clustering method. The X-means clustering determines appropriate number of clusters, or k, of the k-means clustering method based on the Bayesian information criterion. Contours of 84 chirps of free ranging dugongs inhabiting the coastal water around Sibu Island, Johor, Malaysia, were classified using the X-means clustering. The chirps were classified into four different groups. Group A chirps showed up-sweep contour patterns with 33 samples, group Bs were down-sweep chirps with 27 samples, group Cs were up-down sweeps with 23 samples, and group D with only one sample. The samples from Johor were also compared with 64 chirps from anonymous dugongs in Thai waters recorded in 2008, 42 chirps from a 7-year-old captive female dugong in Underwater World Singapore, and 19 chirps from a 25-year-old captive female dugong kept in Toba aquarium. Contours of each of the chirps outside Malaysian waters were different from those recorded in Malaysia. These results support a hypothesis that dugong chirps are unique to individual or local population as suggested in Anderson and Barclay (1995). In general, the signature calls are acquired through vocal learnings by calves from their mothers. Our findings contribute to estimate social structure of wild dugong population.

The evaluation of cetacean strandings on the mediterranean coasts of Turkey between 2009 and 2019

(2) DEU Institute of Marine Sciences and Technology, Balcova, Turkey
Corresponding Author: ilkilinccansu@gmail.com

Although some studies exist about the cetacean strandings on the coasts of Turkey, there are still no

systematic stranding network system for cetaceans in the Turkish Mediterranean. In this study, the cetacean stranding cases that were occurred were assessed according to the parameters such as the number of individuals, species, geographical distribution and the status of case interventions on the Mediterranean coasts of Turkey. The data were obtained based on existing images, reported or validated cases were collected from television and newspaper news, web sites, related dissertations and published articles between 2009 and 2019. 89.5% (N=114) of the stranded individuals belong to dolphins, 9.6% to whales and 0.9% to porpoises. The percentages of the stranded species' individuals are as follows; fin whale (*Balaenoptera physalus*) 0.9%, minke whale *(Balaenoptera acutorostrata)* 0.9%, sperm whale (*Physeter macrocephalus*) 0.9%, beaked whale (Ziphiidae) 0.9%, Cuvier's beaked whale (*Ziphius cavirostris*) 4.4%, *Mesoplodon sp.* 0.9%, bottlenose dolphin (*Tursiops truncatus*) 21.1%, striped dolphin (*Stenella coeruleoalba*) 25.4%, short-beaked common dolphin (*Delphinus delphis*) 8.8%, Risso's dolphin (*Grampus griseus*) 1.8%, harbour porpoise (*Phocoena phocoena*) 0.9% and unidentified specimens 33.3%.

According to the IUCN Red List, the identified individuals' conservation status are as follows; 9.5% DD (Data Deficient), 1.4% LC (Least Concern), 72.9% VU (Vulnerable), 16.2% EN (Endangered). Of the stranding cases occured, 8.8% were alive stranding cases. Necropsies were performed for only 17.5% of the carcasses. While 75% stranded indiviuals' causes of death are unknown, 17% died due to disease (infection, parasite, etc.), deliberate killing, drowning (fishing nets), trauma (internal bleeding) etc., 9% are uncertain. It is thought that the obtained data were below actual figures since there was no functioning stranding network for Turkish Mediterranean coasts. Therefore; a stranding network from where continuous monitoring data to be gathered, and necessary first aid were given to ailing animals should be operational.

Estimation of relationship between density surface of humpback whales and environmental factors in the north Pacific ocean using IWC-POWER data

Inai, Kanako; Kitakado, Toshihide; Matsuoka, Koji
Tokyo University of Marine Science and Technology, Tokyo, Japan
Corresponding Author: m187001@edu.kaiyodai.ac.jp

A new cetacean research programme in the North Pacific Ocean, the Pacific Ocean Whaling and Ecosystem Research coordinated by the IWC (IWC-POWER), started in 2010. Although the ultimate objective of this programme is to provide information on the status of populations of large whales found in North Pacific Waters, knowing the current levels of population is a crucial element of this goal. Among several species, we targeted the humpback whales, which population size was decreased globally once and has been recovered rapidly.

To understand the population size, design-based methods with a line transect survey have been used. Recently, development of model-based methods using information on environmental factors contributing to inferring the distribution and abundance are one of active areas of research. In addition to possible improvement of precision of abundance estimation, outcomes of the approach can contribute to spatial conservation and management. In this study, to examine the environmental factors influencing on the spatial density distribution of the North Pacific humpback whale, the IWC-POWER sighting data were used. The detection function and effective strip half width were estimated by considering wind speed, survey year and cue as covariates. The spatial density distribution was predicted using the generalized additive model (GAM) with location and environmental variable such as the sea surface temperature (SST).

As a result, although different models were selected by different criteria (AIC and deviance explained), the predicted density distribution and abundance estimates were quite similar, which means the results is robust. It is also suggested that the distribution of humpback whales is explained by SST and the ocean depth. The same approach can be applied to other species in the North Pacific, and the integration of analyses may allow us to investigate habitat preferences with link of environmental variables.

Cetacean vertebral trabecular bone mechanical properties and structure among swimming styles and diving behaviors

Ingle, Danielle; Porter, Marianne
Florida Atlantic University, Boca Raton, FL
Corresponding Author: dingle2014@fau.edu

Among cetaceans, interspecific variation in vertebral bone contributes to axial body displacement and skeletal loading during swimming. Previous research on terrestrial mammals has detected links between bone mechanical behavior and architecture, and we expect similar findings in caudal oscillating cetaceans. We quantified trabecular bone mechanical properties (yield strength,

stiffness, and toughness) and structure (bone volume fraction, trabecular thickness, and trabecular number) among cetacean functional groups and regions of the vertebral column. We categorized ten species of cetaceans (Families Delphindae and Kogiidae) into functional groups determined by swimming style (rigid vs. flexible) and diving behavior (shallow vs. deep). We hypothesized that the greatest differences will be observed in shallow-diving species which have rigid torsos, habitually overcome surface drag and wave turbulence, and are associated with enhanced swimming speeds. Vertebrae were dissected from four regions of the vertebral column (thoracic, lumbar, and two caudal) and micro-computed tomography (μCT) scanned at 25-35 μm. Bone volume fraction, trabecular thickness, and trabecular number are being calculated from regions of interest within vertebral bodies. Six mm^3 cubes were then cut from vertebrae and compression tested in three orientations at 2mm/min using an Instron dynamic testing instrument. Stiffness, yield strength, and toughness were calculated from stress-strain curves. We found that rigid-bodied, shallow-diving cetaceans (delphinids) mechanical properties different than those from flexible, deep-diving animals (kogids), while animals with rigid bodies that habitually dive deep (delphinids) were intermediate between the two. These data may indicate that in addition to whole body rigidity, animals that navigate forces at the water's surface have increased skeletal loading during active swimming compared with those that incorporate prolonged glides during deep dives. We seek to understand skeletal mechanics and the bone form-function relationship in fully submerged aquatic mammals, whose bodies are supported by buoyant forces in the water column.

Integrating accelerometer and environmental data into state-space models to investigate harbour seal foraging

Biologging offers important insights into marine mammal underwater behaviour. Spatial movement data and dive depth profiles can be used to identify animal's behavioural states. However, coastal species such as harbour seals consistently make square-shaped bottom dives, making it difficult to characterise core foraging areas or periods of foraging activity.

This study aimed to 1) combine movement and accelerometer data to improve classification of harbour seal at-sea behaviour and 2) assess how spatio-temporal variation in static and dynamic environmental variables influenced their foraging activity.

We used data from two complete foraging trips from each of five adult harbour seals that were tagged with GPS-GSM tags in the Moray Firth, Scotland in 2017. Shed tags were recovered after the moult, providing archived accelerometer data and fine-scale dive profiles. Hidden Markov Models (HMM) were used to classify behavioural states from GPS data, and dive activity parameters and environmental variables were used as covariates. Dive activity parameters were obtained from the accelerometer data, and a water column stratification index was calculated from the temperature data collected by the tag.

Based on GPS movement data alone, the HMM identified three behavioural states: transit, searching and foraging. Several dive parameters derived from accelerometer data (e.g., angles of descent and ascent, prey capture attempts and cumulative mean dynamic acceleration) where found to be in close correspondence to the behavioural states defined by the HMM. These findings were then incorporated into more complex HMM that included both dive metrics and tag-derived environmental covariates. These results provide new insights into the role of static and dynamic environmental variables in shaping harbour seal foraging patterns. Furthermore, they highlight how vast amounts of accelerometer data can be summarised to facilitate data-transmission and how such fine-scale movement and dive summary data can be integrated into location-based movement models.

A Synopsis of Hawaiian humpback whale movements, including migration routes to foraging destinations, from satellite-monitored tracking between 1995 and 2018.

Humpback whales wintering in Hawaii were satellite-tagged between 1995 and 2018 to study movements, migration characteristics, and dive behavior (duration, depth, and lunges/dive) for up to 160 d. Whales used the Maui Nui region and Penguin Bank extensively, and moved between islands. Mean residence time in Hawaii from tagging to departure was 12.3 d. Migratory destinations included northern British Columbia/Southeast Alaska (5) and eastern Aleutian Islands (4), two of which continued to Kamchatka Peninsula and one continued to the Gulf of Anadyr. Incomplete migration trajectories reinforce the importance of Aleutian Islands and Bering Sea as possible destinations. Two humpbacks tagged 19 years apart extensively used an area ~160 km south of Unimak Pass, suggesting this as important feeding habitat. The north and west coasts of Haida Gwaii, British Columbia, were also high-use foraging areas. Tagged whale ID photos submitted to Happywhale identified resights from Washington, Oregon, and Vancouver Island. Photographs of two tagged whales near Vancouver Island documented expected tag-wound healing. In 2018, tags summarized 61% of dives. Breeding ground dives were generally <100 m, occasionally reaching 400 m. Migration dives were similar, except whales made longer (>15 min) and deeper (>200 m) dives at night during the first 7-14 d. The purpose of such dives is unclear, but may be related to acoustic orientation or magnetic navigation. One whale foraging near the Aleutians had diel differences in dive duration and depth, while whales near Haida Gwaii did not. This study revealed new and complex migratory linkages to high-latitude feeding areas. Tagging was concentrated around the Maui Nui region, but additional sampling at other islands and during different parts of the reproductive season would help us understand how whales from different feeding areas throughout the North Pacific may vary in their timing and geographic use of the islands.

Cetacean bycatch intensity in Bangladesh southeastern and south central coastal marine water.

Islam, Mohammad
Cetacean Research & Conservation Program(CRCP),Marinelife Alliance, Bangladesh, Bangladesh
Corresponding Author: marinelife.al@gmail.com

We have been monitoring cetacean bycatch along the southeast coast and south central coast as part of our marine megafauna program in Bangladesh for the last 22 years. Bycatch study includes flagship species viz., sea turtle, all cetaceans, whale sharks. Small to large cetaceans have been recorded along the coast of Cox Bazar, Chittagong, Bhola and Patuakhali coast. Data were collected by offshore marine survey, stranding record, dead washed specimen, live observation, data from offshore fishermen, citizen science and marine megafauna bycatch information. 3151 Artisanal marine fishing boast have so far been investigated during the long 2 decades of years. Habitat diversity included estuary, rivers, coastal channels, intertidal flats, mangrove canals, offshore area etc. The diversity of the cetacean species is the least. The region is a very important trans-boundery habitat with Myanmar marine territory. The recorded species include Indopacific humpback dolphin (Sousa chinensis), Indo-Pacific bottlenose dolphin (Tursiops aduncus), Irrawaddy dolphin (Orcaella brevirostris), Risso's dolphin (Grampus griseus), Spinner dolphin (Stenella longirostris) and Finless porpoise (Neophocaena phocaenoides). The habitat loss mostly happened due to indiscriminate construction of dam for shrimp farming, use of estuarine and marine set bag nets (ESBN and MSBN) as well as fishing gears setting across waterways those entirely blocks cetacean movement especially in Naf river, Moheskhali channel, canals of Sonadia-Moheskhali mangrove. Indo-pacific Humpback and Irrawaddy dolphins have been observed very close to coast at Matarbari, Kutubdia, Haserchar, Sonadia and in several other spots along the Teknaf peninsular coast. Interactions with nearshore fishing activity was observed common along Sonadia west coast, near Reju canal and Naf estuary. Alarming number of dead washed individuals due to bycatch during fishing were recorded every year. Major threats observed; gears across rivers/canals, entanglement in fishing gears in offshore fishing activities, indiscriminate movement of vessel through dolphin habitat.Each of the MSBN has the bycatch record.

Marine mammal biodiversity in Oaxaca analysed through the mitochondrial genetic characterisation of strandings and eDNA.

Strandings of marine mammals can bring a reliable estimation of the biodiversity of this group in a given region. The state of Oaxaca in the Mexican Pacific ranks first in Mexico in biodiversity of terrestrial taxa but little is known about the marine environment. Paradoxically Oaxaca is one of the poorest regions in Mexico which makes it very difficult to obtain funds for dedicated surveys of marine mammals. The most recent study reveals that there are 21 species contained in 5 families present in the region but it is not known if these are resident or pelagic populations. Through the analysis of mitochondrial genetic sequences we can determine or confirm the species present in the area, along with information of the lineages inhabiting these coasts, their genetic variability and their connectivity to neighbouring populations as well as the tempo of their regional appearance. Environmental DNA (eDNA) is a non-invasive technique ideal for biomonitoring that has become an accurate source of species presence information in a given area, but this information is more reliable if there is a reference library of sequences from the taxa that could be detected. We aim to match and compare the information of species richness and its genetic variability obtained using eDNA from sediments and high-throughput sequencing, to the one obtained by strandings. Partial sequences of the mitochondrial control region and COI gene obtained with Sanger sequencing were analysed for a total of 25 individual strandings and compared to the data obtained from a total of 24 samples of eDNA in several localities along the central coast of Oaxaca. These results will provide a reliable and quick tool for monitoring marine mammals in an area where conventional surveys are difficult to carry out.

Sperm whale foraging behaviour during pulsed and continuous navy sonar exposures

Anthropogenic noise sources range from intermittent to continuous, with seismic and navy sonar technology developing applications with more continuous transmission schemes. Continuous active sonar (CAS) may be used at a lower source level than traditional pulsed active sonar (PAS), but with potential for greater cumulative exposure over time and increased auditory masking concern. We conducted at-sea experiments to contrast the relative effects of navy PAS vs. CAS on sperm whale behaviour using animal-attached sound and movement-recording tags (n=16 individuals) in Norway. Changes in foraging effort and proxies for foraging success and cost during sonar exposures were assessed while accounting for baseline variation (individual effects, time of day, bathymetry, blackfish [killer whale or pilot whale] presence) in generalised additive mixed models. We found no reduction in time spent foraging during exposures to medium-level PAS (MPAS) transmitted at the same source sound pressure level (SPL) as CAS. In contrast, time spent in a non-foraging active behaviour state increased by a factor of 2.4 and 3.3 during CAS and higher source level PAS (HPAS) (Wald test, $F=9.9\text{-}19.8$, $p<0.003$) at similar received sound exposure levels (SEL; squared pressure integrated over signal duration), providing clear support for received SEL over SPL as the response predictor. The responses were relatively short in duration and less than 8% of the individual-average time budget was affected. On-going analysis of acoustic indicators of prey search (clicking depth, inter-click intervals) and prey capture attempts (buzz click rates, duration) will test for changes in echolocation behaviour that may indicate responses to auditory masking. The importance of exposure context including the potential impact of presence of blackfish is discussed. Our results highlight the benefit of using SEL to account for noise sources with different signal duration and/or duty cycle, and the need to consider masking effects for more continuous sources.

Distribution of Pacific white-sided dolphin and Dall's porpoise in the western coast of

Hokkaido, Japan.

We compared the environment of distribution area of two small cetaceans, Pacific white-sided dolphin (*Lagenorhynchus obliquidens*) and Dall's porpoise (*Phocoenoides dalli*) which are distributed in sympatric area. We used the sighting data conducted in the western coast of Hokkaido, northern Japan, onboard Research Vessel *Hokko maru* in May of 2015-2016, when two species move northward to the Okhotsk Sea. We compared the environmental factors (water depth, slope, sea surface temperature (SST) and distance from shoreline) of each cetacean's position at 4km grid resolution. For estimate of spatial niche overlap, niche similarity index (Schoner's D) was calculated by Software ENM tools. During the whole survey period, 24 and 114 schools of Pacific white-sided dolphins and Dall's porpoises were observed, respectively. Pacific white-sided dolphins were observed in the southwestern coast of Hokkaido with warmer SST (above 10℃), whereas Dall's porpoises were observed in the northwestern coast with colder SST (7.5-12.5℃). Pacific white-sided dolphins were observed closer to land (range = 2-30 km, median = 10km) than Dall's porpoises (range = 1-120 km, median = 55km). Pacific white-sided dolphins are considered to move to north later and prefer warmer area than Dall's porpoises. In addition, Dall's porpoises were not observed in the northern inshore area even when Pacific white-sided dolphins were not distributed. These differences could result in the low spatial niche overlap (D: 0.32). In the previous study conducted in the eastern coast of Hokkaido in fall, when two species finished to move north, lower spatial niche overlap was also observed. It might be caused by the difference in their feeding habit, that is, Dall's porpoise prefer offshore and deeper area because they commonly feed on mesopelagic fish, not to avoid pacific white-sided dolphins spatially.

Growls and downsweeps: Foraging ground vocalisations of blue whales.

Blue whales are known to use vocalisations for social communication in the breeding grounds. Few studies have reported blue whale vocalisations from foraging grounds, therefore the role of these vocalisations is as yet unknown. In this study, we investigate vocalisations of blue whales in their foraging grounds in Skj*á*lfandi Bay, Iceland. Acoustic and behavioural data loggers were attached to the back of whales using a suction cup. 59 hours of acoustic and behavioural data were obtained, including 1141 deep dives. A deep dive was defined when animals dove more than 10 metres and the dive started from a depth of 1 metre. Maximum, minimum and average dive depths were 131, 18, and 48 metres, respectively. Behavioural data were categorized as foraging, travelling, and resting referring depth and acceleration/compass profiles. Whales emitted two types of sounds: growls and downsweeps. Growls showed broadband frequency structure without any clear frequency peak. Growls were emitted at around 10 metres depth, at the beginning and end phases of foraging dives at random. Blue whales may experience rapid air volume change in their body because double or half of ambient pressure shifting between the surface and the depth at 10 metres. Downsweeps from 100 to 40 Hz were detected during travelling and resting immediately before or after consecutive foraging dives. Previous studies reported similar characteristics of blue whale downsweeps in other areas suggested the function of downsweep sounds is likely related to social interaction. This study suggests that downsweeps may also function as a contact call.

Population status and habitat use of a critically endangered ringed seal population in the Gulf of Finland, the Baltic Sea.

As Europe's inland sea, the Baltic is subject to intense anthropogenic pressure, and the Gulf of Finland is the most affected by human activity. Since the second half of the 1990s the Eastern Gulf of Finland coast has undergone extensive development including the construction of sea freight terminals which increase shipping traffic and lead to decrease of undisturbed natural habitats. The Gulf is inhabited by a population of Baltic Ringed seals (*Pusa hispida botnica*). The population has decreased from estimated 3000 in 1970ies to some hundreds in modern times and the historic continuous distribution has shrunk to the easternmost parts of the sea area. Initially, the decline in numbers was attributed to environmental pollution and unsustainable seal hunting, but the population collapse occurred after a total ban of hunting was introduced in all coastal countries in 1980. Mass mortality of adult seals occurred in 1991, the cause was not established. We carried out aerial census of ringed seals on spring ice in 2018 which resulted the haul-out population estimate of only 113 seals in the sea area. Nineteen ringed seals have been marked with telemetry tags between 1999 and 2018. The sea use patterns in ice free period show decrease of range over time and confinement of distribution to an island-reef system in the eastern part of the gulf. Ice formations at the northeast coast are used for breeding. None of the marked animals left the Gulf, neither any of ringed seals marked in other sub-populations of the Baltic ringed seals have entered the area. The current core habitats are affected by lack of ice due to climate change, exposed to increasing shipping and other anthropogenic disturbance. We find that the isolated population is critically endangered. Dedicated study of health and reproduction success are urgently needed to detect the factors behind the population collapse. IUCN status of the Baltic subspecies, currently 'Least Concern', needs revision.

The active space of sperm whale codas: Inter-click information for intra-unit communication.

Sperm whales (*Physeter macrocephalus*) are a cosmopolitan species with a multileveled social system in which stable matrilineal 'units' often associate with other units within a larger vocal clan. Clan members share a distinctive repertoire of 'coda types', which are defined by a specific and consistent temporal spacing of multi-pulsed clicks. Multiple interpretations of the function of coda communication exist in the literature in which researchers have hypothesized that codas communicate membership in socially segregated sympatric clans, while also proposing that codas are primarily used for social cohesion within a unit. Here, we test these hypotheses by combining measures of ambient noise levels and coda click source parameters to estimate the active space of sperm whale communication. If a coda's active space is closer to the acoustic footprint of an individual unit, it is likely that codas are used primarily for communication within a unit, whereas if the active space is much larger than the footprint of a unit, it is likely codas are also used for radiating clan identify across units. We measured source parameters of coda clicks from female sperm whales off the coast of Dominica by acoustically localizing clicks with a five-element 80-meter vertical hydrophone array. We calculated the source levels of 1598 clicks from 444 codas to be 173 ± 10 dB re 1µPa, making these sounds among the loudest communication sounds in toothed whales. However, together with measured ambient noise levels and modelled sound propagation, these source levels lead to a median active space of 3.8 km (IQR 1.7 to 6.9 km), which likely reflects the footprint of a single foraging sperm whale unit. We conclude that while sperm whale codas may contain information about clan affiliation, their active space, measured here for the first time, suggests codas likely mediate social cohesion via intra-unit communication.

Quantifying the response of Blainville's beaked whales to Naval sonar exercises in Hawaii

Naval use of mid-frequency active (MFA) sonar has been associated with injury and death of multiple species of marine mammals. Deep-diving beaked whales (family Ziphiidae) are particularly susceptible to naval sonar. The US Navy operates multiple training and testing facilities where MFA sonar is used regularly, and where cumulative sublethal impacts of exposure to MFA sonar could have negative effects on beaked whale populations. The goal of this project is to quantify the response of Blainville's beaked whales *(Mesoplodon densirostris)* to sonar on the Pacific Missile Range Facility (PMRF) in Hawaii. One indicator of a behavioral response is reduced foraging activity. In the present study, we use data on Blainville's beaked whale dive starts, which are indicative of foraging activity, collected at 62 bottom-mounted hydrophones before and during six Naval sonar exercises. We fit multiple generalized additive models to dive count data collected before and during each exercise using different combinations of covariates and used the best-fitting model to compare the expected baseline dive counts to dive counts observed during the sonar exercises. We found that the average probability of a dive start decreased by half during general Naval training activity on the range and two thirds when MFA sonar was active as compared to the pre-exercise baseline levels when no Navy ships were present. This suggests that animals are responding to Naval activity other than MFA sonar, potentially because they are habituated to the combination of Naval activity and MFA sonar. To investigate this further, we use information on the intensity of low, mid, and high-frequency sound prior to the onset of MFA sonar to identify the noise components associated with reduced foraging activity. In future, we will expand this analysis to include other US Navy ranges where MFA sonar exercises are conducted.

Bottlenose dolphins (Tursiops truncatus) in the Potomac River and Chesapeake Bay, USA

In the late 1800s, bottlenose dolphins swam not far from where the Lincoln Memorial now stands in Washington, DC. Were they always there? The ecology of the Chesapeake Bay has been heavily studied, but little is known about one of its top predators, the common bottlenose dolphin. To fill this data gap, the Potomac-Chesapeake Dolphin Project launched a study of bottlenose dolphin behavior and population dynamics in the Potomac River and Chesapeake Bay area in 2015. Between July 2015 and October 2018, over 500 individuals were identified within a 37km sq. area with a resight rate of 26%. The linear increase in the number of unique individuals sighted after coding for quality, suggests that many more unique individuals remain to be identified. Although dolphins have been sighted every month between April to October, the mean number of sightings per km of search effort peaks during June (2), July (3.5), and August (3.6), corresponding to peak water temperatures. Group sizes per sighting range from 1 to 163 (n=115) with a mean of 18 animals ($\pm$27 SD). Most groups were observed traveling (67%, n=112), followed by foraging (19%), socializing (11%), and resting (2%). Socializing behaviors, such as mounting, as well as the number of mother-calf pairs (105), including neonates (31) and young of the year calves (33), suggest that the Chesapeake Bay is an important breeding area. Calves have been observed in infant position across multiple years with the longest dependencies extending beyond three years. Dolphins sighted in the Potomac-Chesapeake have been sighted off New Jersey, Virginia Beach, and North Carolina based on contributions to the Mid-Atlantic Bottlenose Dolphin Catalog. Given these matches and the presence of bioindicators (i.e. *Xenobalanus globicipitis*), the animals sighted in the Potomac-Chesapeake likely belong to the Northern North Carolina Estuarine and the Northern Migratory Stocks.

Decreasing whale entanglements in pot and trap fishing gear in Central California.

Jahncke, Jaime[1]; Rockwood, R. Cotton[2]; Ingman, Kaytlin[3]; Hines, Ellen; Nur, Nadav[4]

Whale entanglements in fishing gear are the leading cause of mortality for humpback whales and the second for blue whales off the U.S. West Coast. Whale entanglements have increased from <10 in 2002-12 to >70 in 2016, and most

entanglements occur in crab fishing gear. We examined seasonal and spatial co-occurrence between whales and fisheries to identify management strategies to decrease entanglements. We used 25 years (1993-2016) of daily whale counts collected from Southeast Farallon Island, Central California to examine changes in timing of migration of whales to this area. We found that whale sightings have increased over time for both species. Foraging migration (northward migration and arrival to Central California) has been occurring earlier and is associated with El Niño. Breeding migration (southward migration and departure from Central California) showed little to no change. Humpback entanglements were correlated with increased counts and early arrival to Central California which increases whale exposure to pot and trap fishing gear in the spring. We used 10 years (2008-2017) of crab pot and whale count data collected at sea by the Applied California Current Ecosystem Studies (ACCESS) to model crab pot and whale densities in relation to climate, oceanography, and depth. We used these models to estimate co-occurrence by calculating the product of pot and whale densities as a proxy for entanglement risk. Since whale prey is expected to be compressed close to shore in warm water years, we compared averages of May risk between warm (2010, 2013) and cold (2008, 2009, and 2011) years. Warm years showed higher risk that was more concentrated close to shore. Management actions to shorten the fishing season and seasonal fishing closures in high risk areas would help decrease the risk of entanglement in Central California particularly during El Niño years when whales arrive early.

Harbour porpoise (Phocoena phocoena) local hot spots found using citizen science

Harbour porpoises (*Phocoena phocoena)* live in many Northern Hemisphere temperate coastal waters, especially in the North Sea and the western parts of the Baltic Sea. Large efforts have been made to determine the population numbers and distribution of harbour porpoises. This has been done by large- and small-scale surveys, satellite tagging, and acoustic monitoring. Despite of these efforts, the knowledge about harbour porpoise distribution is rather limited, especially in local areas and for critical periods of their life cycle, such as breeding, nursing their young, and foraging. In this project, we use a newly developed app to obtain detailed information on the distribution of harbour porpoises around the island of Funen, Denmark. The app, available on IPhone, IPad and Android platforms, was distributed via radio programs, web pages and social media, as well as organized meetings with sea-related sports clubs, such as sailors and winter bathers. The app was also distributed to ´common citizens´ by posters. Within three weeks after launch, the app had been downloaded and utilized by more than 400 users actively reporting hundreds of harbour porpoise sightings. After data processing to remove double entries and obviously erroneous sightings, the remaining data were used to identify important harbor porpoise sites around Funen as well as potential calving areas. The data provides insight into the detailed lives of harbour porpoises, which can be used in conservation efforts of this species during the most vulnerable time periods of their life cycle.

Tackling cetacean bycatch on the Indian west coast, using innovation

Jamalabad, Abhishek[1]; D'Lima, Coralie[2]

abhishek.jamalabad@gmail.com

Fisheries interactions are widely known to result in bycatch, threatening cetacean populations and their conservation globally. In Indian coastal waters, existing data that identifies this threat is based largely on fishery landings only. Very little is known about the nature of these interactions, their spatial distribution, and the various aspects of fishing practices that might influence interactions causing bycatch. Further, the logistical constraints of surveying vast areas, the diverse fisheries sector, and the lack of effective monitoring and management, impede effective data collection. We used fisher reporting networks, fisher interview surveys (n=46), and a user-friendly mobile phone application as tools to gather cetacean-fisher encounter data on interaction nature, frequency, distribution, bycatch occurrence and species. Preliminary results indicate that 30% of fisheries reported bycatch of small cetaceans in their gear, including Spotted Dolphin (Stenella attenuata), Spinner Dolphin (Stenella longirostris), and Finless Porpoise (Neophocaena phocaenoides). Through fisher community networks, we received verifiable geo-tagged records of cetacean presence not previously reported by systematic surveys in the

region. These included Orcas (Orcinus orca), aggregations of Common Dolphins (Delphinus capensis), and Baleen Whales (Balaenopetra sps.). Future analysis of these data could be used to model the risk of cetacean bycatch across the Western coast of India. Fishers in the network are keen to voluntarily help conserve cetaceans and mitigate the impact of bycatch, owing to their traditional reverence for cetaceans, and potentially to obtain access to sustainability/conservation-oriented seafood markets. Such interest and active involvement must be harnessed, to understand and tackle the issue of cetacean bycatch and address the related conservation gap along the Indian West coast.

The challenges of monitoring small cetaceans in tidally energetic environments

James, Angharad[1]; Nuuttila, Hanna[2]; Bertelli, Chiara[3]; Mendzil-Griffiths, Anouska[2]; Forrest, Rhian[2]

Great Britain holds great potential for marine renewable energy (MRE) developments to support the reduction in fossil fuel dependency that contributes to climate change. Wales is well positioned for tidal resource utilisation due to its exposure to highly dynamic waters. Tidal energy environments often overlap with sites frequented by small cetaceans but their behaviour at these locations is difficult to monitor. To mitigate the impacts of tidal energy developments, it is important for developers and regulators to understand the main challenges involved in studying target species in order to design an effective monitoring programme for pre- and post-deployment data collection. Here, we examined the challenges of observational and static acoustic monitoring techniques that were used to study the harbour porpoise, the most common and therefore likely cetacean to be affected by MRE developments. We identified logistical, physical and analytical constraints throughout the study and several solutions were explored. Harbour porpoises were visually and acoustically detected at tidal sites and Generalised Additive Models (GAMs) were applied to assess the effects of environmental variables on habitat use. Visual encounters were mainly associated with a tidal race, an area of fast flowing water and surface turbulence influenced by certain tidal states. Although tidally energetic sites are linked with foraging opportunities, it is increasingly difficult to observe small species where sea states above 3 are common, decreasing the chances of observing a surfacing cetacean. To obtain useable, statistically strong data that can relate to wider populations, suitable research techniques should be determined and standardised, incorporating our knowledge on the current issues in the field. We demonstrate that it would be unwise to rely on one method alone and suggest using a multi-methodological approach to study the habitat use of small cetaceans at tidal energy sites.

High use of a risky shallow-water foraging environment by common bottlenose dolphins (Tursiops truncatus) in Namibia – not restricted to resident animals.

James, Bridget[1]; Gridley, Tess[2]; Elwen, Simon[3]

A small population of <100 bottlenose dolphins inhabit the coastal zone (<15 m depth) of central Namibia and regularly forage within a shallow tidal lagoon at Walvis Bay. Here there is a substantial stranding risk, with at least 25% of this population previously live stranded. The lagoon is getting shallower with natural and human induced siltation, while simultaneously increasing in 'value' as a refuge from human activities. This study investigates patterns in the temporal use of the lagoon and whether the assumption of risk is ubiquitous to all individuals or only part of the population. Photographic identification data (Jan 2017 to Dec 2018) were used to compare habitat use between the greater Walvis Bay (69 vessel surveys) and restricted lagoon (44 shore surveys) areas. Occurrence patterns were investigated using autonomous click detectors (CPODs) deployed at two sites - a high use site in the bay (Aphrodite Beach) and within the lagoon mouth (Aug 2017 to Jan 2018). We identified 68 animals of which 44 (65%) regularly used the bay and lagoon, and 24 (35%) were only ever seen in the bay. Of those individuals using the lagoon, 16 were considered resident (seen > 20 times), 6 semi-resident (10-20 times) and 22 were seasonal visitors (< 10 times) within the wider study area. Acoustic detections within the lagoon were more than twice that (mean = 0.34, SD, 2.3; 0.15, SD 1.15 minutes.hr^{-1}) of Aphrodite Beach. A strong diurnal occurrence pattern was detected at Aphrodite Beach but absent within the lagoon, where occurrence was driven by tidal influences, peaking on high and ebbing tides. In conclusion, we found that the majority of individuals within Walvis Bay visit the shallow water lagoon environment where they risk becoming stranded. Understanding how animals

use the lagoon environment is especially important in this rapidly changing ecosystem.

Coastal habitat use of Indo-Pacific bottlenose dolphins (Tursiops aduncus) in Jeju Island, Republic of Korea.

A residential population of about 120 Indo-Pacific bottlenose dolphins resides throughout the year along the Coast of Jeju Island, Republic of Korea. Jeju is one of the most popular sightseeing spots in Korea and its coastal areas are currently undergoing rapid development. The habitat use of this species is poorly understood and conflicts often arise with respect to coastal development and conservation. We investigated spatiotemporal variations in coastal habitat use of Indo-Pacific bottlenose dolphins around Jeju Island for three years from 2014 to 2016. Sighting frequency, behavior type, and activity budgets were collected by land- and boat-based survey. More than 90 percent of dolphin groups were seen in shallow waters <20 m deep and showed no seasonal variations. Ninety-five percent (K_{95}) of the kernel density estimate was used as a measure of alongshore home range, and 50% of the estimate (K_{50}) was used to reveal two core habitat area (CHA) which were located in the northeast and southwest area of Jeju Island. Around the CHA, dolphin groups showed socializing and resting behavior, while traveling and feeding behavior were observed in an area outside of the CHA. This is the first multiyear study of habitat use that defined the core habitat areas for Indo-Pacific bottlenose Dolphins in Jeju Island. This study provides a concrete evidence that both northeast and southwest area of Jeju Island should be preserved to protect the population.

Startle and avoidance reactions of Cuvier's beaked whales to sudden onset sounds

The Cuvier's beaked whale (*Ziphius cavirostris*) is a species that has repeatedly been found stranded in association with naval sonar operations. Controlled exposure experiments have found a clear response to sonar sounds played from scaled sources. Yet, experimental approaches have not revealed responses that would ultimately lead to strandings unless a noise source were to follow a whale.

Apart from received level, the sudden onset of sonar sounds has been identified as a potentially aversive feature that could contribute to strong avoidance responses. In all tested mammal species, sounds with rapid onset times elicit a startle reflex (a rapid contraction of flexor muscles) which can lead to a sensitization of avoidance responses with repeated exposure. In this study we tested the reactions of Cuvier's beaked whales at the surface to repeated startle sounds to investigate whether animals show evidence of sensitization to such stimuli.

We exposed three individuals to sequences of bandwidth-limited startle sounds with a 20 dB bandwidth from 3.5 to 9 kHz. We monitored the animals' muscle contractions using 3D accelerometry recorded with DTAGs and analysed their avoidance behavior focusing on swim speed, vocalization behaviour and distance covered after exposures. We found that Cuvier's beaked whales have a clear startle response that is consistent with descriptions for other terrestrial and marine mammals. All whales ceased vocalizing, increased swim speed and left the playback site when hearing startle stimuli with a rms received level between 135 and 160 dB re 1 µPa. In a second exposure bout, one animal showed avoidance to a received level of less than 104 dB re 1 µPa rms, suggesting conditioned sensitization may be taking place. We conclude that rise time is a significant component of a noise stimulus that has the potential to amplify avoidance reactions shown by beaked whales.

Between a rock and a hard place: Vessel traffic and declining ice cause compounding risks to harbor seals in a glacial fjord.

Cruise tourism has burgeoned in Alaska over the past half-century, with annual visitation recently topping 1 million. Glacial fjords are featured on every cruise to Alaska, with Hubbard Glacier—the largest tidewater glacier in North America—projected to draw 214 ships in 2019, up 40% in two decades. The seasonal peak in vessel traffic in adjoining Disenchantment Bay overlaps with harbor seal pupping, which occurs on floating ice. Long-standing concerns about impacts stimulated research on whether ships threaten glacial-fjord seal populations, whose aggregations are some of the largest in the world. Studies describe the distances at which seals react to ships and flush, the energetic costs of extra time submerged, the frequency of close approaches, and the likelihood of population-wide disturbance. These and other findings prompted NOAA to issue more formal, but still advisory, minimum approach distances and transit corridors to promote seal-ship separation. The aims here were to: 1) compare contemporary vessel behavior with earlier studies to assess changes and compliance with new approach guidelines, and 2) examine disturbance effects on seal distribution using GPS-quality locations of ships and seals. Compared to 2002 (N = 27), we found that vessels during June 2017 (N = 39) increased the area used for transiting by 65%, from 26.4 to 40.6 sq km, with most ships operating outside the recommended corridor. Ships also penetrated deeper into the floating ice pack, approaching the glacier at an average 3.8 km (range 0.7-12.4) compared to 9.6 km (2.1-17.8 km) in 2002; 50% approached closer than the advised 1.5 miles. We believe declining ice cover led to ships operating over larger areas and closer to the glacier, and in turn closer to areas of concentrated seals. We assess possible effects of these shifts by comparing metrics of seal distribution across days with varying ship traffic.

Causes of death of harbour porpoises (Phocoena phocoena) found in Belgium between 1990 and 2017

Between 1990 and end of 2017, 1391 harbour porpoises (*Phocoena phocoena*) were found dead in Belgium (sea, coast, rivers and harbours). There was a significant rise in strandings since the end of the 1990s (on average 5 porpoises/year in the 1990s, 90/year during the last 10 years). The aim of the study is to present the main lesions and causes of death of porpoises and their evolution between 1990 and 2017. Porpoises were selected for necropsy and sampling (histopathology, toxicology, microbiology) following a standard procedure. Frequent observations in the 433 porpoises investigated included net marks, sub-cutaneous and muscular bruises, emaciation, pulmonary blood vessel and airways parasitism, pneumonia and lung congestion and edema. The origin of mortality was determined for 398 porpoises, the two main causes of death were infectious disease (41%) and bycatch (35%). Infectious disease (mainly pneumonia associated with severe parasite infestation) occurred throughout the year. Bycatch was mainly observed in animals that had washed ashore in March and April. Two other causes of death have recently emerged, firstly severe emaciation, combined with lung edema in the absence of other lesions, was considered as evidence of starvation, and secondly grey seal predation with typical lacerations of skin and blubber. Infection by the bacteria *Brucella ceti*was reported in 8% of the porpoises for which it was investigated. The two main reasons for the increase in porpoise strandings during the last two decades are linked with the local increase in density (associated with the southward shift of the population within the North Sea) and the emergence of new causes of death. Increasing numbers of porpoises lead to increased numbers of stranded animals, with the influence of factors such as the emerging phenomenon of predation by grey seals (with populations increasing), bycatch and starvation to be assessed.

Clarifying the taxonomy of the delphinoid cetaceans: A comprehensive review of all nominal species.

Jefferson, Thomas
Clymene Enterprises, Lakeside, California
Corresponding Author: sclymene@aol.com

The taxonomy of several genera of small cetaceans is confused, and often has been for decades or even centuries. Recent taxonomic revisions of some genera (e.g., *Orcaella, Sotalia, Sousa, Lagenorhynchus*) have clarified things, but there

are still other genera that await thorough taxonomic treatments, which are sure to recommend generic recombinations and new or resurrected species (e.g., *Orcinus, Tursiops, Stenella, Platanista*). Among the impediments to such resolution is the challenge of identifying proper nomenclature when taxonomic revisions are made, and when new taxa are proposed. There are 353 nominal species of delphinoid cetaceans (most described in the nineteenth century), yet only 50 of these are currently recognized as valid species. Many of the remainder of these names are currently considered to be *nomina dubia* (i.e., of questionable identity), yet information in the literature and examination of the relevant type specimens have often not been adequately pursued. This study is a long-term project, with the objectives of reviewing the status of all nominal species of delphinoids, and documenting their type specimens. Ultimate goals are to identify as many of the *nomina dubia* as possible, and to facilitate the inclusion of data and material (both morphological and molecular) from relevant type specimens into future taxonomic studies.

Adaptations of biosonar behavior to a deep-diving lifestyle in offshore bottlenose dolphins

Toothed whales are air-breathing, marine predators that depend on echolocation to find prey. Their diverse habitats, ranging from freshwater river systems to extreme depths in the open ocean, pose different challenges to the operation of a biosonar system. Here we test if habitat shapes the biosonar behavior of toothed whales by contrasting the echolocation behavior of coastal and offshore common bottlenose dolphins (*Tursiops truncatus*). Through 2011-2016, we instrumented 68 bottlenose dolphins in Sarasota Bay with acoustic and movement-recording DTAGs during health assessments. We used echolocation clicks from simultaneously tagged mother-calf pairs or bonded males to estimate the difference between tag apparent output and dolphin source level. We found that coastal dolphins produce low-amplitude (SL_{rms}: 186±7 dB re 1µPa), high repetition-rate (median 16 clicks/second) echolocation clicks while foraging in shallow water <10m depth. In August 2016, we instrumented three offshore bottlenose dolphins in Bermuda with DTAGs as part of a larger collaborative investigation into the ecology and physiology of offshore bottlenose dolphins. DTAGs remained attached for up to 23 hours, and all individuals foraged to depths of 400-500m overnight, with dives of up to 1000m recorded on long-term TDR tags. When echolocating near the surface, these animals used source levels of 199±5 dB (~6 clicks/second), but when foraging during deep dives, they increased source levels to 212 ±3 dB (~8 clicks/second), 26 dB higher than typical levels of Sarasota dolphins. These behavioral adaptations increase detection range and therefore search efficiency in an open ocean setting, and thus facilitate efficient exploitation of their deep-water feeding niche. Additionally, peak source levels rival those seen in target detection tasks that investigate the biosonar limits of trained dolphins. This study therefore underscores the flexibility of the bottlenose dolphin biosonar and shows that even within species, habitat is important for determining how animals operate their biosonar.

Environmental influences in the summer and winter movements of satellite monitored fin whales in the Gulf of California

The movement of the population of fin whales inhabiting the Gulf of California (GoC) was described for the first time through the use of telemetry technology. It seems, that they have seasonal movement from south to north (winter to summer) related to their prey. However, sightings at the beginning of summer at Bahía de La Paz (BLP) and their absence at the end, led to the hypothesis, that their movements are more complex. Here we present new information of their movement from seven Argos satellite tags deployed at BLP (July, 2018) and Puerto Libertad (January, 2019). The behavior mode was related with remote sense data (*SST, Chlo-a*, *POC*, bathymetry) and distance to shoreline. A hierarchical Difference Correlated Random Walk Switching Model was applied to the satellite tag's data to characterize

movement behavior as either "area-restricted searching" (ARS, an indication of foraging) or "transiting" between foraging patches. In both seasons the predominant behavior identified was ARS (77 and 67 %), during which travel speed was slower (1.6±1.09km/h) than during transiting mode 4.07±2.33km/h. The ARS mode was related to shallow waters (-135±147m) and faraway to the coast line in summer and close to it during winter (32-41km). On January fin whales occupied areas with high *POC* (369±137 mg/m^{-3}) and *Chlo-a* (1.5±0.86 mg/m^{-3}) values for feeding activities and they did not move to the south of the GoC. On July two individuals moved to the Midriff Islands. One retuned to BLP. For the first time there is evidence of one fin whale leaving the GoC with ARS mode at the Pacific waters; probably feeding on sardine. Our finding suggests, the part of the population may present spatial segregation related with high productivity areas for feeding (year around) and probably reproductive activities in winter. And a second seasonal movement to the Midriff Islands during summer.

What will it take to protect whales in the Antarctic Peninsula? How innovative science and collaboration can inform Antarctic conservation and policy.

Johnson, Chris[1]; Friedlaender, Ari[2]; Johnston, David[3]

The Western Antarctic Peninsula is a hotspot of global environmental change manifesting in warmer temperatures and decreased sea ice annually. Commercial krill fishing is concentrated in this area and overlaps with key feeding areas for baleen whales. Tourism is growing with large ships operating in areas that increase the risk of ship strikes and underwater noise pollution. Whales that undertake long migrations from their breeding grounds in tropical waters to the Peninsula navigate additional risks including bycatch in fishing gear and growing pollution.

The Southern Ocean surrounding Antarctica is critical habitat for most of the southern hemisphere's great whale populations. But, with increasing challenges comes opportunity to respond and there is much to be optimistic about. Innovations in whale research including new digital tags, unmanned aerial system technologies, new molecular techniques and access to platform of opportunities are advancing our knowledge allowing us to explore new areas previously impossible to pursue.

Establishing broad, well-managed marine protected areas (MPAs) are a vital part of delivering effective biodiversity conservation. Antarctic ocean life is conserved through coordinated international management by the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR) which can make binding, consensus decisions and has committed to establishing a network of MPAs surrounding the continent. However, whales are delegated to management under the International Whaling Commission (IWC) and are not considered in CCAMLR's ecosystem-based management decisions related to commercial fishing and long-term monitoring.

We highlight collaboration between research teams from the University of California, Santa Cruz and Duke University with the World Wildlife Fund (WWF) to bring innovative science to public and policymakers identifying critical habitats for MPA design and monitoring and informing better management of the krill fishery. We share a case study highlighting knowledge exchange to achieve policy impact and protect whales for generations to come.

Probability of passive acoustic detection of right whales from autonomous platforms equipped with a near real-time monitoring system

Mitigation of anthropogenic impacts on North Atlantic right whales and other at-risk species is critical but challenging given the cryptic nature of whale behaviour and the limitations of conventional visual surveys. Using passive acoustic monitoring (PAM) to alert ocean users to whale presence in near real-time can provide an effective mitigation option. The Woods Hole Oceanographic Institution (WHOI) has developed the digital acoustic monitoring (DMON) instrument and low-frequency detection and classification system (LFDCS) to detect and classify baleen whales in

near real-time from autonomous platforms (e.g., buoys and gliders). A limitation of many PAM systems, including the DMON/LFDCS, is the uncertainty in acoustic detection range from the PAM platform. Our goal was to determine the range-dependent probability of detection of the DMON/LFDCS on mobile and fixed platforms. Over a 4-week period in spring of 2017, we concurrently deployed a 4-element vertical line array (VLA), an 8-element horizontal line array (HLA), a DMON/LFDCS-equipped Slocum glider, and a DMON/LFDCS buoy at a shallow (~30m) site ~15 km southwest of Martha's Vineyard, Massachusetts, USA. We used a normal mode back-propagation technique with the HLA/VLA data to localize right whale upcalls, and then conducted a quantitative call-by-call comparison among calls detected on the HLA/VLA and those detected by the glider or buoy using logistic regression to determine the range-dependent detection probability among platforms. The results improve our interpretation of DMON/LFDCS detection data from different platforms, which in turn informs how we use this tool to disseminate more accurate information about whale distribution and near real-time locations to research, government, and industry stakeholders.

Is natural selection shaping Florida manatees? An investigation into the body shapes between the subspecies of the West Indian manatee.

The West Indian manatee (*Trichechus manatus*) is currently divided into two subspecies: the Antillean (*T. m. manatus)* and Florida manatee (*T. m. latirostris)*. Florida manatees are found at the northern extreme of the species range, primarily inhabiting the waters around the Florida peninsula, while the Antillean manatee inhabits the remaining range from the Caribbean islands to western Brazil. Only in the range of the Florida manatee do waters dip below 20ºC during the winter, and these manatees have to seek warm water refuge for thermal regulation. Allen's rule predicts that in colder climates animals will adapt to have smaller surface area to volume ratios (SA:V). It has been reported that on average, Florida manatees are larger in absolute body size than Antillean manatees. However, no one has explored differences in body shape independent of size between the two subspecies. This study proposes that Florida manatees have stockier body shapes (smaller SA:V) compared to Antillean manatees due to the selective pressure of the colder water. Data on Florida manatee morphometrics (n=834) were obtained from the Florida Fish and Wildlife Commission, while Antillean measurements (n=93) came from live captures in Yucatan and Tabasco, Mexico. SA:V was calculated by creating a geometric model of manatee shape using the standard morphometric measurements. Our study found Florida manatees were significantly longer in length than Antillean manatees ($p=9.91x10^{-3}$). In addition, an ANCOVA on SA:V controlling for total length indicated that the SA:V of Florida manatees was significantly smaller ($p=1.68x10^{-4}$). Therefore, it appears natural selection has not only increased the total body size of Florida manatees, but also altered the body shape in relation to Antillean manatees. Our results lend further support for Allen's rule and indicate that Florida and Antillean manatees are diverging on separate evolutionary paths.

New active and passive sound and movement tags enable long-duration studies of behaviour, ecology and effects of disturbance

Sound and movement tags (e.g., DTAGs) are powerful tools for exploring the sensory, foraging and social behaviour of cetaceans, and their responses to environmental noise. These tags continuously record wide bandwidth sound along with data from accelerometers, magnetometers and pressure sensors, providing a wide array of behavioural inferences. However, high data rates and associated power consumption typically limit the recording duration to just a few days, constraining the range of behaviours and biological conditions that can be sampled. Here we show that recording durations can be greatly extended by

careful electronics and software design that enhance memory and power efficiency with little trade-off in performance. The resulting DTAG-4 tags have yielded 3-8 week continuous high resolution sound and movement recordings on harbour seals, elephant seals and manatees enabling studies of noise exposure, respiration rates, prey encounters and time/energy allocation. Smaller versions of the tag record for 5 days on penguins and fur seals. An active biomimetic sonar version of the tag with 1-2 month duration collects fine-scale data on the biotic environment experienced by marine animals and predator-prey interactions that have only previously been possible with echolocating toothed whales. With such long recording durations, accurate positioning is needed to georeference behaviours, prey encounters and noise events. To this end the tags contain a tightly-integrated, low-power snapshot GPS which is interpolated by dead-reckoning. Combined with data from AIS logs, the closest approach distance and ship speed can be calculated for each vessel pass, enabling detailed investigations of shipping noise. We offer a roadmap showing the range of species and tasks to which the new long-duration tags are being applied as well as software tools for data analysis. To help identify suitable applications, we also provide a simple methodology to estimate tag lifetime as a function of sampling rate and sensor type.

Automated cetacean identification and measurement using drones and deep learning.

Photogrammetry has begun to contribute meaningfully to the study of individual and population health, population structure, and understanding changes within marine mammal communities. The flourishing application of drones within marine science provides more opportunity to conduct photogrammetric studies on large and varied populations of many different species. While these new platforms are increasing the size and availability of imagery datasets, established photogrammetry methods require considerable manual input, allowing individual bias in techniques to influence measurements, increasing error and magnifying the time required to apply these techniques. Here we introduce a novel automated image analysis workflow for species identification and morphometric assessment of large marine vertebrates, utilizing a convolutional neural network to demonstrate the potential of a deep learning-based photogrammetry system. We then validate the accuracy of these workflows with traditional approaches to photogrammetry. Our results compare favorably across both techniques. Our automated system correctly predicts whale species with 98% accuracy (57/58) for humpback whales, minke whales, and blue whales. Ninety percent of automated length measurements were within 5% of manual measurements, providing sufficient resolution to inform morphometric studies and establish size classes of whales automatically. In addition to presenting substantial new cetacean body morphology data, this work demonstrates the broad applicability of combining drone-based data collection with neural networks for monitoring of marine animals, highlights the challenges and opportunities in this combination, and is broadly adaptable for future research questions.

Niche partitioning in the largest Antarctic fur seal, Arctocephalus gazella, colony revealed by stable isotopes in whiskers

Jones, Kayleigh[1]; Votier, Stephen[2]; Ratcliffe, Norman[3]; Stowasser, Gabriele[3]; Dickens, John[3]; Newton, Jason[4]; Staniland, Iain[3]

Corresponding Author: kaynes85@bas.ac.uk

Niche partitioning relaxes competition for resources and can enhance the effective carrying capacity of a population. It may play a crucial role in population dynamics of marine predators, which are typically colonial and exhibit central place foraging as breeding locations are limited. We aimed to quantify resource partitioning of Antarctic fur seals breeding at South Georgia, which hosts the highest densities of the species in the world. Antarctic fur seal whiskers, which grow continuously and are not moulted, were collected from 20 males and 20 females at Bird Island, South Georgia. Stable isotope ratios were quantified every 5mm along the length of each whisker. Nitrogen isotope ratios ($\delta^{15}N$) were used as proxies for trophic level, while carbon isotope ratios ($\delta^{13}C$)

were used as broad indicators of foraging habitat. Synchronous oscillations in $\delta^{13}C$ values corresponded to annual migrations and revealed that on average male whiskers grew 1.5 x faster than female whiskers. Spatial segregation was evident between the sexes: $\delta^{13}C$ values were significantly lower in males than females, indicating that males generally spent more time foraging south towards the Antarctic continent. The $\delta^{13}C$ values in females revealed two main foraging strategies: 6 out of 20 females spent most time foraging north of the Polar Front and the remainder to the south of the Polar Front. Female seals that foraged north of the Polar Front had higher $\delta^{15}N$ values and consumed different prey species to those foraging elsewhere. Antarctic fur seals in these age and sex classes face different degrees of inter-specific competition as well as environmental and anthropogenic stressors. This study emphasises the requirements to consider the variability in ecological niches among sex and age groups when formulating plans to conserve species and highlights the importance of niche partitioning in enhancing population carrying capacity.

Re-evaluation of the ocean-basin-wide movement patterns of North Atlantic humpback whales, Megaptera novaeangliae

The structure of the North Atlantic humpback whale (*Megaptera novaeangliae*) population has not been studied on an ocean-basin scale since the Years of the North Atlantic Humpback (YoNAH) survey of 1992-1993. Despite the lack of updated knowledge, a recent ruling under the United States' Endangered Species Act (ESA) delisted the species globally and split humpbacks in the North Atlantic into two Distinct Population Segments (DPS): the West Indies DPS and Cape Verde Islands (CVI) DPS. The work presented here quantifies the ocean-basin-wide movement patterns of humpbacks over four decades. Our analyses used data from the North Atlantic Humpback Whale Catalog (NAHWC), curated by Allied Whale at College of the Atlantic, for years 1970 – 2015. These data include over 38,000 photographic-identification images of 9,500 whales contributed by over 700 groups and individuals. We estimated transition probabilities between all known mid-to high-latitude feeding areas and breeding/calving areas to elucidate ocean-basin-wide movement patterns and detect differences between breeding regions. Based on emerging trends, our analyses further divided the West Indies into two distinct breeding populations: the Greater Antilles and the southeastern Caribbean. Migratory patterns between feeding areas and the southeastern Caribbean were more similar to those from the CVI breeding segment than the geographically-closer area in the Greater Antilles. Breeding to feeding area transition probabilities were highest from the Greater Antilles to western feeding grounds, from the southeastern Caribbean to eastern feeding grounds, and from CVI to eastern feeding grounds. Thus, the movement patterns of whales breeding in the Greater Antilles are different from those in the southeastern Caribbean, suggesting that whales from these two regions are behaviorally distinct. These findings have implications for DPS delineations under the ESA as well as the international management of whale stocks in the North Atlantic.

Male-female interactions in humpback whales during the breeding season are affected by relative body size and male aggressiveness

Breeding aggregations of humpback whales (*Megaptera novaeangliae*) are comprised of individuals that vary in sex, reproductive class, age-class, and body size and condition, but how this range of individual physical characteristics and physiological states influences male-female interactions during the breeding season is poorly understood. We investigated how relative body size, age-class and aggressive behavior by lone male humpbacks interrelate and contribute to variability in female time budgets, behavior, and movement patterns. Focal follows with 36 female no-calf groups (male-female pairs) and 29 female-calf groups (escorted mother-calf groups) were conducted on the Hawaiian breeding grounds. Relative fluke size (n=30) and age-class (n=9, sighting histories) was determined for 39 individuals within these groups. Multiple and direct approaches by males to < 1 body length of the female, and chasing, which included multiple approaches, and led to high-speed, energetic chases that persisted over time significantly impacted female behavior. Females with calves (FC) were significantly more likely to be chased by lone males than females without calves (FNC) suggesting that increases in energy expenditure are greatest for lactating females. Overall, 21.4% (22/103) of FC groups were chased compared to 2.2% (2/89) of FNC groups. Chased females swam significantly further distances at increased speeds and spent less time resting than females that were not chased. A significant relationship between fluke size, age and male behavior was also found. Although fluke sizes ranged up to 4.53m in males and 4.61m in females, none of the males that chased females or females that were chased had flukes larger than 4.1m, and none of the males or females of known maturity chased or were chased. Our results suggest that, similar to other mammals, male aggression toward females with calves is commonplace, and raise the possibility that lone, sub-adult males may use this as an alternate mating tactic.

Continuous-time state-space models for marine mammal tracking data: Validation, quality control and behavioural inference.

State-space models (SSMs) are increasingly relied on to filter error-prone locations from marine mammal telemetry data. In this context, SSMs predict a series of locations using a model to describe animal movements coupled with a model to describe the error-prone observations. Focusing on locations collected via the Argos satellite system, we develop and evaluate continuous-time SSMs that can be easily and rapidly fit to large, multi-individual data sets. The data can comprise CLS Argos' Least-squares- or Kalman filter-derived location estimates, or even a mixture of both. Although several SSM approaches exist to perform quality control of Argos tracking data, few have had their accuracy validated. Using a variety of species' double-tagging data sets, we validate our SSM's predictions against high-resolution GPS data. We then show how SSM's are essential for quality control of ocean observations made via animal-borne telemetry and touch on extensions to our approach for rapid behavioural inference along marine mammal movement paths.

Variations in ecological niche in norwegian killer whales (Orcinus orca) inferred from dietary descriptors and observational evidence

Killer whales (*Orcinus orca*) in Norway have long been thought to rely on Atlantic herring (*Clupea harengus*) as main food source. However, recent observations in various regions and seasons report additional fish and marine mammal prey species. Prey preferences yet remain poorly understood. We summarize field observations over six years from 2013 to 2018, and dietary descriptors (stable isotope profiles) from skin samples collected in 2017 and 2018 (n=38) of individual killer whales focal-studied throughout the year to draw the first comprehensive evaluation of dietary preferences among killer whales in this region. Of the 1,082

marked identified individuals in northern Norway, 91% (n=988) had wintering herring as seasonal food source. Further, 31% (n=339) were observed in the spring and summer months, after the herring has departed. Identification of prey consumed revealed pinnipeds and lumpfish (*Cyclopterus lumpus*) as alternative prey resources for these whales, with a seasonal diet switch for a minimum of 75 individuals. Low isotope variance and non-overlapping ecological niches confirmed seasonal prey specialization of herring and lumpfish-eating killer whales, reflective of temporary prey abundance. Higher trophic position and wider isotopic niche measured for seal-eating killer whales sampled in all seasons suggested predation on pinniped prey throughout the year, and an inclusion of both fish and mammalian prey to the diet for these groups. Because foraging ecology may influence genetic structuring by shaping social behaviors in killer whales, our results are relevant to assess both the conservation status and role of killer whales in marine ecosystems.

Distribution, site fidelity and habitat utilisation of common bottlenose dolphin in the Gulf of Marseille, southern France (Mediterranean Sea)

The bottlenose dolphin (*Tursiops truncatus*) has been studied along the French Mediterranean coast since the 90's, but little is known about this species within the Gulf of Marseille. The temporal distribution of dolphins, group dynamics, site fidelity, and habitat utilisation were assessed through mark-recapture photo-identification methodology. A total of 343 hours of boat-based observation, spanning 70 days, were spent at sea between January 2017 and March 2019 in the 2 600 km^2 study area. During this period, dedicated surveys along with opportunistic sightings resulted in 26 groups of bottlenose dolphins being photo-identified. A total of 141 individuals were identified, 35% of which were seen more than once, with sighting frequency ranging from one to twelve. School membership was mixed, typical of fission-fusion societies already described for bottlenose dolphins. 85% of schools were linked by common members. The discovery curve indicates that a large part of the population remains undiscovered. Bottlenose dolphins were observed throughout the year, although seasonality was apparent with more encounters during spring and summer. Photo-identification highlighted that 13 individuals used the Gulf of Marseille on a regular basis, while others were present less often. Thirty-nine dolphins were previously identified in the sector and 4 catalogued dolphins were known from surveys at other coastal sites as far as Genova (Italy) or Barcelona (Spain), thus demonstrating large scale movements of some individuals using the Gulf of Marseille. Foraging was the most frequent behaviour observed. One group was observed feeding on white seabream (*Diplodus sargus*). Most groups (70%) included young, while neonate calves were observed in only two groups. Adults accounted for 85% of all individuals photographed, while young and neonate calves represented 13% and 2% respectively. Further perspectives include contribution of this study to a long-term and integrated monitoring of the population along the French Mediterranean coast.

Fine-scale 3-D whale movement: A simulation model to assess the impact of noise exposure to naval exercises in range.

There are a number of individual-based animal movement models that can be used to estimate the cumulative exposure of individual marine mammals to sound over the duration of a single navy exercise. However, information on whether or not an individual animal experiences disturbance during a particular navy exercise is not sufficient to assess the broader scale consequence of multiple disturbance over the course of a biologically-meaningful period (e.g., 1 year). We have developed a 3-d movement methodology that uses a Metropolis-Hastings sampler whose horizontal movement is informed only by a density surface that reflects habitat preference. The whale density surface informs the acceptance of a proposed "step" in the movement model. When naval sonar disturbance occurs, the probability of a whale response is mediated through a "dose-response" function tailored to the type of sonar. The strength of the response is treated through the magnitude of the "memory" parameter that informs the directional persistence of the whale away from the source of the initial disturbance. The depth dimension of the sampler is informed by D-tag dive

data from resident and migratory whales in the off-shore naval range of southern California (SOCAL). The whale density surfaces were developed specifically for this region and include monthly temporal resolution. We demonstrate the tool for fin whales and Baird's beaked whales using 3-d acoustic model outputs from a naval exercise completed in this region.

Behavioral responses of satellite tracked Blainville's beaked whales (Mesoplodon densirostris) to mid-frequency active sonar.

The vulnerability of beaked whales (Family: Ziphiidae) to intense sound exposure has led to considerable interest in their behavioral responses to mid-frequency active sonar (MFAS, 3–8 kHz). Here we present satellite-transmitting tag movement and dive behavior records from Blainville's beaked whales (*Mesoplodon densirostris*) tagged in advance of naval sonar exercises at the Atlantic Undersea Test and Evaluation Center (AUTEC) in the Bahamas. This represents one of the largest samples of beaked whales individually tracked during intensive sonar operations (n = 7). The majority of individuals (5 of 7) were displaced between 28 km and 68 km from their initial locations at the onset of MFAS exposure and generally moved away from the core area of sonar activity in a north-northwest direction. Of the individuals that were initially located on or near AUTEC range all individuals returned within 2-4 d after the end of the exercises. Modeled sound pressure received levels were available during the tracking of four individuals and three of those individuals showed declines from initial maxima of 145-172 dB re 1 µPa to maxima of 70-150 dB re 1 µPa following displacements. Dive behavior data from tags showed a continuation of deep diving activity consistent with foraging during MFAS exposure periods, but also suggested reductions in time spent on deep dives during initial exposure periods. These data provide new insights into behavioral responses to MFAS and have important implications for the modeling of population consequences of disturbance.

Marine megafauna distribution and threats along the offshore Islands of Trat Province, Thailand.

Marine megafauna distribution around the offshore Islands of Trat Province, eastern Thailand, was investigated via systematic aerial surveys on 28 January–3 February 2018 (7 flight days). This is the first time that aerial survey methods have been employed in this area. Since 2013, boat-based surveys conducted around the islands yielded only four sightings in 11 survey days. This survey was conducted using parallel line transects and covered the waters of Ko Chang, Ko Mak and Ko Kud. These islands are tourism destinations. Fifty-two sightings were observed in water depths ranging 12-15 m, and the total area surveyed was 3382.4 km^2. Minimum six marine megafauna species were identified such as Hawksbill turtle, Green turtle, Indo-Pacific bottlenose dolphin, Irrawaddy dolphin, Dugong, and Whale shark. The sighting of sea turtles comprised 13.4% (n=38) of sightings and were mostly in the shallow reef areas, dolphin sightings comprised 10.0% (n=7) of sightings, while dugong sightings comprised 2.1% (n=4) of sightings and were observed around seagrass areas. The Department of Marine and Coastal Resources have been collecting data on stranded marine megafauna from 2014-2018 resulting in a total of 175 carcasses of sea turtle and cetacean. Necropsies and observations indicated causes of deaths were from incidental catch in fishing gears such as hooks, longline hooks and gillnets (6% n=10), sickness (13% n=23), and garbage (1% n=1). Our survey provides valuable information on the relative abundance and density of animals at particular locations but is not adequate to measure trends or further discern habitat preferences. More surveys over a longer duration will assist in filling

those information gaps. However, our survey enables us to discern areas of marine megafauna overlap with that of human activities. Currently, these Islands are being developed rapidly as tourism destinations, so that conservation and management actions may be recommended.

From feast mode to least mode: How lunge filter feeding biomechanics constrain rorqual foraging ecology across scale.

Large body size is widely recognized to confer many benefits, including reduced transport costs and enhanced diving capacity. Such advantages should allow divers to increase their ability to forage at depth, thereby increasing overall foraging efficiency. Rorqual whales engulf a large mass of prey-laden water at high speed, which in some species is greater than the body mass of the whale itself, and filter it through baleen plates, retaining prey. This lunge feeding mechanism incurs a large energetic cost due to high drag, but provides the animal with extraordinary prey consumption rates. However, as engulfment capacity increases with body length across species (Engulfment $=\text{length}^{3.2} * 10^{0.612}$, $r^2=0.964$), the surface area of the baleen filter does not increase proportionally (Baleen area $=\text{length}^{1.85} * 10^{0.181}$, $r^2=0.827$). Therefore, we hypothesized that these scaling differences would lead to longer filtration time (Filter time α $\text{length}^{1.5}$) for rorquals of larger body size because the baleen surface area must filter a disproportionally large amount. We tested this hypothesis on five rorqual species using 97 cetacean-mounted video and 3D accelerometry tag deployments with corresponding drone photogrammetry. This data provided direct measures of body size, lunge rates, and filtration times for 15 568 lunges using accelerometry and 233 lunges from direct video observations that confirmed our method. Our findings show that filter time increased with body length (Filter time $=\text{length}^{1.8} * 10^{-0.7}$, $r^2 = 0.76$), whereas the number of lunges per dive decreased with size (Number of lunges per dive $=\text{length}^{-0.8} * 10^{1.7}$, $r^2=0.55$). Although larger rorqual whales should have increased diving capacity, the disproportional cost and filter time required to engulf larger volumes progressively limits dive time that could otherwise be spent selecting the highest quality prey patches. Because larger rorquals commit more resources into relatively larger gulps, they are reliant on dense prey patches to meet their increasing energetic demands.

The plight of Galápagos sea lions: Population decline and future prospects of a colony in the centre of the archipelago.

Predicting population trajectories based on age-specific vital rates can increase our understanding of relevant population processes, crucial in a conservation context. The Galápagos sea lion population on Caamaño has been monitored since 2003 and declined over the last years. Future population trajectories were predicted by using deterministic and stochastic matrix models based on observed variation in vital rates of two different time periods, an early one where adult female survival rates were still close to 0.95 (2003-2008) and one where all years between 2003 and 2015 were considered and adult survival was 0.83. An elasticity analysis was conducted to determine which vital rates are most critical for recovery. In the deterministic models, the population growth rate (λ) over the next 50 years was predicted to be positive, based on vital rates of the early time period (λ=1.028), but negative based on those of the total time period (λ=0.897). Prognoses worsened when environmental stochasticity,

represented by recent years' sea surface temperature anomalies, was included (λ2003-2015=0.840, λ2003-2008=0.963), and even more when the increase of 0.9°C in mean SST predicted by the IPCC was considered (λ2003-2015 = 0.829, λ2003-2008=0.950). These results imply that over the next 50 years, the sea lion population is facing a danger of extinction. λ was most influenced by adult survival as shown by elasticity analysis. However, survival rates of all age classes are low in comparison to other pinnipeds, indicating a common factor influencing survival. The reasons behind the negative predicted population trajectories could be a decline in prey abundance either due to an increase of El Niño events, general increase in SST, and/or the collapse in sardine abundance which has happened simultaneous to the Galápagos sea lion population decline since the 1970s. These results strongly suggest that current conservation efforts are not adequate for the Galápagos sea

Determing the preferred swimming styles of leopard seals through skeletal muscle physiology.

The majority of pinnipeds swim using either hind-flipper or front flipper-propulsion. In all of the pinnipeds we have measured, there was a significantly greater aerobic capacity and oxygen storage in their swimming muscles as compared to their non-swimming muscles. Based on this information we set out to determine the preferred locomotory style of the leopard seal by measuring the physiological profiles of both the longissimus dorsi (the main propulsory muscle for hind-flipper locomotion) and the pectoralis major (the main muscle for front-flipper propulsion). The combined results for male and female leopard seals show no difference between the two muscle groups indicating that leopard swim using both forms of propulsion. However when we separated the data into male and female groups, we found a very interesting result. There was a significant difference in males showing that they preferentially swim with their hind-flippers where as it was the females that use both forms of propulsion. This data in combination with our data on fuel utilization and dive behavior will allow us to establish energetic profiles for both male and female leopard seals and permit us to predict their energetic requirements in a changing climate.

Recycling data: A publicly available, annotated acoustic data set with potential uses for marine mammal research and classifier development

Barkley Canyon is a productive submarine canyon approximately 60 km southwest of Vancouver Island, Canada. The canyon's nutrient flow is affected by multiple regional currents, and draws aggregations of euphausiids, hake, and herring, as well as various marine mammal species. The Barkley Canyon node of the North-East Pacific Time-series Undersea Networked Experiments (NEPTUNE) observatory, operated by Ocean Networks Canada, is instrumented with a variety of oceanographic instruments including a hydrophone. A subset of acoustic data collected from the 2013-2015 hydrophone deployment on the upper slope of the canyon was manually annotated for marine mammal presence as part of a research project focusing on marine mammal habitat use, and in support of development of a random forest classifier. This data set, which is being made publicly available for further use, includes strong-label annotations of phonations from blue whales (*Balaenoptera musculus*), fin whales (*Balaenoptera physalus*), humpback whales (*Megaptera novaeangliae*), sperm whales (*Physeter macrocephalus*), orcas (*Orcinus orca*), Pacific white-sided dolphins (*Lagenorhynchus obliquidens*), Risso's dolphins (*Grampus griseus*), and other delphinids that could not be identified to species. All regional orca communities are represented within the data set, and phonations are labelled to ecotype level and to pod level when possible. This data set could be further used in a number of ways, including classifier development, investigations into habitat use and seasonality, or combining the acoustic data with data collected from co-located oceanographic instruments to investigate links between marine mammal presence and oceanographic conditions.

"Squeak-Thunks": Sequences of multi-element calls produced by bottlenose dolphins while foraging and socializing off Bimini, The Bahamas.

Bottlenose dolphins (*Tursiops truncatus*) produce a variety of calls across different behavioral contexts, including low-frequency vocalizations. While descriptions of low frequency calls vary across bottlenose dolphin populations, low-frequency calls in some populations have been described as occurring in sequences and/or in combination with other vocal elements. Low-frequency calls are usually recorded in social or foraging contexts. In this study, we documented occurrences of low-frequency "squeak-thunk" vocalizations and sequences produced by bottlenose dolphins off Bimini, The Bahamas, and described the acoustic parameters and behavioral contexts in which they were produced. Squeak-thunks were defined as a call that contained a squeak, or short, narrowband whistle that overlapped with a thunk, a broadband low-frequency pulse (range: 300 – 4000 Hz); these calls may be biphonal in nature. A squeak-thunk sequence could include several repetitions of squeak-thunks, as well as combinations of additional low-frequency elements such as other thunks, gulps, or wheeze gulps (gulps with multiple harmonics). Bottlenose vocalizations were recorded during 17 encounters across 2010-2018 (~8 hours of recording). Group size ranged from 2 – 15 dolphins. Squeak-thunks were present in 9 of these encounters. We analyzed 99 individual or sequences of vocalizations that included squeak-thunks. We found that the behavioral states during which squeak-thunks were recorded were foraging and/or socializing. Squeak-thunk sequences appear to be similar to bray-type sequences reported by other researchers and may be representative of an excitement or a food-related call. Analysis is ongoing to continue to describe and document occurrences of squeak-thunks near Bimini to better understand their function.

Socio-spatial dynamics of a coastal delphinid in a heavily anthropogenically impacted estuarine seascape

Indo-Pacific humpback dolphins (*Sousa chinensis*) inhibiting the Pearl River Delta (PRD) region, southeast China, are among the world's most anthropogenically impacted coastal delphinids. Although recognized as high conservation priority, the effectiveness of local/regional conservation strategy remains hampered by insufficient quantitative data from the field. We used 7 years of photo-ID mark-recapture data collected in eastern PRD, between Hong Kong in the East and Zhuhai/Macau in the West, to model the dolphins' habitat-use pattern, their spatial connectivity and social dynamics. Spatially, the dolphins display strong preference to areas with relatively natural coastline, within 1 km off the shore, where intensive man-made constructions and coastline alterations have not yet taken place; their habitat-use pattern is predominantly driven by their foraging needs. Over a long-term, individuals exhibit limited ranging and restricted dispersal (~10 km, only a fraction of the study area) with considerable fidelity to specific key habitats. Movement between core areas, although occurs, remain relatively infrequent. Socially, the dolphins form a complex and highly interconnected society with multiple (4-5) closely interacting social clusters. While the clusters partially overlap spatially, which contributes to maintaining social connectivity, they have notably different core areas corresponding to the key coastal habitats. Within a highly fluid grouping pattern, inter-individual associations are non-random but generally weak, with no significant differentiation between sexes or age classes. The temporal pattern of grouping and individual associations appears to be primarily governed by individual preferences to specific habitats and foraging grounds, rather than individual social bonds. However, the importance of dolphin key habitats and habitat connectivity has not been sufficiently recognized in local/regional coastal management planning and majority of these areas are not protected nor prioritized for future conservation. A major realignment of regional approach to conservation is urgently needed if the "urban dolphins" of the PRD are to escape local extinction.

Effects of anthropogenic sound on harbor porpoises (Phocoena phocoena) and harbor seals (Phoca vitulina): Masking and temporary hearing threshold shifts.

Anthropogenic underwater noise may interfere with, or 'mask', the acoustic communication signals of marine mammals. Even though noise often fluctuates in amplitude, only masking due to constant-amplitude noise has been studied in harbor seals and harbor porpoises. Consequently, the critical signal-to-noise ratios derived in these studies, when used in environmental impact assessment models, result in overestimation of masking effects of both natural and anthropogenic noise. To assess masking more realistically and obtain information about masking effects of variable-amplitude noise, we tested masking by white noise that was modulated in amplitude at different rates and varying in modulation depth and sound pressure level. The higher the noise modulation rate, the higher the masking, except for masking levels close to the unmasked thresholds. The gaps in the noise levels likely enable detection of the signals.

In addition to masking, anthropogenic noise may induce temporary and even permanent hearing threshold shifts (TTS and PTS) in marine mammals; thus, safety criteria are needed to protect their hearing. In harbor porpoises and harbor seals, susceptibility to TTS has only been tested for small parts of their hearing ranges. We tested TTS susceptibility for those parts for which no TTS information existed (i.e., 0.5 & 16-88.4 kHz for porpoises and 0.125-40 kHz for seals). Our preliminary results show that TTS susceptibility in porpoises is very frequency dependent, but in seals it is less variable except for the low frequencies. Once TTS susceptibility has been quantified for the entire hearing range of these two species, auditory weighting functions may be derived for cetaceans that echolocate at high frequencies and phocid seals.

The masking study was funded by the Joint Industry Program (JIP) of the International Association of Oil & Gas Producers. The TTS study was funded by the US Navy's Living Marine Resources (LMR) program.

Tidal drivers of harbour seal Phoca vitulina fine-scale movement, behaviour, and spatio-temporal distribution

Quantifying the effects of environmental conditions on the movement and behaviour of apex marine predators is crucial for understanding their ecology and informing conservation management. Recent evidence demonstrates that marine mammals utilise tidally energetic areas for important behaviours, such as foraging, however an understanding of how animals respond to changes in tidal conditions remains limited. This information is of crucial interest biologically to improve our understanding of the strategies used by marine predators to exploit energetically challenging conditions. It is also essential in an applied context, as the marine renewables industry target tidally energetic locations to install energy generating devices, raising concerns about potential impacts with marine mammals, such as collision risk. Between 2001 and 2007, 34 harbour seals *Phoca vitulina* (11 females, 23 males) were captured from three locations (Rømø, Denmark, and Lorenzenplate and Helgoland, Germany) in the Wadden Sea, an area boasting a high tidal range and fast water currents. Seals were instrumented with Global Positioning System (GPS) devices and Time-Depth Recorders (TDRs) to record data on their free-ranging movements and behaviour. Here, using a hidden Markov model (HMM) framework, we model these data against high resolution tidal information provided by the German Hydrographic Institute to investigate the influence of changing tidal conditions on the movement, behaviour, and spatio-temporal distribution of seals. We quantify the probability for seals to transition between behavioural states, given tidal phase, and model how their movement speed and heading varies in response to the strength and direction of tidal currents. This framework enables us to quantify within- and between-individual variation, key to obtaining greater understanding of population-level responses. Our results offer novel insights into how apex marine predators utilise and respond to variations in tidal conditions, providing important information towards improving our general understanding of seal ecology and deriving implications for conservation management.

Deep-diving northern elephant seals forage in temperature features measured in three dimensions by biologgers.

A crucial question in marine ecology, especially in a rapidly changing climate, is the influence of oceanographic processes on foraging success. Associations between marine predators and oceanographic features have been observed across species and systems. These studies have primarily used satellite-derived temperature or altimetry data to identify surface oceanographic features such as fronts and eddies; few utilize subsurface oceanographic data at the scale and resolution of an animal's behavior. Subsurface hydrographic data are especially important when considering deep-diving predators whose prey are further removed from near-surface oceanographic processes. We deployed time-depth recorders or conductivity-temperature-depth data loggers measuring in situ temperature on 154 adult female northern elephant seals (*Mirounga angustirostris*) between 2004 and 2010 to investigate the foraging behavior of a mesopelagic predator relative to temperature features in three dimensions. Horizontal temperature gradients were calculated from tag temperature measurements and foraging behavior distinguished from non-foraging behavior using transit rate and dive profile shape. Temperature gradients from near-surface to 250 m were significantly higher where seals exhibited foraging behavior than where they exhibited transit or drift dive behavior ($p<0.001$). Seals showed increased foraging behavior in primarily submesoscale temperature features (third quantile of horizontal extent of features < 20 km), scales which are challenging to resolve using satellite data. These analyses demonstrate a positive relationship between foraging behavior and variability in water temperature, providing evidence that deep-water prey congregate around such water column features. Recording behavior of a predator utilizing the understudied mesopelagic zone provides valuable insight into the distribution of prey relative to three dimensional oceanographic features, which also sheds light on the spatial foraging ecology of other more cryptic marine mammals, such as beaked whales, that similarly rely on mesopelagic prey.

An acoustic survey of beaked whale and Kogia in the Mariana Archipelago using drifting recorders.

During the 2018 Mariana Archipelago Cetacean Survey (MACS) a network of 8 drifting hydrophone recorders was deployed on the west side of the Mariana Archipelago with the goal of improving acoustic detection of beaked whales and *Kogia*. These Drifting Acoustic Spar Buoy Recorders (DASBRs) contained a two-element vertical hydrophone array at 150 m depth, sampling at 576 kHz for 2 min of every 5 min. DASBRs generally drifted from east to west between the Mariana Archipelago and the West Mariana Ridge. They collectively sampled from south of Guam north to Pagan along 1,449 km of drifting track during the 19-day sampling period. Periods of clicking were identified using the Click Detector Module within PAMGuard (version 2.00.14c), and each 2-min period was classified based on the spectral and temporal characteristics of the clicks. We found frequency modulated (FM) pulses characteristic of Longman's, Cuvier's, Blainville's, and Cross Seamount beaked whales (BWC), along with narrow-band high frequency clicks from *Kogia.* Collectively, these species were present in more than 500 (3%) 2-min files. The encounter rate was significantly higher for all species on the 5 tracks between Saipan and Pagan than for those drifts occurring farther south. Conductivity-temperature-depth casts conducted during the same period suggest differences in the oceanographic characteristics between the north and south regions that may impact foraging opportunities. Additionally, acoustic detections of beaked whales and *Kogia* on the DASBR tracks were much more numerous than those from the towed array efforts during MACS, highlighting the benefit of using autonomous platforms to augment ship-based surveys. The DASBR data will enhance understanding of the distribution of these species in the Mariana Archipelago and guide future survey efforts in the region.

Ship strike mitigation scenarios within a proposed shipping lane: A pre-emptive decision framework in the remote coastal waters of Pacific Canada.

Keen, Eric[1]; Wray, Janie[2]; Hendricks, Ben; Alidina, Hussein; Picard, Chris

Corresponding Author: ericmkeen@gmail.com

As marine shipping routes expand and their traffic rates increase, ship strike is a pressing conservation concern for whale populations throughout a growing percentage of the world's coastal zones. Unfortunately, given that strike modeling studies tend to be focused on established shipping routes in otherwise urbanized waters, ship strike science is often a descriptive exercise rather than a preemptive tool in coastal management. Here we report on three years of visual and acoustic monitoring of whales and vessel traffic within a newly proposed shipping route through remote but culturally, ecologically, and economically important coastal waters in northern British Columbia, Canada. We use these surveys to characterize whale and vessel distribution throughout the year, parameterize vertical habitat use models, and determine current strike risk within the proposed route. Collision models based on current shipping activity are used to estimate the current expected strike rate for fin whales (*Balaenoptera physalus*) and humpback whales (*Megaptera novaeangliae).* We then permute these models by escalating traffic rates according to the variety of proposals under consideration by local managers. We examine the effects of various mitigation measures, ranging from minor route alterations to seasonal and diel traffic control, on expected collision rates in each scenario. Our conclusions are framed within a decision framework to which coastal First Nations may refer as they contend with increasing interests in intracoastal shipping within traditional waters.

Implementing the Population Consequences of Disturbance (PCoD) Framework: A case study for marine mammals of the California current.

The increasing overlap of anthropogenic activities and marine mammal populations is of major concern in conservation and resource management, necessitating the development of decision frameworks and quantitative models to assess the population-level effects of disturbance. The Population Consequences of Disturbance (PCoD) framework is one approach, and requires assessing a population's likelihood of exposure and linking disturbance-induced changes in individual behavior with changes in health, vital rates, and population dynamics. Significant progress has been made applying the PCoD framework to individual species. For this study, however, we apply the PCoD framework to forecast the effects of disturbance for multiple species (or populations/stocks), using a simulated 3D seismic survey offshore southern California as a case study. We begin by using a decision framework (developed under the Office of Naval Research-funded PCoD+ project) to identify and prioritize species for which detailed population-level assessments are needed based on species-specific life history and residency patterns relative to survey activities. We also consider the duration and exposure probability for a given individual and population based on current distribution from sightings and tracking data for available species (e.g., blue, humpback, and Cuvier's beaked whales). Once priority species are identified, we use bioenergetic models to estimate the energetic costs of the seismic survey on female and calf/pup survival, and the resulting impacts on population dynamics. For species with limited data to parameterize the model (e.g., beaked whales), we provide guidance for how to apply existing data based on life history traits. The PCoD framework is a powerful tool to quantify the potential impacts of disturbance on a population, as well as explore the potential consequences of changes in disturbance, including environmental variation, on long-term population dynamics. Ultimately, this information can be used to inform practical risk assessments, as well as effective management and conservation strategies.

An investigation of the cervical gland secretion of the pygmy sperm whale (Kogia breviceps).

In odontocete cetaceans, chemoreception, including the senses of olfaction and gustation, are considered to be absent or highly reduced. It is also generally accepted that odontocetes lack specialized exocrine glands, which function in terrestrial mammals to produce chemical signals involved in communication. In 2016 and 2018, though, Keenan-Bateman and colleagues described a morphologically complex, cervical exocrine gland, associated with the false gill slit pigmentation pattern, in *Kogia breviceps*. The goal of this study was to provide preliminary chemical analyses of the cervical gland to gain insights into its potential functions through comparisons with known exocrine gland secretions of terrestrial Cetartiodactyla. We used multiple techniques, including seriate histochemical protocols, paired with polarized microscopy, to examine glandular secretory components; and scanning electron microscopy with energy dispersive X-ray spectroscopy (EDAX), and Raman and mass spectrometry, to provide elemental identification and quantitative composition of the secretion. Our results demonstrate a histochemical transition of the secretory epithelium, as cells mature and progress from the basal lamina to the lumen, where they slough off to form a holocrine secretion. Histochemical and EDAX results demonstrate that the secretion is a chemically complex mixture of protein, carbohydrate, and lipid. A highly unusual constituent of the secretion is crystalized uric acid. Crystallization of uric acid within mammalian tissues is usually considered pathologic, but these crystals appear to be an important, natural component of the cervical gland's secretion. Thus, like the specialized exocrine glands of terrestrial mammals, the cervical gland of *K. breviceps* is species-specific (absent in *K. sima*), constrained to a unique anatomic location, and morphologically and chemically complex. While the presence of uric acid is very unusual, together these attributes suggest the cervical gland produces a chemical signal that may be used in communication, although the function of that signal remains unknown and warrants further investigation.

Characterising injuries and pathology of common dolphin (Delphinus delphis) mortalities in the South Australian sardine fishery

Mortality of dolphins in fishing operations is a concern worldwide yet its magnitude is often under-estimated, as shown by studies of beach-washed carcasses. Linking evidence obtained during necropsies with fishing method is fundamental to understanding the extent of mortality. The South Australian Sardine Fishery (SASF) has operated in inshore waters since 1991, with mortality of common dolphins high prior to 2005. Our study characterised the injuries and pathologies associated with mortality in this purse seine industry. Forty-nine dolphins were collected from SASF (2006–2019). Necropsies were performed, and life history and skeleton fractures later evaluated. Neonates, calves and juveniles accounted for 59% of the sample. Of mature females (n = 14), 11 were pregnant and/or lactating. Body condition was robust 48 dolphins. Externally, bruising was observed in all dolphins. Net and rope marks were seen on 75% of dolphins, mostly on the head, trunk and peduncle. Broken/missing teeth were noted in 65% of dolphins, sometimes associated with superficial cuts. All dolphins had subdermal haemorrhaging (moderate to severe in 96%), particularly around the head. Deep haemorrhaging was common, including on occipital and flipper condyles, and organs. Abundant fluid was present in the thorax and abdominal cavities of half of the dolphins. Fluid and froth were observed in lungs of 98% and 38%, respectively. Acute, unhealed bone fractures were documented in 48% of dolphins, primarily for the skull, ribs and vertebrae, and most were associated with haemorrhaging. Stomachs contained partially digested prey in 61% of dolphins. We conclude that blunt trauma was the primary cause of death. Many dolphins also had mild heart pathology that in preliminary results showed little similarity to dolphins from Eastern Tropical Pacific tuna purse seining, a different method from SASF. Future research includes investigating South Australian beach-washed carcasses in relation to the characteristics described in our study.

Novel, non-invasive methods for neurophysiological monitoring during rest behavior in phocids.

One of the least understood physio-behavioral states for marine mammals is how and when they sleep, especially at sea. Studies examining sleep and rest in wild animals have traditionally relied on either behavioral observations exclusively or invasive surgical procedures. This study utilizes and develops two novel, non-invasive methods to investigate the neurophysiology of rest in phocids. It represents the first application of cerebral near-infrared spectroscopy (NIRS) on a northern elephant seal (n=1) as well as the first non-invasive electroencephalography (EEG) recordings of pinnipeds (n=5) using surface-mounted electrodes. Rest categories included inactive periods for dry-docked and submerged seals, as well as sedation for veterinary examination. NIRS recordings were performed on a freely-swimming wild juvenile elephant seal temporarily housed in a 5-foot pool at Long Marine Lab. NIRS data during 52 repetitive, restful (low-activity, often stationary) dives in the elephant seal revealed that peripheral vasoconstriction was insufficient to maintain constant levels of brain oxygenation, resulting in a mean decrease of -3.74 µmol Hb_{Oxy}*L^{-1}*min^{-1} (mean de-oxygenation rate weighted by dive duration with SD=±10.7 µmol Hb_{Oxy}*L^{-1}*min^{-1}). Furthermore, brain oxygenation does not monotonically decrease during a dive, possibly due to the release of additional pulsed oxygen stores. EEG recordings performed on five anaesthetized northern elephant seals investigated brain wave patterns during Telazol-induced anesthesia (with and without isoflurane maintenance), tested electrode configurations for future field applications, and revealed periods of delta slow wave activity closely resembling slow wave sleep in humans, but also periods of lower amplitude EEG characteristic of waking. In conclusion, variability in blood volume, oxygenation, and electrical activity during these different rest states suggests that the phocid brain is actively engaged in restorative mechanisms during sedentary periods that may explain both the ability and imperative of diving mammals to sleep during long transits at sea.

Booth in a box: An innovative tool to help right whales (Eubalaena glacialis).

There are approximately 411 North Atlantic right whales in the world, of which around 100 are breeding females. The time to act for this species is now. The Year of the Right Whale is a project whose mission is to protect the North Atlantic right whale through celebration, education and action. The project consists of social media outreach, in-person events and fundraising initiatives to engage the public in learning about right whales and supporting recovery efforts. We will evaluate our efforts in 2020, when we reflect on our successes and hopefully have made progress on our goal of protecting North Atlantic right whales with a measurable decrease in threats to the species. A key strategy used in this campaign is the innovative "Booth in a Box," which includes tools to educate the public about right whales and engage them in protecting them. These include a right whale model, baleen/feeding activity, children's activity booklet, banners with facts, interactive games and talking points for the person staffing the table. This tool is freely available to organizations, whale watch companies, students, etc. to be used in fairs, festivals, schools and other venues. This will enable these organizations to provide an interactive, educational booth that can be staffed by a volunteer or other interested party, which provide booth visitors with concrete actions they can take to protect right whales. This presentation will discuss the components of the Booth in a Box, and successes and lessons learned so far.

Interactions between small-scale fisheries and marine mammals in the Eastern Mediterranean: Case studies from the South Adriatic and the Levantine Sea.

In the Eastern Mediterranean Sea, bycatch rates are unknown, underestimated or seriously underreported, while information on fishing effort and marine mammal populations is widely absent. Yet, fishery is considered as one of the main threats on marine mammal populations in the Mediterranean Sea. It is, therefore, crucial to evaluate the magnitude of this threat to reveal possible impacts on the regional population status. The current pilot study aims to assess the extent of the interactions between small-scale fisheries and marine mammals in the Eastern Mediterranean Sea and intends to delve into the unexplored research niche that exists in the region; case studies from the Levantine Sea (Antalya Bay, Turkey) and the South Adriatic Sea (Montenegrin/Albanian coastline) were examined. The following methodology was chosen, representing a mix between quantitative and qualitative data-gathering: i) interviews with local fishermen, ii) spatial data on marine mammal distribution and iii) GPS logger data on small-scale fisheries operations. ArcGIS was used for habitat and fishing effort mapping. Overlap was observed between the core zones of targeted species distribution and the fishery territories in certain occasions. Gillnetting is the fishing method that was mostly implicated in bycatch in all study sites. The resulting overlap between fishing operations and marine mammal distribution poses a threat towards both directions: higher risk of species entanglement and economic burden on fishermen due to net destruction. At the same time, it reveals possible foraging grounds for marine mammals since in these areas there is high prey abundance. Lastly, by identifying the overlapping zones, specific management and conservation actions shall be proposed, with the aim to reduce bycatch pressure on key populations.

Interpreting multiple types of geospatial scientific information to protect marine mammals: A practical guide for decision-makers.

Marine mammal protection is increasingly being carried out in a spatially explicit management context. Examples include Biologically Important Areas in the United States, the Marine Noise Registry developed under the European Marine Strategy Framework Directive, and the international effort to identify Important Marine Mammal Areas led by the IUCN Marine Mammal Protected Area Task Force. In turn, the scientific community has responded by advancing the generation and collation of geospatial data, and developing geospatial analytical techniques to inform these efforts, including habitat models, satellite telemetry data, genetic information, and expert opinion. The protection of marine mammals is best informed through the collective consideration of these multiple types of geospatial information; however, differences in methodologies, spatial and temporal scales, and associated caveats and uncertainties can make it extremely challenging for decision-makers to interpret and apply them collectively in their decision-making. To help address this challenge, an international collaboration of scientists has developed an interactive and practical guidance

document for decision-makers to assist in the evaluation of different types of geospatial scientific data, and to aid in its collective interpretation and application to marine mammal protection efforts. Accompanying the guidance document, interactive ESRI Storymaps provide decision-makers with hands-on opportunities to become familiar with different types and qualities of geospatial data, and to work through case studies demonstrating how geospatial data may be integrated to inform a variety of decision-making contexts. The intent behind the guidance document is not to provide yet another management tool, but rather to be broadly applicable to a wide variety of protection processes across regions and scales. The guidance will therefore help to ensure that geospatial scientific information is more comprehensively and effectively used in marine mammal protection efforts.

Annual variation in female humpback whale (Megaptera novaeangliae) pregnancy rates, calving rates and physiological state linked to changes in prey abundance in the Gulf of St Lawrence

The consequences of shifting environmental conditions as a result of climate change are of concern for many marine mammal populations worldwide. Data on the reproduction, health and energetic status of individual animals from long-term sampling efforts can help to monitor these potential consequences. Steroid hormones were extracted from blubber biopsy samples (n = 185) collected from photo-identified female humpback whales (*Megaptera novaeangliae*) between 2004 and 2017 in the Gulf of St Lawrence, Canada. Blubber progesterone was quantified as a marker of pregnancy status. Cortisol, a glucocorticoid hormone involved in the long-term regulation of both energy intake and storage, was quantified as an indicator of physiological state. Annual calving rates declined over the study period (range between 0.05 and 0.52 with an overall decrease of 0.02 per year), and were positively correlated with pregnancy rates in the previous year (linear model: $p < 0.001$). The decline in observed calving rates could therefore be the result of decreased pregnancy rates rather than a reduction in calf survival.

Environmental data were collated from satellite images (phytoplankton bloom magnitude), the Atlantic Zone Monitoring Program (zooplankton biomass and copepods abundances) and fish stock assessments (herring and mackerel). A generalised additive model (GAM) showed that blubber cortisol concentrations were negatively correlated with the magnitude of the spring phytoplankton bloom, the summer zooplankton biomass, and the herring spawning stock biomass in the previous year (GAM: $R^2 = 0.3$, deviance explained = 38%). These relationships were strongest for pregnant and immature females showing that the highest cortisol concentrations, indicating increased lipolysis, were measured in years of reduced primary productivity and prey abundance particularly for these reproductive classes. A better understanding of baleen whale reproductive and physiological state, and their links to environmental conditions is fundamental to appreciate how populations will be affected by changing environments in the coming decades.

Common minke whale calves (Balaenoptera acutorostrata) in high latitudes of the Northeast Atlantic during winter months

Common minke whales (*Balaenoptera acutorostrata*) occur throughout the North Atlantic, yet their seasonal movements and the location of important habitats are poorly known. Adults and sub-adult minke whales are sighted throughout the year in Irish waters, however mother-calf pairs are rarely observed during winter months. A common hypothesis describes autumnal migration to low latitude breeding and calving grounds, although this has previously been challenged. Herein we report high latitude winter sightings of unweaned minke whale calves in offshore waters of the northeast Atlantic, almost 200 km from the Irish coast. These sightings support the hypothesis that some individuals within a population forego the typical migration route by over-wintering and

perhaps calving at high latitudes in the warmer waters of the North Atlantic Drift. The inherent difficulties of offshore visual data collection during winter months challenges our understanding of species distribution and habitat use. Thus, rare sightings such as these reported are vital for understanding animal movement ecology and implementing appropriate conservation measures.

Migration patterns of eastern North Atlantic humpback whales revealed by satellite tracks

Humpback whales undertake long seasonal migrations between high latitude feeding and low latitude breeding grounds. Whilst whales in the northeast Atlantic follow this pattern, fundamental questions about their migrations and their year-round distribution remains unknown. During the last nine winters, humpback whales unexpectedly aggregated in coastal waters of northern Norway, likely in response to a shift in overwintering herring distribution. This might constitute a new or re-established stop-over site on the southward migration of whales feeding in the Barents Sea. We present the first direct observation of eastern North Atlantic humpback whale migration to breeding grounds based on Argos derived tracks. We obtained tracks from individuals instrumented during winters 2015-2019 on the coast of northern Norway (19) and on the Barents Sea feeding grounds in September 2018 (10). Part of the individuals from the Barents Sea headed towards the Norwegian coast, while others traveled directly towards the Caribbean. Recorded destinations spanned from the Dominican Republic to Dominica, with large variation in observed migration routes between Greenland and the Norwegian shelf. Importantly, the migratory timing of these whales appears off-beat, as they arrive delayed in regards to the main breeding season described for the Caribbean. This mismatch in timing suggests that individuals may travel to behaviorally distinct population segments within the southeast Caribbean with a later breeding season. Furthermore, some individuals were observed to turn back immediately or before arriving to known breeding grounds. This suggests that these individuals might not breed that given year but instead migrate to give birth. Therefore we assessed individual re-sighting history and sex, as well as pregnancy status of the tracked individuals. Finally, we compared our results to observations from the known distribution range in the eastern North Atlantic, which was so far primarily based on photo identification.

Photo identification plays a major role in endangered species research and conservation, and recent developments in artificial intelligence promise to increase the efficiency of matching photographs to known individuals. At the last Society for Marine Mammalogy conference, we presented on the Kaggle data science competition to automate the identification of endangered North Atlantic right whales based on 7,000 aerial images. The winning algorithms developed by

deepsense.ai were able to identify individuals with 87% accuracy using a series of convolutional neural networks. Since that time we have brought in many more collaborators as we move from prototyping to production. Leveraging the existing infrastructure by Wild Me, the developers of Flukebook, we are creating a website platform that allows biologists with no machine learning expertise to automatically identify right whales. New models will be generated using both the winning deepsense.ai algorithms and the Wild Me HotSpotter algorithm (used for humpbacks, jaguar, giraffe, and other species). Given the morphological similarity between the North Atlantic right whale and closely related Southern right whale, our goal is to create an automatic identification system that will benefit right whale researchers worldwide. The updated dataset will incorporate the largest long-term photo-identification catalogs including over 400,000 images from the United States and Canada curated by the New England Aquarium; 12,311 images from Australia from Curtin University; 8,461 images from South Africa from the University of Pretoria; 8,952 images from Argentina from the University of Utah; 5473 images from Brazil from Instituto Australis; and 2,913 images from New Zealand from the University of Otago. We hope to encourage researchers to embrace data collaboration and computer vision to increase our understanding of wild populations

High risk, high reward: Sex-specific foraging and life history strategies of northern elephant seals.

Sexual selection and intraspecific niche divergence can result in behavioral, morphological, and physiological differences between the sexes. These sex-specific differences often lead to diverse strategies for maximizing fitness. Northern elephant seals (*Mirounga angustirostris*) are an extreme example of sexual dimorphism, as males possess dramatic secondary sexual characteristics and are nearly three times the size of females. Using a large comparative dataset of male (n=39) and female (n=152) seals, we examined sex-specific foraging and life history patterns exhibited by northern elephant seals and evaluated the costs and benefits of different behavioral strategies. We analyzed 37 metrics relating to the geospatial patterns, diving behavior, and foraging success of each seal. We found little to no overlap between male and female foraging strategies (ANOVA, $p \leq 0.05$), indicating that the sexes occupy different ecological niches. Males have small foraging areas in which they undertake benthic foraging dives (mean: 230 ± 95m) on the continental shelf. In contrast, females have large foraging areas and undertake deep pelagic foraging dives (mean: 550 ± 44m) to capture mesopelagic prey in the open ocean. Males are extremely consistent in their at-sea behavior, while females exhibit seasonal variability in behavior. These sex-specific differences appear to result in a trade-off between foraging success and survival. Males have higher foraging success (measured as greater mass and energy gain; ANOVA, $p \leq 0.05$), yet also have a higher at-sea mortality rate (males: 44%, females: 13%). Males likely adopt a riskier strategy to attain and maintain the large body sizes required to compete for mating opportunities, while females adopt a risk-adverse strategy that maximizes lifetime reproductive success. The balance between risk and reward is a fundamental selective pressure shaping the life history of northern elephant seals, driving intraspecific differences in behavior between the sexes of this extremely dimorphic species.

Behavior of adult female and its weaned calf in the Amazonian manatee after releasing into the river.

The Amazonian manatee (*Trichechus inunguis*) is endemic to the Amazon region. Amazonian manatees are difficult to observe in natural environments, due to the water turbidity and their solitary, cryptic behavior. In this study, we monitored the behavior of adult female and its weaned male calf after releasing into the river, in order to investigate the interaction between mother and its weaned pup. Adult female was rescued and kept in captivity for 10 years and its calf was born

in the semi-captive lake, 2 years in captivity. We confirmed that the male calf was already weaned before releasing. Two types of animal-born digital recorders were attached to the adult female in order to monitor the behavior and underwater sounds, and behavioral recorder was attached to the male calf. Recording duration was 2.5 and 0.5 days in adult female and male calf, respectively. Four hours after releasing, male calf seemed to separate from his mother. He showed repeated diving, while adult female stayed shallower depth. After 13 hours, he seemed to rejoin with his mother. Vocalizations were confirmed in the adult female, and it continued for up to two days. But there was no vocal response by another manatees. We considered that mother seemed to have a high motivation to communicate with its calf after weaning. And weaned calf also seemed to have a motivation to reunite with his mother, while he showed join and separate without vocal response to his mother.

First-ever vocalization study of wild Indo-Pacific Bottlenose dolphins (Tursiops aduncus) at Jeju Island, Republic of Korea: Whistle characteristics and its response to ambient noise.

Kim, Mi Yeon[1]; Koshima, Shiro[2]

(2) Wildlife Research Center of Kyoto University, Kyoto, Japan
Corresponding Author: miyeonkim88@gmail.com

Dolphin vocalization mediates complex social behavior and navigation while obtaining environmental information. Indo-Pacific bottlenose dolphins, *Tursiops aduncus*, produce numerous type of acoustic emissions including clicks, pulsed signals, and tonal calls. Tonal calls are the diverse repertoire of whistles and signature whistles for communication which exhibits a variation between geographically separated populations of *T. aduncus*. Additionally, recent studies have shown the importance of both natural and anthropogenic ambient noise on the whistle production of dolphin in response to signal masking. First, the baseline study of whistle characteristic was conducted by measuring the following: whistle class, contour inflections, harmonics, beginning frequency, end frequency, maximum frequency, minimum frequency, and duration. Whistles occurred in the frequency range of 0.011-23.34 kHz (mean 6.75-11.7 kHz) with durations of 0.32 – 1.86 s. The whistle characteristics are significantly different from the closely located *T. aduncus* population in Japan and showed a less whistle contour complexity. To further investigate the whistle production, we examined the effect of concurrent natural and anthropogenic ambient noise (both the broadband signal (20 Hz–24 kHz) and one-third-octave band levels centered on frequencies from 20 Hz to 22.4 kHz). The linear regression analysis indicated that the minimum frequency had significant positive relationships with the ambient noise present at the time of the whistles. Also, an increase in anthropogenic noise mainly caused by dolphin-watching vessels below the dolphin's call bandwidth resulted in shifting up of the produced whistles on the minimum frequency, and reduction of whistle repetition. The noise induced change of dolphin acoustic behavior may reduce the overall effectiveness of communication. Additionally, the shift in whistle characteristic during a continuous disturbance by dolphin-watching vessels may result in group separation and significant loss of energy in efforts for group cohesion.

Fishing for change- development alternative fishing gear for saving the Vaquita

The Vaquita porpoise (*Phocoena sinus*) has almost been driven to extinction by incidental by-catches in gillnet fisheries in the Upper Gulf of California. The Mexican government has thus banned the use of gillnets in the entire distribution range of the Vaquita. To find alternative fishing gears for the enrolled gillnet fishers, a project developing vaquita-friendly fish pots was pushed forward by ECOFT (Expert Committee on Fishing Technologies) supported by the Mexican government and in collaboration with WWF Mexico. The aim was to create fish pots, as an alternative fishing gear to gillnets in the no-gillnet zone of the Upper Gulf of California. To ensure the best performance of the pots, an experiment was conducted testing three different baits available to the fishers. Three baits were selected and tested in the area of San Luis Gonzaga, Mexico. Fish attraction were recorded using GoPro cameras. The results showed that in daylight Flat-iron Herring proved to be the most effective bait, whereas the results from the night were inconclusive. In total three different pot types were tested, two floating and one bottom standing. The results showed that the bottom standing pot design had the highest fish catches but the species caught were very area dependent. During the trials the average catch per fishing journey was 25 kg. Total catches, however, can be improved by increasing the numbers of pots used, placing the pots at the best possible fishing

grounds and leave the pots in the water with optimal soak times. Thus if fishers are willing and capable of fulfilling these requirements, fish pots can turn out profitable and become a viable alternative to gillnets in the Upper Gulf of California. However, more trials are needed to conclude this.

Assessing cetacean presence and ocean noise in and around one of the busiest waterways in the world: The New York Harbor.

One of the most pressing concerns for marine conservation at national and international levels is increasing ocean noise from anthropogenic sources. Potential impacts range from acute injury to sub-lethal effects , all of which may have long term impacts on population viability. Along the Atlantic coast, NOAA has declared an Unusual Mortality Event (UME) for humpback whales, minke whales and North Atlantic right whales (2017-2019), which may be directly or indirectly related to anthropogenic impacts. Within the New York Bight, cetaceans have been documented with increasing frequency in recent years. However, there is currently only limited knowledge of the ambient noise environment and potential impacts, and particularly within the New York Harbor; the largest and busiest port on the Eastern Seaboard. SoundTrap ST300 recorders were deployed in the lower New York harbor area over a one-year period from 2018-2019. Both automated and manual methods were used to document cetacean species presence, distribution, and soundscape characteristics. To visualize measured sound levels at each location, broadband and third-octave band spectrograms were generated using the RavenX toolbox , and a quantitative assessment of median equivalent sound levels ($L_{eq\text{-}50}$) was conducted for each location. A variety of sound sources were identified including anthropogenic activity, natural biological noise sources, cetacean vocalizations, and fish vocalizations. Overall, anthropogenic noise was pervasive throughout the study area, and measured sound levels were elevated compared to other locations within New York (3-12 dB re 1µPa higher in low frequency bands). Therefore, cetaceans within the New Harbor are exposed to noise levels that are often associated with long-term physiological and behavioral effects due to anthropogenic sound. With the growing conservation concerns for cetaceans within New York waters, this project along with additional monitoring efforts will help to inform marine spatial planning initiatives to ensure sustainable ocean use.

Coordination is key: Vocal mechanisms underlying cooperation in dolphins.

Cooperation can be found across all levels of biological organization, from eukaryotic cells to social insects, as well as from baboons to humans. Yet studies have demonstrated that animals can behave in ways that function cooperatively without actively and intentionally cooperating. Previously, we have shown that bottlenose dolphins can understand their partner's role in a cooperative context by using a cooperative button-pressing task that requires precise behavioral synchronization. During this task members of a dyad were required to swim across a lagoon and each press their own underwater button simultaneously (within a 1 s time window), whether sent together or with a delay between partners of 1–20 s. We showed that individuals will work together with extreme precision, even when they have to wait for their partner. Here, we investigate how bottlenose dolphins use vocal signals to coordinate their behavior during these cooperative tasks. A male dyad was exposed to six trial phases that increased in task difficulty, ranging from the cooperative partners being sent together, to progressive delays between partners, to partners being unable to see one another when they pressed their buttons. We recorded the vocal behavior of the dyad during these tasks and used acoustic localization to determine how individuals used vocal signals when working together. Overall, the dolphins were more likely to exchange whistles prior to pressing their buttons during successful trial than during unsuccessful trials. Moreover, in phases that the dolphins found particularly difficult (as measured by success rate), they produced more whistles during successful trials than during unsuccessful trials. Bottlenose dolphins are well known for cooperating extensively in the wild and for their vocal flexibility. Our results suggest that vocal signals play a key role in coordinating their cooperative efforts.

Hormones reflect impacts of reproductive rest on subsequent pregnancy in Weddell seals

A season of reproductive rest increases chances that an adult female Weddell seal (*Leptonychotes weddellii*) will successfully give birth during the optimal timeframe the following year. To identify mechanisms linking offspring production to subsequent birth likelihood and timing, this study compares reproductive physiology between female Weddell seals that skipped pupping in the current year (skip females, n=45) and seals that recently gave birth (postpartum females, n=87). Serum concentrations of reproductive hormones (progesterone, estrogen, luteinizing hormone (LH), follicle stimulating hormone (FSH), and prolactin), body mass, and body condition (% lipid) were measured during the breeding period and early gestation. Field ultrasonography was used to image ovaries and detect early pregnancies, while range-wide censuses conducted the next year determined if females successfully gave birth. Progesterone and LH concentrations indicated that skip females ovulated before postpartum seals (mean date=November 19 vs. December 1), which corresponded with earlier parturition the following year. This forward shift in reproductive timing likely benefits seals that tend to give birth late in the season; later birthing seals ovulated at fewer days postpartum (χ^2=6.286, p=0.012) and were less likely to bring pregnancies to term (χ^2 =3.999, p=0.0455), suggesting tight temporal constraints on reproduction. During early gestation, serum concentrations of both progesterone and estrogen were higher ($F_{1,91}$=7.12, p=0.002; $F_{1,84}$=37.18, p<0.0001) in skip females than postpartum seals. While skip females were larger and fatter than postpartum females during the breeding period and early gestation (all p<0.0001), neither mass nor condition had a significant direct link to the likelihood of subsequent pupping. This study reveals that advanced ovulation timing and elevated sex steroid levels may enhance future reproductive success in Weddell seals that skipped pup production in a given year. Phenotypic plasticity in reproductive timing may be an important mechanism by which Weddell seals and other long-lived species buffer consequences of environmental change.

Fatty acids and diving development: Age class and sex differences in skeletal muscle fatty acid compositions the northern elephant seal (Mirounga angustirostris).

Fatty acid oxidation provides approximately 90% of energetic requirements in northern elephant seals (NES), yet little is known about the composition of their skeletal muscle fatty acids (FAs). Here, we report the skeletal muscle FA composition of NES within different age classes (adults {AD}, 1-year olds {1YR}, weaned pups {WP}) and sex. We analyzed 207 samples, spanning from 2012-2016, via GC-FID (WP n=102, 1yr n=32, AD n=73; male n=116, female n=91). A subset of 17 FAs, accounting for 93% of FAs, were normalized and transformed using an additive logratio transformation. Saturated fatty acids (SFAs) dominated muscle tissue (74%-78%) in all age classes, monounsaturated fatty acids (MUFAs, 10-15%) were the second most abundant and polyunsaturated fatty acids (PUFAs) were the least abundant (9-11%). Muscle tissue was predominantly composed of four FAs, C16:0, C18:0, C18:1n9c and C20:2 (78% total FA). Multivariate analysis (MANOVA) of FA groups (SFA, MUFA, PUFA) and chain-length/double-bond groups (MC-SFAC18:0, MC- MUFAC18:1 and PUFA) both indicated a significant effect of age class (F[4,248]= 14.40 p<0.0001; F[8,244]= 8.46,p<0.0001) but not sex. A significant effect for age class (F[4,388]=31.22,p<0.001) and sex (F[2,194]= 8.92, p<0.0001) was reported within the 17 FAs. Univariate statistics with post hoc tests revealed WP significantly differed from both AD/1YR across FA groups and chain-length/double-bond groups (p<0.0001 for all ANOVA/Tukeys; no sig difference for AD*1YR). Weaned pups drove the model sex effects through four FAs (ANOVA, F[1,1138]=1.21,p<0.000; Tukeys p<0.0001 C11:0, C16:0, C16:1, C17:0). WP differed from AD/1YR for 8 FAs (5 SFAs, 2 MUFAs, 1 PUFA, Bonferroni p<0.017) and differed from 1YR for 4 FAs (1 SFA, 2 MUFAs, 1 PUFA, Bonferroni p<0.017). These results suggest there may be a developmental difference in NES skeletal muscle FAs, possibly relating to the period of diving development that occurs between weaning and becoming a deep diving NES.

The 'Dolphin pump'? Dolphins mediate the translocation and recycling of allochthonous oceanic nutrient subsidies to coral reefs.
Kiszka, Jeremy; Nelson, James; Heithaus, Michael
Florida International University, North Miami
Corresponding Author: jeremy.kiszka@gmail.com

Cetaceans have the potential to consume considerable portions of total production in a system owing to their large body sizes, relatively high trophic levels, potentially high abundances, and high metabolic rates. In addition to their ecosystem roles as predators, cetaceans may also be important vectors of nutrient transport within or between habitats or ecosystems. Cetacean-mediated nutrients can enhance primary production and increase population sizes of lower trophic level organisms beyond what *in-situ* nutrient availability could support. We investigated the importance of two abundant tropical dolphins (*Stenella longirostris* and *Stenella attenuata*) around an Indian Ocean coral island in mediating the transport and recycling of nutrients in a nitrogen-limited coral reef ecosystem. Both species forage primarily at night on offshore epi- and mesopelagic prey and rest, travel and socialize along the outer slopes of the barrier reef. Based on field estimates of dolphin abundance combined with data on metabolic and excretion rates, we estimated that these species excrete 55,240 kg N yr^{-1} along the barrier reef. We determined the relative contribution of dolphin excretions and local organic matter sources to reef species using a Bayesian stable isotope mixing model based on particular organic matter (POM), seagrass and dolphin samples collected from the lagoon, reefs and open-ocean. Concentration-dependent percent contributions of each source were calculated for several fish species occurring in seagrass, inner reef and outer reef habitats. Model results suggest that dolphin-derived nitrogen contributes to 10-45% of the available production in the reef food web, and the primary route appears to be via nitrogen uptake by benthic producers. Our results are an order of magnitude higher than those published for other predators such as sharks on similar reef systems. Because dolphins bring offshore nitrogen to the oligotrophic reef systems, these fluxes may be critical to supporting the productivity of coral reef communities.

Statistical modelling for spatio-temporal population mixture for marine mammal species
Kitakado, Toshihide
, Tokyo, Japan
Corresponding Author: kitakado@kaiyodai.ac.jp

A new approach for spatio-temporal modelling is proposed for expressing population mixture over space and time. The study was inspired by the fact that migration patterns of multiple populations of marine mammal species could change over years, which implies that their spatial mixture patterns can accordingly be altered dynamically. The study was also motivated by another fact that understanding of spatial and temporal population structure is one of crucial components for developing better conservation and management plans. Some mixture models are constructed with simple random walk models or latent random fields accounting for spatio-temporal patterns in mixture probabilities. Here, use of genetic data is assumed, and an integrated likelihood function is employed for parameter estimation and model selection. Parameters of primary interest are those describing the population mixture. In addition, other many population specific parameters such as genetic allele frequencies are also estimated simultaneously. As a computational algorithm, software implementing a Laplace approximation with automatic differentiation is used. Better precision for estimating mixture pattern by models with spatial and temporal structure was demonstrated compared to conventional approaches. In addition to the theoretical aspects, the practicability to marine mammal species is discussed. Furthermore, a possible extension of model with use of other non-genetic sources of information such as morphometric data is examined to increase the information on the mixture since genetic differentiation between populations tend to be weak for marine mammal species.

Increasing the understanding of multispecies feeding events in marine hotspots by medium term instrumentation and tracking.

From a case study focusing on surface rate behavior of minke whales, we tracked a vhf tagged whale for multiple days in the waters of Svalbard , Norway, in 2007. The tag was deployed with the whale-tag-launcher ARTS (Aerial Remote Tag System), and the tracking was enabled by the radio directionfinder ADF setup with 4 yagi antennas. The VHF tag had a signal path of 240ppm, with 30ms signals length, which gave 2 to 6 signals during a surfacing. The data was sampled by a custom made voice recorder including a computer linked to a GPS and a microphone. However, the spinoff of this project was all what the tag did not record, and is what we would like to spotlight here. That would be the time between and the residence time at different Hotspots, and the mix of co-

species and other species in these Hotspots observed during the 116 hours tracking event. A total of 193 nm biological track was registered during these days, crossing the waters of Storfjorden, mapping in total 4 Hotspots, with a residence time varying between 2 hours to 12 hours, with all from very dense areas to wider spacing. Observations during the presence in Hotspots 1-4, included for all a number of minke whales and fin whales, while for some also humpback whales, white-beaked dolphins, harp seals, fulmars and kittiwakes. Multiple returning pattern of the tagged whale, was observed for Hotspot 1 (residence time 6 hours) and Hotspot 4 (residence time 12 hours). The development of tag sensors, tag attachment and tracking abilities the last decade, make now this type of ecological approach to an ecosystem using an individual tagged whale as a biological track possible, and would also be extensively strengthened while combined with prey field mapping and trawl sampling along the track.

Geometric morphometric analysis of sterna of harbor porpoises using spherical harmonics (SPHARM) reveal heteromorphic variation

Harbor porpoises are the only cetacean species, which reproduces in German waters of the North Sea and Baltic Sea. Previous morphometric analysis on the skull of harbor porpoises have shown that porpoises in the North Sea, the Danish Straits and the Baltic Proper can be separated into three different populations. This separation is supported by microsatellite and single-nucleotide polymorphism genetic analysis. However, morphological and genetic variation between subpopulations in the Baltic Sea are small. To establish and optimize a geometric morphometric approach and to increase the accuracy of a potential separation we used SPHARM (Sperical Harmonics; Center for Computational Biology and Bioinformatics, Indiana University School of Medicine) on a simple bone with high variability: the sternum of the harbor porpoises. Fourty sterna of porpoises found in the North Sea, the Danish Straits and the Baltic Proper were scanned using a computer tomograph (SOMATOM Definition AS, Siemens). The resulting picture files were processed with Amira (FEI, ZIB, Mercury Computer Systems, Berlin). A three-dimensional volume rendering of each bone was used to generate a triangular mesh surface. On this surface nine pre-defined homologue three-dimensional landmarks were positioned. The triangular mesh surface including the landmarks was used as a template for the SPHARM-models. SPHARM calculates a complex Fourier-Transformations of spherical harmonics coefficients used for a bone comparison based on principal component analysis. The results show allometric scaling and no separation of the three different populations, sex. Therefore, a geometric-morphometry analysis of the sternum of the harbor porpoise cannot be used to establish population differences based on this limited dataset. However, the methodology can now be implemented for other bone material and may allow for more morphological discriminative power for instance using the skull.

Whales, dolphins, fish, and boats: Why defining the contributors of soundscapes in Australian Marine Parks matters for policy and management.

Soundscape characterization of acoustic data results in information on the biological and anthropogenic contributors present within marine environments. Marine mammals and other soniferous species provide a unique view of the status and health of environments, such as marine parks, in which changes can be tracked through long-term monitoring. Quantifying the level of human activity in and around Australian Marine Parks is an essential component for managers concerned with enforcing restrictions on illegal activities. Understanding the degree of vessel activity at sea is challenging, especially for large

and remote parks. However, vessels have well-documented acoustical signatures and vessel noise is often omnipresent in coastal marine soundscapes. As an initial step to establishing a broader monitoring program, three SoundTrap 300 recorders were deployed for one month in two marine parks off of southeastern Australia between July and September 2018, one recorder in Cod Grounds Marine Park and two in Solitary Islands Marine Park (SIMP). Using Raven Pro 2.0, the hourly presence of humpback whale (*Megaptera novaeangliae*) song; delphinid clicks, burst pulses, and whistles; fish chorusing; and vessel noise was identified for both parks. Relative distance of vessel sounds were modelled to estimate the number of vessels within the boundary of SIMP. Results showed that humpback whales and snapping shrimp were continuously present, while delphinids were present more at night and were more often present in SIMP. Fish chorus patterns differed between parks. Forty-three discrete vessels were considered to have occurred within SIMP. Vessel presence inside of the park was greatest on weekdays (Tuesday through Thursday) between 05:00 and 18:00 AEST, peaking in the latter 3 hours. Individual vessels typically stayed in the park for less than one hour. These data develop new methods aimed at understanding vessel behavior and compliance as well as providing baseline information on marine biological activity.

Adapting nanopore (MinION) next generation sequencing methods to detect novel RNA virus genomes in Alaskan marine mammal species.

Emergence of RNA viral infections is a growing concern among North American marine mammal species. Morbillivirus (phocine and cetacean distemper viruses) and influenza A viruses are pathogenic, negative sense RNA viruses that cause serious infections in the respiratory, gastrointestinal and sometimes central nervous systems. In 2018, an unusual mortality event was declared for over 2000 grey seals (*Halichoerus grypus*) and harbor seals (*Phoca vitulina*) stranded along the Atlantic coast (NOAA UME 67). Preliminary diagnostic PCR indicates mortality was caused by phocine distemper virus (PDV). Influenza A was also detected, however, it is not considered the main cause of mortality. Preliminary detection of PDV and influenza A, using PCR diagnostic assays, have been observed in Alaskan marine mammals including PDV in sea otters (*Enhydra lutris*) and morbillivirus in a Steller sea lion (*Eumetopias jubatus)*. Existing viral diagnostic methods are not optimized for understanding genotypic variation, pathogenicity or transmission properties across different wildlife interfaces. We are analyzing complete virus genomes using Oxford Nanopore Technologies (MinION) to map virus variation among different geographical regions. MinION offers an inexpensive and portable means of genetic sequencing virus genotypes and host biomarkers in real time. Following an RNA extraction and purification protocol, we are using a panel of virus-specific primers in a multi-segment (MS-RTPCR) for influenza or tiling (RT-PCR) approach for PDV to obtain full genome amplicons as input cDNA in library preparation. Raw nanopore read data is processed and mapped to viral genomes using reference-based assembly, to generate consensus sequences for evolutionary analysis and virus genome annotation. Analysis of viral genome variation is crucial for understanding virulence, transmission, and susceptibility of marine mammal species to RNA viruses among different environmental interfaces. This data can be integrated into the evaluation of how ecological and physiological factors impact the health of marine mammal populations in Alaska.

Educating marine audiences about the benefits of rope-less fishing technologies

Klyver, Richard Zack
Blue Planet Strategies, LLC, Bar Harbor, ME
Corresponding Author: zackklyver@yahoo.com

Rope-less fishing technologies for fixed fishing gear could provide a long-term solution to the annual entanglement and death of dozens of large whales in US waters. Whales are especially vulnerable to the millions of fixed gear lobster and crab traps fished in the waters of New England, the Gulf of Maine, and from California to Alaska. The development and use of rope-less fishing gear systems may prove essential to the recovery of the endangered North Atlantic Right Whale, as their population numbers just 411 animals (2018 NOAA estimate). Photographic studies conducted by scientists have shown that 85% have signs of rope scars and necropsies of dead animals show that fishing entanglement is the highest documented cause of mortality.

A variety of rope-less designs concepts have and are being rapidly developed. The first may have been a system called the Fiobouy that was invented by Fiomarine systems in Tasmania, Australia in the 1990's. A Washington State non-profit engineering team called SMELTs, Sea Mammal Education Learning Technology Society collaborating with Teledyne technologies, and have built a lift bag system that is launched be an acoustic signal from the surface and inflates an airbag. Dessert Star Systems in California have completed an acoustic release control unit system and free rope-less fishing app for fishermen to track their gear. Many other systems are being developed around the world.

Feasibility of using reduced breaking strength ropes (1700 lbf) in fixed gear fisheries

Knowlton, Amy[1]; Werner, Timothy[2]; Kraus, Scott[3]; Malloy, Richard[3]

NOAA Fisheries, with guidance from the Atlantic Large Whale Take Reduction Team, is developing regulations to mitigate entanglement impacts from buoy lines on North Atlantic right whales (Eubalaena glacialis) which will include broad implementation of 1700lb breaking strength ropes in waters off New England. To evaluate the efficacy of 1700lb ropes we conducted studies to determine 1) if reduced breaking strength rope can ensure effective hauling of fishing gear and 2) whether entanglement complexity and injury severity is likely to be reduced for any whale that gets entangled in 1700lb ropes. First, we modeled hauling loads under normal fishing operations with OrcaFlex software to inform strategies for at-sea testing. We then conducted at-sea testing of "south shore sleeves", a rope strength modification developed by the South Shore Lobster Fishermen's Association in Massachusetts. Sleeves manufactured by Novatec Braids at <1700lb breaking strength were integrated every 40 feet into buoy lines of nearshore trap fisheries. This modified gear was used by eight fishermen on lobster gear, in waters up to 300 feet deep, and compared to adjacent gear rigged with regular strength buoy lines of ~3900lb breaking strength. No significant increase of gear loss was detected after a season of fishing with modified gear (8.5% control vs 11.8% modified gear loss) and all but one of the ropes parted during soaking versus hauling. In parallel, the Virtual Whale Entanglement Simulator showed how these ropes could be parted by whales while maintaining sufficient strength for typical fishing operations. Additional studies are underway with the offshore lobster fishery to evaluate deeper water gear configurations that would support the use of 1700lb ropes. In the years following rule implementation, careful documentation of rope length, entanglement complexity, injury severity and resulting fate of all entangled large whales will be necessary for evaluating effectiveness of this gear.

Decreasing sociality of male sperm whales (Physeter macrocephalus) with age.

Male sperm whales leave their natal unit before sexual maturity, and form groups consisting of males of about the same age. The sizes of male groups generally become smaller as the members get older. However, how group size decreases with growth is not understood. We examined the change in social relationships with growth among male sperm whales using photo-identification data obtained in the Goto Submarine Canyon and Nemuro Strait, Japan. We photographed flukes of whales for individual identification and measured the distance to the whales using a laser-rangefinder to estimate their body lengths. The correlations between network statistics calculated from association indices with body length were examined for 45 animals from which body length estimates were obtained more than once. All network statistics were negatively correlated with body length (Spearman's rank correlation test, $p<0.05$). Association strength continued to decrease as males aged, while maximum association indices and clustering coefficients declined rapidly when between 13 - 14 m long. However, our previous study found that large males can have long-term social relationships. Thus, males have less social life but do not become completely asocial as they age. Although the cue for changes in sociality is unknown, the decline at 13 - 14 m coincides approximately with sexual maturity and may relate to changes in the endocrine system such as testosterone level.

Occurrence of false killer whales in Ryukyu Archipelago including Okinawa Islands, Japan.

Kobayashi, Nozomi[1]; Okabe, Haruna[2]

Corresponding Author: n-kobayashi@okichura.jp

Although false killer whales are known to distribute throughout the tropical and subtropical waters in the world, the species is one of lesser unknown large odontocete. Using the data corrected in Ryukyu Archipelago from 1982 to 2019, we investigated the seasonal occurrence, the distribution, the water depth and the group size of false killer whales in this area. We analyzed the stranding data corrected between 1982 and 2019 as well as the boat sighting data corrected between 2007 and 2019. As a result, 10 stranding and 37 sighting records were confirmed within the years. According to both records, false killer whales were found only during winter to summer (December to August) and none of them was observed in fall (September to November) when the mode of occurrence was in the beginning of spring (February and March). 78% of all the sightings were confirmed in the water depth shallower than 350m. The estimated number of individuals in a group was 1 to 100 (Average=17.3). A total of 536 estimated individuals were observed in 37 groups and 90.3% of all the groups were groups of less than 40 individuals which shows similar trend reported in Hawaii and New Zealand. We identified 68 individuals with the photographs of distinctive scars or characters on their dorsal fins and all of them were observed only once within the 12 years of the survey period. In Hawaii and New Zealand, same individuals were observed several times in years. Our result indicating that the false killer whales in Ryukyu Archipelago are possibly migrating seasonally around this area and move to the other areas mainly during the fall seasons. Although, the results obtained basic information on false killer whales in Ryukyu Archipelago, further researches are essential to understand more detailed life history of this species in this area.

Observation of the periodontal tissue of Delphinidae.

Corresponding Author: kodera-r@tsurumi-u.ac.jp

Mammalian teeth are in the oral cavity and used to hold, cut, crush, and grind food. What plays an important role in these performances is not only the dental hard tissue, but also periodontal tissue that support the teeth. The periodontal ligaments are collagenous fibers that fill the gap between the roots and the alveolar bone (periodontal space) . The ligaments hold the teeth in the alveolar sockets and function as a cushion giving mobility to the teeth. In the odontocetes, the alveolar sockets are large for the size of teeth. This was assumed to mean the development of periodontal ligaments.

In the present study, we observed dolphins teeth roots, periodontal ligaments, and alveolar sockets with a light microscope for decalcified tissue section and micro CT. We used some samples of Delphinidae which died of accidents or diseases in some aquariums. As a result, the alveolar bone was crude and spongy like the cancellous bone. The lamina dura which is a hard layer of the alveolar surface was not observed and the teeth are attached directly to the spongy bone. These characters are not found in other common mammals. The periodontal ligaments were highly developed and composed of two layers. The inner layer fibers radially spread out from the cementum like humans and mice. On the other hand, the outer layer fibers penetrate the spongy bone and run in a complicated way. Between these inner and outer layers, a thick nerve fiber bundles were running that could not be found in human or mice periodontal ligaments. Therefore, we conclude that there is a possibility that the periodontal ligaments of dolphins are more sensitive than humans and mice.

Mixed-species groups of common dolphins and bottlenose dolphins in the Alonissos National Park, Greece.

Mixed species groups (MSG) occur among different mammalian species, ranging from related species to species belonging to different orders. MSG may enhance foraging and predator avoidance, or provide social benefits. These advantages, however, may not be equally distributed between the participating species. Although the habitat of Mediterranean common dolphins *Delphinus delphis* (Dd) and common bottlenose dolphins *Tursiops truncatus* (Tt) often overlaps, few reports exist of associations between these species. During boat-based visual surveys conducted in the summers of 2017 and 2018, we recorded 8 MSG of Dd and Tt in the coastal waters of the National Marine Park of Alonissos, Northern Sporades, Greece. These MSG accounted for 8 of a total of 29 Dd encounters (28%), and 8 of a total of

10 Tt encounters (80%). MSG, observed in non-consecutive days, were composed of 6–15 individuals, with a prevalence of either species. The longest observation lasted 94 min, though animals were associated when encountered and remained associated when left. Of a total of 471 min of MSG observations, 125 min (27%) included both species engaged in the schooling and chasing of epipelagic fish (possibly sardines) near the surface. Observations, occurring over depths ranging between 3 and 250 m, and distances from shore ranging between 3 and 3720 m, also included synchronous diving or travelling. The largest MSG (12 Dd, 3 Tt) included one Dd calf and one Tt juvenile (the latter being observed swimming in a tight formation with adult common dolphins, and bowriding with them). Future research should focus on the reasons behind these associations, their potential benefits, the occurrence of actual cooperation between the two species, and whether MSG may occur as a consequence of common dolphin low and declining abundance.

Diving apart together: Exploration of vertical call propagation in long-finned pilot whales.

Staying in touch can be of vital importance for animals that live in social groups. To keep contact, far-reaching acoustic signals can be critical, especially when the habitat is dark or cluttered with vegetation. Many deep diving odontocetes live in long-term stable social groups at the surface. However, these groups temporarily separate when they start foraging individually at depth. Odontocetes are well-known for their vocal behaviour, but are their calls detectable over large vertical distances? We combined theoretical and empirical investigation to investigate if calls can be used for detecting group members in long-finned pilot whales (*Globicephala melas*). First, we used acoustic propagation modelling to investigate the potential for call detectability over the distance that our study animals were separated. Second, we verified our propagation model with acoustic recordings from simultaneously tagged pilot whale pairs in the same social group. Finally, we investigated how call characteristics and environmental features at the producer and the receiver were correlated to call detectability on the tag. Our results showed that long-finned pilot whales can indeed use calls to detect each other when vertically separated. Predicted call detection was correlated to variation in call characteristics such as duration and amplitude, while ambient noise levels also affected detection. Combined, our results reveal how acoustic signals can aid sociality and how different acoustic features can contribute to optimal signal transmission in a deep-diving whale. Since ambient noise levels in the ocean have increased due to anthropogenic activities, it is important to get more understanding of the acoustic detection between foraging pilot whale group members and how their behaviour might be affected by the changing ambient noise.

Visual, tactile, and acoustic interactions among captive Belugas (Delphinapterus leucas)

Belugas (*Delphinapterus leucas*) exchange distinct pulsed sounds, called "creaking calls (Mishima et al. 2018); however, information about their visual and tactile interactions are limited. We compared visual, tactile, and acoustic interactions among captive belugas to reveal how belugas use such communications. We obtained 14-h recordings via simultaneous video and stereo sound recordings for 11 days from two adult females and one juvenile male in 2015 and from one juvenile male and one female calf in 2018 using two hydrophones at Shimane Aquarium, Japan. An initiator and a receiver were observed for visual and tactile behaviors. Furthermore, an initiator who produced the first creaking call and a responder who called back by creaking call within 1 s were identified using time difference in sound arrival. Visual (pair swim, head jerk, mouth open, flee, face, watch, pass-by, approach, and leave), tactile (bite and contact), and other behaviors (play catch) were significantly higher between calves than between an adult and a calf and between adults (Kruskal-Wallis test: $x2 = 32.66$, 38.21, and 17.73, respectively, $p < 0.001$, Tukey-Kramer HSD test:$\alpha = 0.05$). In contrast, sound exchanges were significantly higher between adults than between others (Kruskal-Wallis test: $x2 = 27.24$, $p < 0.001$;

Tukey-Kramer HSD test: $\alpha = 0.05$). Time differences between the first and the next creaking calls (call-call response) were significantly shorter than those between a creaking call and the next behavior (call-behavior response), between a behavior and the next creaking call (behavior-call response), and a between behavior and the next behavior (behavior-behavior response) (Mann-Whitney U test with Bonferroni correction: $p < 0.01$), implying that belugas respond to the creaking calls of others by creaking calls, and not by other behaviors. Overall, belugas maintain their relationship by sound exchange among adults and by visual or tactile behaviors among calves.

First report of striped dolphin (Stenella coeruleoalba) strandings due to dolphin morbillivirus in Greece.

In the past 30 years cetacean morbilliviruses (CeMV) infections have occurred in many marine mammal populations around the world. In the Mediterranean Sea, two major episodes of mortalities due to *dolphin morbillivirus* have been reported in striped dolphins (*Stenella coeruleoalba)* in the years 1990-1992 and 2006-2008. In this report we present the resurgence of *morbillivirus* in the Greek coasts in the year 2018. Unusual strandings of 70 striped dolphins occurred between April and October 2018 in the Aegean and Ionian Sea, East Mediterranean. Fourteen striped dolphins (12 males and 2 females) stranded alive; they were calves or juveniles (0,80 - 1,60m tbl). All had similar clinical signs, sush as disorientation, swimming and diving impairment, tremors, depression and lethargy. Despite supportive first aid treatment, within a few hours all animals showed severe neurological signs, e.g convulsions, seizures, and died. Full necropsy and tissue sampling were feasible in 12 animals. These dolphins showed moderate body nutritional condition and empty stomachs. Gross lesions were mainly found in the central nervous, respiratory, lymphoid and digestive systems. Heavy parasitism was present in 7 animals. Brain, lung, kidney, liver, lymph node, spleen, heart and skin samples were taken for histopathological and virological testing. Histopathology consistently revealed lesions characteristic of morbillivirus-associated bronchointerstitial pneumonia and non-suppurative meningoencephalitis. Inflammatory and degenerative lesions in liver, intestine and lymph nodes were also frequent findings. Samples from nine dolphins were examined using a real-time RT-PCR targeting the P/V/C gene of morbillivirus. The assay was strongly positive in brain and lung of all (9/9). Sequencing of a 359bp amplicon showed 99% identity with homologous genomic regions of dolphin morbillivirus (DMV) strains. These findingssupport the diagnosis of a fatal acute and subacute DMV infection in the striped dolphinpopulations of the Eastern Mediterranean Sea for the first time. Further research to characterize the virus strain and its epidemiology is needed.

An evaluation of the ecological needs and effects of a potential sea otter reintroduction to Oregon, USA.

From the mid-1960's to early 1970's, managers translocated sea otters (*Enhydra lutris*) from coastlines along southwest and southcentral Alaska

to regions where sea otters were extirpated during the Maritime Fur Trade. Translocations to Southeast Alaska, British Columbia and Washington were successful and have led to growing populations. The translocation to Oregon was not successful, as sea otters disappeared shortly following release. There is renewed interest in reintroducing sea otters to Oregon. Managers seek improved understanding of the potential for coastal habitats to support sea otter populations and factors likely to affect translocation success. We meet this need by investigating the population potential for sea otters in Oregon. We adapted and applied a recently-developed model of habitat-specific carrying capacity (*K*) for southern sea otters to estimate spatial variation in potential sea otter abundance (at equilibrium). The habitat-based *K* model predicts equilibrium densities at small spatial scales as a function of a suite of habitat features (substrate type and bathymetric profiles) and environmental variables (kelp abundance and nearshore productivity). Areas of high predicted population potential were related to a range of human activities (i.e. fisheries effort, protected areas) to assess their degree of spatial proximity and overlap. We predict a total carrying capacity of 4,665 (95% CI: 1,487, 10,771) sea otters in Oregon. We found more suitable habitat along the southern coast, from Coos Bay to the Oregon-California state border, near a marine reserve and high crab fishing effort. We anticipate minimal interaction between sea otters and human activities on the central and northern coastlines due to the region's relatively lower predicted sea otter densities. This study provides the first carrying capacity estimate of sea otters in Oregon. Results could inform and support the reintroduction decision-making process, and help set targets and expectations for sea otter recovery and future research in Oregon.

Changes in sei whale feeding habits in response to fish species replacement in the western North Pacific during 2002-2018.

Konishi, Kenji[1]; Isoda, Tatsuya[1]; Nakai, Kazuyoshi; Tamura, Tsutomu[2]
(1) Institute of Cetacean Research, Chuo-ku, Japan

Western North Pacific sei whales *Balaenoptera borealis* feed on a wide spectrum of prey species such as zooplankton and small pelagic fish. The prey availability of sei whales is highly dependent on small pelagic fish transported into offshore waters of the western North Pacific by the Kuroshio Current. Japanese anchovy *Engraulis japonicus* and Japanese sardine *Sardinops melanostictus* are important prey species for sei whales in this region. These fish species fluctuate in occurrence and abundance in decadal scales. Recent fisheries catch statistics show that Japanese anchovy was replaced by Japanese sardine during the last decade in the western North Pacific. We hypothesized that, given their greater availability, Japanese sardines should be the predominant prey species for sei whale in the recent years. This study investigates the changes in feeding habits of the sei whales in response to decadal-scale changes in prey species. The study was based on the analysis of stomach contents of sei whales sampled by the Japanese Whale Research programmes during the 2002-2018 summer seasons. The prey species of sei whale in the 2000's was diverse including Japanese anchovy, copepods (*Neocalanus plumchrus, N. cristatus*), euphausiids and mackerels (*Scomber japonicus*, *S. australasicus*). The occurrence of Japanese anchovy in the stomachs decreased after 2011, and the Japanese sardine became the predominant fish prey species after 2013. In fact, in 2017 and 2018, the diversity of prey species decreased and the Japanese sardine became the most dominant prey species for sei whales. Changes in the diversity of prey species in sei whales reflected changes in the availability of prey species through the years. As expected, the intensive feeding of sei whale on Japanese sardine in the last decade, especially in 2017 and 2018, reflected the greater abundance and availability of this fish species in the western North Pacific.

Group composition and social behavior of migrating Steller Sea Lions on a haul-out in Hokkaido, Japan.

Corresponding Author: kooriyam@rakuno.ac.jp

The Asian stock of Steller sea lions (SSLs) reproduces at rookeries in Russia from June to September, and the group migrates to the Hokkaido coast from October to May every year. However, little is known about how the group is maintained and socially composed except that the mother-infant relationship continues during the migration period. In this study, we characterized the group composition and social behavior of SSLs during their migration. SSLs use a haul-out (tiny island) to rest in the waters off Otaru, Hokkaido, Japan between feedings on herring from January to March. We continuously observed SSLs on the haul-out using a 24-hour fixed-point video camera for 55 days. We analyzed the number and hourly pattern of landings and entry into the water at the haul-out. We also classified the groups into types by comparing the group type with that seen at and around the rookeries. The social behavior of the

SSLs was classified and the frequency of the behavior was analyzed. SSLs became active and entered the water at sunrise around 0600–0700, and they returned to the haul-out at sunset at 1700–2000. The average number on the haul-out changed from 65 to 34, from January to March. It was revealed that the SSL group types were similar to those in the rookeries. We named the groups Bachelor-like (a dozen bulls only), Idle Bull-like (a few bulls), and the Harem-shifted group (several bulls, 5–10 females and 5–6 pups). Affiliative behavior was frequently seen between mothers and pups in the Harem-shifted group. Threatening behavior was shown as territorial behavior against SSLs from the haul-out. In the present study, we clarified the group composition and sociality of SSLs during migration, and showed that some SSL groups may be sequential between the Russian rookeries and the Hokkaido haul-out.

Revelations from an aerial perspective: How hungry whales work smarter not harder.

Humpback whales are well known for their exceptionally long pectoral fins. To date, most studies that have addressed this have considered their role in shallow water navigation, rapid acceleration, and increased maneuverability. In this study, we document a novel behavior in which humpbacks use their pectorals during bubble net feeding at salmon hatchery release sites and surrounding areas. Specifically, we analyzed video footage and photographic sequences of two whales to assess the use of humpback whale pectorals during foraging events. Innovative technology has enabled aerial perspectives that greatly enhance our understanding about how these dynamic animals aggregate, capture, and manipulate prey. From aerial footage, we found a previously undocumented technique regarding the use of humpback whale pectorals during a bubble net feeding event. We defined this technique as "pectoral herding", with two methods of execution: "horizontal pectoral herding" and "vertical pectoral herding". We believe that the whales we observed used a bubble net to corral hatchery-released salmon, followed by directed movements of their pectorals to establish a secondary boundary that further condenses the prey field, increasing foraging efficiency. These observations demonstrate that prey aggregation and capture is not limited to movements of the head, caudal peduncle, and tail flukes. Our results also provide evidence of behavioral plasticity and suggest considerable variation among individual humpback whale foraging strategies. Further investigation would enhance our understanding about whether the pectoral herding technique is used as a principle foraging tool across the species as well as the conditions that promote its use.

Cetacean Virtopsy: 3D surface and radiological scanning and reconstruction for postmortem investigation

Kot, Brian Chin Wing; Tsui, Henry Chun Lok
City University of Hong Kong, Hong Kong, Hong Kong S.A.R., China
Corresponding Author: briankot@cityu.edu.hk

In the course of the pioneering virtopsy-driven stranding response program in Hong Kong and adjacent waters, virtopsy using three-dimensional surface scanning (3DSS), computed tomography (CT), magnetic resonance imaging (MRI) and ultrasonography have been implemented to provide supplementary or complementary information to conventional necropsy. Since March 2014, a total of 189 deceased cetaceans were confirmed in the Hong Kong waters. Either whole body or regional virtopsy of 150 carcasses were performed and analyzed for biological health and profile investigations. Two cetacean species, *Sousa chinensis* and *Neophocaena phocaenoides* (55 males, 64 females, 31 unknown sex; calf to adult; 50–365 cm in length), were included, with the carcass code ranging from 1–5.

The 3DSS protocol had been developed to provide surface documentation of external patterned injuries. CT was useful in diagnosing fatal hemorrhage, organ herniation, and pathological gas collection, as well as determining the number, shapes and characteristics of the fractures sites and the direction of external force. MRI was effective in evaluating soft tissue lesions, musculoskeletal injuries, integrity of spinal cord and brain herniation. Radiological assessment of the degree of epiphyseal fusion/ossification at postcranial skeleton allowed individual age-at-death estimation, supplementing the data obtained by dental growth layer group pattern. Gradual increment of postmortem gas accumulation in various tissues could be quantified with CT, which might gain invaluable insight to the individual death interval.

This long-term study demonstrated virtopsy is a potentially powerful tool, providing non-invasive and objective measurements to supplement the necroscopic findings for cetacean biological health

and profiles investigation. Virtopsy could also facilitate veterinary personnel to perform image-guided target specimen necropsy and sampling for histology and toxicology. The calibrated 3-D documentation and analysis of virtopsy findings would lead to qualitative improvements in conventional
necropsy, and pose precise conservation measure of local cetaceans caused by anthropogenic and natural injury.

Abundance estimation of Striped dolphins (Stenella coeruleoalba): Spatial models with distance sampling methods in the area of the Hellenic Trench.

Abundance estimations for cetacean populations are fundamental for conservation and wildlife management. Striped dolphins (*Stenella coeruleoalba*) are one of the most common species in the Eastern Mediterranean Sea and have been set as "Vulnerable" by the IUCN Red List. There has been no abundance estimate for striped dolphins in the Greeks seas before. In this study, we used spatial distance sampling method, in a series of data obtained from 12 years survey effort (1999-2009, 2014) along the Hellenic Trench. In total, 143 schools (2158 individuals) of striped dolphins were recorded in 13172 km surveyed. Detection function estimation was fitted to perpendicular distance data using R and "Distance package. The covariates that were consider as explanatory variables for detection were depth, swell, beaufort, and group size of dolphins observed. The best fitted detection function was a hazard rate model with covariates, affecting the detectability, sea state condition and group size of dolphins (AIC=1766.003). Detection probability derived from the detection function for the overall surveys was on average p= 4.394 (CV= 0.2911879) and the goodness of fit test showed a good fit: Cramer-Von Mises test (unweighted) statistic= 0.176656, p-value = 0.317657. The effective strip half width (ESW) is 773.07m with detection probability p=0.5. Spatial models were constructed using generalized additive models. For the abundance estimation the environmental covariates that were admitted were chl-α, sea surface temperature (SST) and sea level anomaly (SLA) and oceanographic features depth, slope and distance from shore. Results will confirm the main sub areas with high density and suitable habitat conditions for the species and variances amongst the years. Abundance trends suggest a decrease in striped dolphins within the study area. These findings will highlight the importance of long-term studies to understand variation in abundance in a specific area, subject to conservation activities.

Marine mammals in a changing Arctic

Kovacs, Kit M.
Norwegian Polar Institute, Tromsø
Corresponding Author: kit.kovacs@npolar.no

Ice-associated marine mammals in the Arctic are threatened by sea ice habitat loss combined with "borealization" of Arctic food webs and increasing human traffic. Seasonally resident marine mammals are expanding northward, increasing the risk of competition with resident species. Killer whales are spending extended seasons in previously ice-covered areas. In the Barents Sea region, where sea ice losses are occurring 2-4x as rapidly as elsewhere in the Arctic, ringed seals are maintaining body condition, but they are working harder to access food – diving more and resting less - home ranges are shrinking and they are increasingly tightly associated with glacier fronts. In other areas, condition and reproductive declines have been documented. Some species are displaying dietary changes and shifting their behaviour in adaptive ways. For example, white whales have shifted some of their foraging effort away from their normal feeding areas in front of tidal glaciers in the Svalbard Archipelago toward open-water areas in fjords, likely reflecting a broadening of their diet. Polar bears (and other species) are shifting their distributions to track suitable foraging and denning habitats. In the Barents Region this has meant abandoning southerly denning areas that no longer have sea ice connections at the time of den entrance and shifting foraging northward and eastward. Bears in this region are also spending more time on land and they are eating more terrestrial food (ground nesting bird in particular). Monitoring marine mammal populations in the decades ahead will be essential to determine the plasticity possessed by endemic Arctic species and to inform management and policy bodies regarding their status and conservation needs.

Where to find Spitsbergen bowhead whales – and why?

Kovacs, Kit M.[1]; Heide-Jørgensen, Mads Peter[2]; Vacquie Garcia, Jade[3]; Shpak, Olga[4]; Glazov,

Dmitry[5]; Lydersen, Christian[1]

The Spitsbergen bowhead whale stock was hunted almost to extinction in the first commercial whaling venture, starting in the early 1600s. At the start of the 21st century, it was assumed to consist of some few 10s and currently it remains classified as Endangered by the IUCN. In recent decades, passive acoustic monitoring in Fram Strait has given cause for optimism regarding recovery of the stock; revealing a nearly year-round presence of bowheads in the region and significant song diversity in winter. Additionally, aerial surveys in the marginal ice zone north of Svalbard from the Russian border westwards during August 2015, estimated 343 (CI 136-862) bowhead whales in the 52,000 km^2 ice-covered study area; no animals were seen from the ship, whales were sighted only on transect lines inside the ice. These data stimulated the initiation of a tagging program using helicopters to locate individuals in this highly ice-affiliated population of bowheads. During the summers of 2017 and 2018, 25 satellite transmitters were deployed on bowhead whales between East Greenland and Svalbard. Over the course of each year, the tagged whales ranged broadly, covering much or all of the range historically suggested for the Spitsbergen stock, extending from coastal waters of East Greenland eastward beyond the islands of the Franz Josef Land Archipelago. Commonly occurring time gaps in the records prevented interpolation of locations into full period tracks; so positions were used in habitat analyses. A combination of LME and GAMMs determined that bathymetry (deep water), shelf-slope-angle (steep), distance to the coast (often far offshore), SST (longer stays in cold water) and distance to ice edges (strong preference for ice-covered areas) were all important habitat features for this stock in some seasons. Unlike other bowhead populations, the winter distribution of this stock is more northerly than its summer distribution.

Is there a time and place to start singing? The timing and distribution of western North Atlantic humpback whale singing behavior in the fall.

Kowarski, Katie[1]; Moors-Murphy, Hilary[2]; Cerchio, Salvatore[3]
(1) JASCO Applied Sciences
(2) Fisheries and Oceans Canada, Dartmouth, Nova Scotia, Canada
(3) Anderson Cabot Center for Ocean Life, New England Aquarium, Boston
Corresponding Author: katiekowarski@gmail.com

Humpback whale songs have been described in detail on winter breeding grounds and studies of singing on high latitude summer feeding grounds have increased. However, there are few descriptions of the timing and manner of song onset during the fall. This limits our ability to understand the drivers of song onset, be they spatial, temporal, environmental, hormonal, and/or cultural. Recent work indicates that humpback whales display an acoustic transition period during the fall when song fragments are produced prior to an increasing prevalence of full song. We describe here an expansion of that study, documenting the ontogeny of humpback whale singing behavior through one fall season at locations along the western North Atlantic coast (inshore and offshore) ranging from Newfoundland and Labrador, Canada to Massachusetts, U.S.A. We tested the null hypothesis that singing behaviour begins simultaneously at all locations irrespective of variables such as latitude or depth. Seven bottom-mounted acoustic recorders collected data during September to December 2015. Humpback whale acoustic occurrence was determined through the manual review of the middle 60-70 sec of contiguous to near-contiguous 10-11 min acoustic files. The highest quality recordings were selected for acoustic behaviour analysis and the occurrence of non-song, song fragment, and full song vocal behaviour was verified. Results thus far suggest that singing behaviour begins in early September but is rare until the first week of October when it becomes common at all locations. Song fragments ceased by early November to early December and full songs continued until humpback whale vocalizations ceased or recordings ended. These results suggest that the trigger for humpback singing behaviour is related to time of year, with potential links to seasonal cultural and/or hormonal shifts, rather than latitude which would be more indicative of environmental triggers (e.g. length of day, depth, or sea surface temperature).

The biogeography of common bottlenose dolphins (T. truncatus) of the southwestern USA and Mexico.

Kownacki, Alexa[1]; Weller, Dave[2]; Torres, Leigh[3]

kownacka@oregonstate.edu

Common bottlenose dolphins (*Tursiops truncatus*) inhabit tropical and temperate waters worldwide and frequently occupy urbanized, coastal environments. Off the west coast of the United States this species occurs as genetically distinct coastal and offshore ecotypes. The coastal ecotype generally occurs in waters < 1 km from shore between at least northern Baja California, Mexico and northern California. The offshore ecotype occurs > 2 km from shore, spanning at least the entire Pacific coast of the United States. The biogeographically distinct distributions of these two ecotypes are well-suited for comparative analysis of ecological drivers related to habitat selection, distribution patterns and exposure to threats. Since the 1980s over 430 standardized surveys for coastal ecotype dolphins have been conducted, resulting in 6,136 sightings. Starting in 1992, periodic surveys for offshore ecotype dolphins have been conducted off southern California, resulting in over 50 sightings. These sighting data are used to develop species distribution models for each ecotype relative to sea surface temperature, depth, upwelling, temporal factors, and large-scale oceanographic indices (e.g., El Niño) and describe and compare factors influencing observed distribution patterns between 1981 and 2015. Although these ecotypes are influenced by similar large-scale environmental processes within the greater California Current Ecosystem, we predict that smaller-scale static and dynamic environmental patterns impact distribution patterns in divergent ways. For instance, results will be provided describing how the distribution of coastal and offshore ecotype dolphins were affected by nine El Niño events that occurred in the study area between 1983 and 2010. With multiple marine protected areas along the California coastline, the results of this study will help guide proactive population and habitat management actions designed to maintain healthy bottlenose dolphin populations.

Discrimination of vortex ring size by a stationary harbour seal (Phoca vitulina)

Krüger, Yvonne[1]; Miersch, Lars[2]; Hanke, Wolf[2]; Dehnhardt, Guido[2]

Corresponding Author: yvonne.krueger@uni-rostock.de

Harbour seals perceive water disturbances with their highly sensitive vibrissae. This enables them to track hydrodynamic trails left behind by prey fish. These trails differ depending on the fish species, the fish's body shape, size, and swimming style and may thus reveal information about their generator. Most of these complex fish trails contain vortex rings as a main hydrodynamic component. Even single vortex rings, created in C-start escape responses or other natural situations, might convey useful information to a seal. In a previous study we could show the ability of blindfolded stationary harbour seals to perceive a variety of artificially generated single vortex rings and furthermore that they are able to analyse them regarding directional information. As vortex ring size correlates with the size of a potential prey fish, it can be considered important information for a seal. In this study, the harbour seal's ability to differentiate two vortex rings based on their size has been investigated. In a pool two vortex ring generators were fixed under water on either side of a point directly ahead of the stationary seal. Single vortex rings with predefined sizes, velocities, and accelerations similar to those found in natural fish wakes were generated consecutively by each generator. One of the two vortex rings travelling to the seal's vibrissae was bigger than the other one. The animal had to identify the bigger vortex ring and responded by pushing its snout against one of two response targets in a left/right forced choice procedure. The seal was able to successfully differentiate vortex rings at least to a size difference of 17.63 mm. In natural situations in which no complex hydrodynamic trail is available, the ability to successfully analyse single vortex rings regarding their size by using hydrodynamic reception should be advantageous for harbour seals when hunting fish.

Global phylogeography and genetic diversity of the long-finned pilot whale Globicephala melas, with new data from the Southeast Pacific

The matrilineal long-finned pilot whale presents an antitropical distribution in temperate to cold waters and is divided in two subspecies. *Globicephala melas edwardii* is found in the Southern Hemisphere, while *G. m. melas* is restricted to the North Atlantic and Mediterranean. To date, population genetic and phylogeographic studies on this species have included localities around most of its Northern Hemisphere distribution, while in the Southern Hemisphere only the Southwest Pacific has been included in such studies. Here we add new genetic data (n=90) from the unsampled Southeastern Pacific to the published sequences, obtained from two mass strandings in the Chilean Patagonia. Low mitochondrial and nuclear diversity was encountered in this new area, as previously reported for other localities. Four haplotypes were found, with only one new for the species. In the global dataset, fifteen haplotypes were detected, underlining the low diversity of the species. As previously reported, both subspecies shared two haplotypes and presented a strong phylogeographic structure (Snn phylogeographic test =0.830, P<0.001). The current geographic distribution of this species has been related to dispersal and colonization events associated to the Last Glacial Maximum. Using the complete genetic dataset and Approximate Bayesian Calculations, this study supported this historical biogeographic scenario. Approximate dates were estimated for the range expansion at around 18.200 years ago and the subsequent post-LGM distribution split and growth 9.750 years ago. From a taxonomic perspective, even if genetic analyses do not support the subspecies category, this study endorses the incipient divergence process between both hemispheres. Thus maintaining their status and addressing them as *Demographically Independent Populations* is recommended.

Welfare and cognitive bias in captive killer whales (Orcinus orca).

Robust methods to assess nonhuman animal emotion are essential for ensuring the welfare of animals under human care. A promising tool for assessing animals' emotional states is the cognitive bias test. It measures an individual's tendency to judge ambiguous information based on its emotional state or mood. In humans, cognitive biases are known as "optimism" and "pessimism" and it has been shown that being more optimistic is correlated to better subjective well-being. The cognitive bias as a tool to evaluate animals' emotional states has been implemented in a number of mammals and birds, and very recently for bottlenose dolphins (*Tursiops truncatus*) whereas generally very little research on welfare indicators has been conducted in cetaceans. In the present study, we describe for the first time the characteristics of cognitive biases in killer whales (*Orcinus orca*), evaluate intra-individual and inter-individual variability and investigate the interrelation between their cognitive bias and other potential welfare indicators (behaviour, hormones and vocalisations). Our study aids in establishing further research directions and can be practically implemented to improve the welfare of captive killer whales, e.g. by testing the efficiency of (cognitive) enrichment programs and training protocols.

Pearls before porpoises - modifying gillnets to reduce harbor porpoise bycatch.

The interaction between gillnet fisheries and harbor porpoises has been recognized as a fatal problem since several decades. The exact reason, why harbor porpoises entangle in gillnets is not yet identified, but a possible explanation is that they fail to recognize the net as an obstacle they cannot penetrate. One way to mitigate this issue could be the addition of objects to the net at short distances to make it appear as a wall. In a systematic study, we modelled the acoustic reflectivity of a large range of objects for different combinations of object size and material properties. We found that acrylic glass spheres of less than 8mm in diameter resonate at 130 kHz. The spheres have a similar target strength as a table tennis ball and a qualitative sonar image of a prototype gillnet with spheres showed that the net becomes highly visible compared to a standard net. In order to quantify the efficacy of the spheres to reduce bycatch of harbor porpoises in a commercial setting, 10 paired hauls with 5 days of soak time each, are carried out in the

Turkish part of the Black Sea between June and September 2019. Two sets of gillnets (total: 2000m) are equipped with 8mm acrylic glass spheres at around 0.3m distance and compared to a standard net of the same length and equal net characteristics. A reduction of bycatch in the modified net while keeping fish catches constant could be a possible solution for the conflicting interests between nature conservation and fisheries.

Marine mammal and finfish predation explain high natural mortality and lack of stock recovery in weakfish

Effective stock management relies on quantifying trophic interactions between marine mammals and fish. Despite fisheries regulation to reduce mortality, weakfish (*Cynoscion regalis*) along the United States Atlantic coast has experienced a precipitous population decline from 1982 to 2014. Concurrently, weakfish natural mortality (*M*) increased, yet the cause for the increase is poorly understood. We identified five primary predators based on published accounts of diet, and spatial and temporal distribution of weakfish during the winter and compared the predator consumption of weakfish with the biomass attributable to *M*. During 1982 to 2014, the biomass of weakfish consumed was estimated using population size, diet, and feeding rates; uncertainty for this estimate was calculated using a Monte Carlo resampling method. Predators consumed on average 6,767 t of weakfish (80% CI 1,740 to 14,388 t) during the time-series, of which 55% was consumed by common bottlenose dolphins (*Tursiops truncatus*), 21% by striped bass (*Morone saxatilis*), 17% by bluefish (*Pomatomus saltatrix*), and 7% by summer flounder (*Paralichthys dentatus*) and spiny dogfish (*Squalus acanthias*). The biomass attributable to *M* from the stock assessment and biomass of weakfish consumed during winter were similar, indicating that high estimates of *M* are realistic and the cause is most likely winter predation, as the average biomass from fishery landings in the last 10 years of the time-series was 29 times less than that by predator consumption. Predators consuming weakfish during their first winter have resulted in a recruitment bottleneck, as evidenced by relatively constant age-0 indices but decreasing trends in age-1 weakfish abundance during the time-series. The significant influence of predation on weakfish population dynamics and their importance as prey highlight the need for multi-species management.

Long-term population and distribution dynamics of an endangered Irrawaddy dolphin population under rapid industrial development in Balikpapan Bay, Indonesia.

Worldwide, cetaceans are impacted by human activities and those populations that occur in shallow-nearshore habitats are particularly vulnerable. The paper presents a long-time study of the response of such a population, in terms of distribution and abundance, to widespread changes within a restricted environment.

Boat-based, line-transect surveys were conducted over 15 years between 2000-2015 (totaling 76 days and 4045 km), in Balikpapan Bay, East Kalimantan, Indonesia. Irrawaddy dolphins were sighted on 164 occasions. In addition, Indo-Pacific bottlenose dolphins, finless porpoise and dugongs were sighted here as well on 8, 6 and 10 occasions. The density of Irrawaddy dolphins was estimated through distance analysis. A decrease was noted from 0.47 dolphins/km2 in 2000-2001 (CV=25%) to 0.38 dolphins/km2 in 2008 (CV=30% as well as in 2015 (CV=29%). Mark-recapture analysis indicated a population size of 47 in 2008 (CL=46-56) and of 56 (CL=52-79) in 2015. Individuals exhibited high site-fidelity during this seven-years period.

In 2000-2002, Irrawaddy dolphins occurred throughout the Balikapapan bay area, however, by 2008-2015, the population appeared to be restricted entirely to the upstream areas of the bay. Throughout the study period, an increased boat presence, continued unsustainable fishing practices, ongoing pollution and sediment deposits were all observed and these factors likely contributed to changes in the Irrawaddy dolphin population density and distribution.

A large-scale oil spill, which took place on 31 March 2018 and affected an area of 20,000 ha, urges the need for continuous monitoring of the cetacean populations. The dependence of the Irrawaddy dolphin population on a relatively small and restricted habitat requires that appropriate coastal spatial planning be implemented as a matter of urgency. The area has been identified as an important marine mammal area by the IUCN-MMPA Taskforce and has been marked as such in the new government 20-years coastal spatial-planning document in progress, which may provide some concrete protection needed.

Human-related and natural body scars in coastal dolphins off Hurghada, Northern Red Sea, Egypt

Anthropogenic threats to dolphins, particularly in coastal areas, are rapidly increasing worldwide. The prevalence of body injuries, scars, and entanglements can provide measures of human-related or natural threats, hence, offering important information for the assessment of conservation strategies. To date, most studies on the origin of body scars and injuries in living cetaceans have been investigated based on photographs collected in boat-based surveys or capture-release studies. However, boat-based surveys mainly permit the inspection of the dorsal body area of individuals and therefore, likely miss marks on lower lateral,- and ventral body parts. This study applied a worldwide unique research approach as it additionally included underwater-based research data collected during SCUBA dives, which allowed for complete body assessments. Photographs and videos from Indo-Pacific bottlenose dolphins (*Tursiops aduncus*) off Hurghada, Northern Egyptian Red Sea, collected since 2009, were investigated based on descriptions in the public literature and cross-validations from experts. Marks were classified into injuries resulting from human interaction (fisheries interaction, boat strike) and natural sources (shark predation, intraspecific interaction). Results show that most dolphins with distinctive scars not attributable to conspecific interactions were of anthropogenic origin with fishing gear scars and entanglements being most prevalent, followed by boat injuries and shark-inflicted scars. This study contributes to the ever-growing body of evidence that human activities are considerable threats to coastal dolphins. Furthermore, it urges the necessity for discussing adequate conservation management strategies with regards to fisheries interaction and boating activities, including dolphin tourism.

Life histories of Galápagos sea Lions: Variation and population consequences.

Variation in life history traits is directly linked to individual fitness. This interplay is complicated by environmental perturbations
in an unpredictable habitat. This study provides first estimates of life history traits and trade-offs of a tropical apex predator, the Galápagos sea lion (*Zalophus wollebaeki*). Thirteen years of individual data on birth mass, early growth and offspring, and environmental data allowed the examination of factors influencing reproductive performance of adult females and calculation of pupping rates. Females became primiparous between ages 4 and 9. Neither oceanographic nor body condition in the females' first year of life influenced age at primiparity. Age at primiparity had no effect on a female's birth rate, on average one pup every 2 years. Until age 6, females showed a lower birth rate (< 0.40). Fecundity was higher between age 6 and 14 (birth rate 0.40–0.48). We could not detect an influence of inter-annually differing oceanographic conditions on pupping rates.

We also used these life histories to estimate survival rates of females. Pups had the lowest (0.688) and adults the highest (0.825) average survival rate. Survival varied among years (pups: 0.345-0.872, juveniles: 0.484-0.939, adults: 0.665-0.979), but overall showed a significant decrease since 2003. Colder sea surface temperatures and large birth mass positively affected survival, particularly in pups.

From these estimates of vital rates, we constructed a demograpic matrix model. The population growth rate for the next 50 years was predicted to be clearly negative (λ=0.897) with a population decrease of 11% per annum. Prognoses worsened when environmental stochasticity, i.e. sea surface temperature anomalies (SSTa), was included (λ=0.840), and even more when the increase of 0.9°C in mean SST predicted by the IPCC was considered (λ=0.829). These results strongly

suggest that current conservation efforts are not adequate for the Galápagos sea lion.

Ranging patterns of indo-pacific humpback dolphins (Sousa chinensis) in the matang important marine mammal area in Perak, peninsular Malaysia.

Understanding the ranging patterns of threatened wildlife is important for informed decisions for conservation. This study investigated the ranging patterns of Indo-Pacific humpback dolphins (*Sousa chinensis*) in the inshore and coastal waters of Matang, an IUCN Important Marine Mammal Area. Between 2013 and 2016, 14 boat-based surveys were conducted over 125 days to collect positional, photo-identification and behavioural data in the inshore, north coastal and south coastal strata. A total of 128 sightings were recorded and 206 distinctive individuals were identified. Of the 112 distinct individuals sighted inshore, 17 were sighted 10-17 times and their home range sizes varied between 75 and 287 km^2 (mean 191.1 ± 67.7 km^2). These individuals mostly occurred within 8 km from the estuaries, and moved alongshore for up to 50 km. Approximately 13 to 20 km farther from the estuaries, 28 and 66 distinct individuals were identified in the north and south coastal strata respectively and were mostly sighted once. Four individuals were sighted three to five times solely in the north coastal stratum, while three individuals were sighted three times solely in the south coastal stratum. Dolphins sighted close to the estuaries appeared to be locally resident with an alongshore range. Conversely, the dolphins sighted farther from the coast were not sighted in the estuaries and were likely to have a wide ranging area, ranging beyond the boundaries of the study area. Behavioural observations suggested that the inshore and north coastal strata serve as important feeding, foraging and nursing grounds, whereas the south coastal stratum were mostly used as socializing and mating grounds. Further investigation including genetics and social structure studies expanded beyond the study area are needed to verify if the individuals sighted in the north coastal, south coastal and inshore strata are distinct social units.

Overview of the U.S. navy's living marine resources (LMR) program.

In its ongoing effort to reduce potential impacts to marine mammals while meeting at-sea training and testing requirements, the U.S. Navy supports both basic and applied research to improve the understanding of marine mammals in regards to occurrence, exposure, response, and consequences. The Living Marine Resources (LMR) program is responsible for funding applied research, and works to address the Navy's key research needs and transition the results and technologies for use within the Navy's at-sea environmental compliance and permitting processes, with the goals of improving marine species impact analysis (including marine mammal take estimates), mitigation measures, and monitoring capabilities. The program's funding priorities includes:

1. **Data to Support Risk Threshold Criteria**
2. **Improved collection and processing of protected species data in areas of Navy interest**
3. **MonitoringTechnology Demonstrations**
4. **Standards and Metrics**
5. **Education and Outreach, Emergent Opportunities**

The LMR program is currently heavily invested in data to support risk threshold criteria, passive acoustic monitoring technologies, and automated methods of acoustic data analysis. These methods are seen as an integral component of the Navy's current monitoring plan. We present an overview of the LMR program, how we fit and work with the Office of Naval Research's marine mammal program and the U.S. Navy's marine species monitoring program and LMR's current investments related to marine mammal research. The LMR program is sponsored by the Chief of Naval Operations (CNO) Energy and Environmental Readiness Division (N45) and managed by the Naval Facilities Engineering and Expeditionary Warfare Center (EXWC). An advisory committee, comprised of representatives within the US Navy, solicits input from all commands to establish the annual research needs

topics and assist in evaluating and selecting projects for funding.

Coping with climate change in conservation of the endangered Saimaa ringed seal

Kunnasranta, Mervi
University of Eastern Finland, Joensuu, Finland
Corresponding Author: mervi.kunnasranta@uef.fi

The endangered Saimaa ringed seal (population size 400) is suffering from by-catch mortality and changing climate. Warming winters pose a risk for this population, which is dependent on snow and ice as its breeding habitat. For improving pup survival, novel conservation approaches have developed. Today we have a network of volunteers, who are willing to shovel snow for the seals and in 2014, over 95% of pups were born in man-made snowdrifts. The second ambitious step is enhancing seal breeding during winters with no ice by developing floating 'nest boxes'. The first pup was born in an Art-nest in 2018.

Opportunistic use of game camera traps to assess rare subpopulation of the Baltic ringed seal

Kunnasranta, Mervi; Niemi, Marja; Arponen, Heidi
University of Eastern Finland, Joensuu, Finland
Corresponding Author: mervi.kunnasranta@uef.fi

The southern subpopulations of the Baltic ringed seal (*Pusa hispida botnica*) in the Gulf of Riga, the Gulf of Finland and the Archipelago Sea are few in number and vulnerable. Climate change poses a significant threat, not only for the breeding success, but also for the reliability of population monitoring of those stocks. Mild winters hamper accurate aerial surveys and therefore novel monitoring approaches are urgently needed for estimating the status of these subpopulations. Ringed seals are known to have permanent, unique ring-shaped fur patterns, which enable individual identification and the usage of photo-ID approaches for varied purposes. During open water seasons May–August in 2016 to 2018, game cameras with time lap (one photo in every 60 minutes) were set in a terrestrial haul-out site in the Archipelago Sea (regional population estimate 200-300 seals) in south-western Finland. The biggest numbers of seals were recorded at the beginning of the study periods annually, which indicate moulting of the seals. Pilot camera-trapping effort produced some 30 500 images and around 30 individuals were identified manually, based mostly on fur patterns of their belly. Images provided new info on site fidelity, regional numbers and behaviour patterns of ringed seals. In addition, images showed long term and relatively common (over 15% of identified individuals) unknown sinus infection of the seals. This relatively small camera-trapping effort, provided already versatile info on the local seals. Therefore, camera trapping as a monitoring tool should be incorporated into long-term monitoring programs of rare southern ringed seal stocks.

Function of the tubercles on the dorsal ridge of East Asian finless porpoises, Neophocaena asiaeorientalis sunameri.

East Asian finless porpoises (*Neophocaena asiaeorientalis sunameri*) have numerous tubercles on their specific dorsal ridge. However, their function is still unknown. In this study, we examined the tubercles histologically to consider their function.

The tubercle had conic shape with approximately 1 mm in diameter at its base and 0.5 mm height. In the dorsal ridge area (tubercle area), the epidermal layer except tubercles was constituted of the cells having nucleus, showing that the region is keratinized incompletely and soft. Contrarily, the tubercles were composed of the cells lacking nucleus and less stained by HE staining. Therefore, it is indicated that the tubercle is keratinized completely and very hard. In addition, there are many mechanoreceptors such as Meissner corpuscles, Krause end bulbs, and Golgi-Mazzoni corpuscles, which participate in senses of touch and pressure, in the dermal layer and the dermal papillae (10.5 mechanoreceptors per a section of 2 cm-square). Furthermore, some undescribed nerve corpuscles were found. Free nerve endings running into the epidermal layer were also confirmed. In the cervical area (non-tubercled area), the epidermal layer was composed of the incompletely keratinized cells. Few mechanoreceptors and few free nerve endings were also observed (0.15 mechanoreceptors per a section of 2 cm-square).

In summary, there are much more mechanoreceptors in the dorsal ridge are than in the cervical are. This result indicates that the dorsal ridge is a highly sensitive area for touch and/or pressure. It is also notable that conical and very hard tubercles on the soft epidermal layer. When the tubercles are touched or pressed, they are easy to roll, and the both ends of tubercle bottom must swing largely. In other words, it is considered that

the structure that the hard cones placed on the soft layer has a role to amplify the vibration.

Clicks-sound production and frequency determining mechanism in the head of small toothed whales; Functional morphology with acoustical interpretation.

Click sounds of toothed whales are roughly divided into wide band (WB) clicks with a gentle peak in 30-100 kHz and narrow-band high-frequency (NBHF) clicks with one peak only around 130 kHz. The current ratio of extant NBHF species is about 20% of whole toothed whales. While the generating mechanism of NBHF clicks has been discussed for a long time, most conventional studies have been focused on the structural comparison of NBHF species and WB species without acoustical investigation. From the structure of sound source of clicks, NBHF clicks might be generated by reducing the bandwidth of WB clicks on the propagation path, leading to the idea of silencing mechanism in the lower frequency band by silencers. Some NBHF species had vestibular sacs with structure with many folds, considered to filter the sound with frequency below 100 kHz. Here, authors proposed this idea as “silencer hypothesis” and investigated the hypothesis in the current study. To confirm folded vestibular sacs work as a silencer, transmittance around the folded vestibular sacs of harbor porpoise (NBHF) and Dall’s porpoise (NBHF) were calculated. To confirm the head of NBHF species works as a high-pass filter, frequency response was measured by using real heads of melon-headed whale (WB) and harbor porpoise (NBHF). To confirm only NBHF species have folded vestibular sacs, anatomical structure of almost all toothed whales were investigated using conventional studies and CT data. From the results of these investigations, the silencer hypothesis was acoustically supported as a possible producing mechanism of NBHF clicks. However, the producing mechanism of NBHF clicks could not be explained by a single mechanism, because some NBHF species did not have any folded structures but quite similar head structure as WB species.

Recent status and fate of the north-eastern Mediterranean monk seal populations.

The endangered Mediterranean monk seal (Monachus monachus) is represented by approximately 350-450 individuals in Eastern Mediterranean waters in the form of small, fragmented and isolated groups. The North-eastern Mediterranean coast of Turkey being the host to one of the last continuously breeding populations, has vital importance for the survival of the species. Small populations inhabiting this region have been studied extensively for the last 25 years. The recent surveys showed that fragmented populations are still exposed to severe threats as a consequence of anthropogenic impacts. Therefore, in this study we focused on three previously documented populations in the southern coast of Turkey to update their status by utilizing photo-identification method, to estimate the size of the populations with Champan modification, to elucidate the dispersal among populations and to test the impact of dispersal on the survival of the populations through population viability analysis (PVA). Within this context, 20 caves were monitored with infrared camera-traps between the years 2015 and 2018. 37 individuals were identified and the overall population size estimate was 37 ± 5 (95% CI) seals. Among them were three adult females mobile between Western and Central groups which makes the mobility range of seals almost six times larger than previously documented in the same region. When compared to former studies, mortality rates increased whilst fecundity rates decreased. The results of the PVA analysis showed that populations have higher chance of survival in the case of dispersal. However, both isolated and dispersed populations have failed to survive within the next 100 years. Moreover, PVA models were easily affected by carrying capacity which highlights the importance of breeding caves. Therefore, continuity of monitoring studies focusing on threats and establishing Marine Protected Areas considering the suitable seal habitats and mobility of seals has vital importance for the future of the species.

Virological and serological surveillance of canine morbillivirus infection among caspian seals (2007-2017).

Canine morbillivirus (canine distemper virus, CDV) infection in Caspian seals (*Pusa caspica*) has been reported since 1997 and implicated in mass mortality of this species in 2000. CDV is caused by a single-stranded RNA virus of the family *Paramyxoviridae* (genus *Morbillivirus*). In this study, we conducted virological and serological survey of morbillivirus infection among Caspian seals. Samples as nasal, buccal, urogenital, rectal swabs and blood were collected from 176 animals in three locations of the Kazakhstan's part of the Caspian Sea between 2007 and 2017. The samples were screened for presence of morbilliviruses by reverse-transcriptase polymerase chain reaction (RT-PCR), with oligonucleotide primers targeting conserved sequences in the phosphoprotein (P) gene of that virus genus. As a result of RT-PCR, the expected products of 429 base pairs have been found in six seals out of 13 sampled in 2008. All the positive specimens belonged to individuals under two years old. The nucleotide sequences of PCR-positive for morbillivirus samples corresponded to those of CDV and differed from other members of the genus *Morbillivirus*. Further, no positive specimens were detected in the samples of broad timespan of subsequent years (2009-2017). Advanced research of materials using «Pan-paramyxovirus» primers specific for L-gene of all *Paramyxoviridae* family members also gave negative results. Since 2009, juvenile Caspian seals were not sampled and mostly large and adult animals were caught for satellite marking purposes. In serological analyses, antibodies to CDV were detected in six out of 74 seal serum samples (8.1%) harvested from 2007 to 2017. Three positives belonged to adult seals out of 18 sampled in 2016. The obtained data demonstrates possible decreasing trend of CDV prevalence in the Caspian seal population in last decade.

Do porpoises (Phocoena phocoena) have an acoustic fovea?

Echolocation represents an interesting evolutionary case of simultaneous evolution of the relevant stimuli and the sensory apparatus. Some bats (Constant Frequency - CF bats) use Doppler information to detect fluttering prey and these bats possess an acoustic "fovea", an area of the basilar membrane with dense neural representation and very high filter quality (Q). Echolocation signals in these animals are extremely narrow band, and high Q values are associated with low hearing thresholds at very high frequencies. An acoustic fovea is often morphologically associated with areas of increased innervation in the cochlear. Such an area has also been reported in the harbour porpoise cochlear from anatomical investigations. Here we test the hypothesis that porpoises have an acoustic fovea by measuring click-evoked auditory responses in a captive harbour porpoise exposed to impulse responses from 3rd octave bandpass filters at ANSI-frequencies 64-160 kHz. Evoked response magnitudes were dramatically increased at 100 and 125 kHz compared to 64 and 80 kHz, despite documented very similar hearing thresholds between 16 and 140 kHz. This pattern supports the hypothesis of an acoustic fovea around 125 kHz by means of denser neural innervation. We suggest that this neural overrepresentation in the echolocation frequency range offer porpoises a high spontaneous firing rate so that there are always responsive neurons to encode dense target echoes across a large dynamic range. The function of the porpoise fovea is therefore quite different than those of Doppler detecting CF-bats, since porpoise clicks are stereotyped and far less narrowband (lower Q), and face relative predator-prey speeds that render them Doppler insensitive.

Mercury in toothed whales: A systematic review about brain concentrations and detoxification mechanisms.

Toothed whales (Odontoceti) are top predators of marine food webs with great life expectancies and

they move around wide areas in the oceans, which makes them possible extraordinary accumulators of persistent pollutants. They also possess developed brains, complex behaviors and complicated social structures. Mercury can impair brain normal functioning; however, information about Hg in brain tissue and the derived neurotoxic effects in these species is extremely scarce. We carried out a systematic and extensive review in Google Scholar, PubMed & Scopus from 1976 to 2017 in order to know the status of this knowledge.We only found 22 studies which provided Hg concentration in brain tissue, which added up 333 samples from 9 different species worldwide. Odontocetes have shown to possess extremely high Hg concentrations in brain (range 0.00-48.60 ppm ww) and these values exceed in many cases those neurotoxicity thresholds established for mammals. High values of $[Hg_{liver}]/[Hg_{brain}]$ ratio were obtained (range 4.89-32.16; median 16.63), which could suggest liver Hg sequestration as a protection mechanism against neurotoxicity. Additionally, other detoxification pathways as MeHg demethylation also appear to be quite efficient in odontocetes brain, as MeHg proportion in relation to total Hg is much lower than in other species. Hg and Se antagonism mechanisms could explain the aforementioned. Thus, researchers have found very strong positive correlations of Hg and Se in brain of odontocetes. Furthermore, Se:Hg molar ratios in brain are usually higher than 1, which virtually implies Se availability to counteract Hg neurotoxicity. Nevertheless, despite these apparently efficient detoxification mechanisms, odontocetes accumulate extremely high amounts of Hg in their brains which could overwhelm their capacity to face its toxic effects. Further research is needed to consider whether mercury is causing a decline in health of toothed whales populations and by which mechanisms it does occur.

Comparative anatomy of the Saimaa (Pusa hispida saimensis) and Baltic (Pusa hispida botnica) ringed seals.

Laakkonen, Juha; Nihtilä, Heini; Jernvall, Jukka
University of Helsinki, Helsinki, Finland
Corresponding Author: juha.laakkonen@helsinki.fi

The Saimaa ringed seal is thought to have originated from the Baltic ringed seal population and it became landlocked about 9500 years ago. Previous studies have shown that the genetic differentiation between these subspecies is high, and that the Saimaa ringed seal teeth have a unique molar phenotype compared to that of the Baltic ringed seal. The aim of our research was to study the anatomy of these seals further to see if there were also soft tissue differences. Our study methods include anatomical dissection, preparation of silicone casts, as well as computed tomography and magnetic resonance imaging. We found relatively few soft tissue differences between these subspecies. Nevertheless, the tongue of the Saimaa ringed seal was more oval-shaped and the bifid apex of the tongue more rounded than those of the Baltic ringed seal. The origination point of the first segmental bronchus from the right caudal lobar bronchus differed between these subspecies, and there was some variation in the number of floating ribs but more specimens are needed to confirm this. Combined with genetic analyses, our data will improve our understanding on the evolutionary phenomics of mammals.

Important area of conservation for cetaceans in southern iberian peninsula

Information available on the occurrence and distribution of cetaceans in mainland Portugal is still very limited, despite recent efforts to improve this. Most information available comes from strandings, limited surveys and interviews with fishers. In the Southern coast of the country (Algarve) data is even scarcer although the region seems to be particularly interesting for marine megafauna species. Since 2010, we have been conducting surveys using a dedicated vessel and whale watching boats. Surveys take place over six months of the year allowing us to collect increasingly consistent data on the cetacean species present in the area. Eleven species were recorded corresponding to over 4500 sightings. Odontocetes accounted for the majority of the encounters, while only 3% were mysticetes. The common dolphin (*Delphinus delphis*) and the bottlenose dolphin (*Tursiops truncatus*) together made up 88% of the sightings. They were followed, in decreasing order of number of sightings, by the harbour porpoise (*Phocoena phocoena*), the minke whale (*Balaenoptera acutorostrata)*, the Risso's dolphin (*Grampus griseus*), the striped dolphin (*Stenella coeruleoalba*), the killer whale (*Orcinus orca*), the fin whale (*Balaenoptera physalus*), and finally the humpback whale (*Megaptera novaeangliae*), the long-finned pilot whale (*Globicephala melas*) and the sei whale (*Balaenoptera borealis*) each with the same number of encounters. Most records were within 15 nmi from shore, however, due to topographic features this distance corresponds to sizeable differences in depth. Records of the harbour porpoise and the bottlenose dolphin, protected species by the EC Habitats Directive

(92/43/EEC) and also considered in the ACCOBAMS agreement, were registered every year (ca. 250 and 1200 sightings in total, respectively) confirming both species are regular users of the area. Year-round surveys and more extensive habitat use studies are essential to provide a better assessment of the importance of this region for cetaceans and to fill the gap of knowledge.

Species distribution models and a novel approach to include soundscape information for north atlantic right whales and other species at risk

LaBrecque, Erin[1]; Hodge, Lynne[2]; Ashe, Erin[3]; Williams, Rob[4]

Species distribution models (SDMs) are a suite of analytical tools that relate species distribution data with information on the environmental and/or spatial characteristics of those locations. SDMs typically incorporate static (e.g., depth and distance to shore) and dynamic (e.g., temperature, salinity, and distance to ephemeral oceanographic features) environmental variables that describe the physical environment. Despite the importance of the acoustic environment for marine organisms, acoustic attributes have not been incorporated into SDMs. Given recent developments in the field of marine acoustics, we can now provide richer insights into species distributions related to the acoustic environment. Our ability to use acoustic detections of marine mammals in SDMs is challenged by the uncertainties inherent in passive acoustic data such as animals being present but silent and masking during periods of increased ambient noise in addition to variability in detection distances of animal calls due to the dynamic nature of soundscapes. Adding to the complexity, sound can influence an animal's behavior and movement patterns in various ways, such as altering communication space, alerting predators to the presence of prey, and causing avoidance of the sound source. SDMs could be improved by the incorporation of soundscape data and acoustic species detection data. Here, we devise novel methodologies for incorporating acoustic data into SDMs, both at a species level using endangered North Atlantic right whales as a case study and at a community level focusing on richness and diversity, to provide a generalizable framework for ecological inference from these types of models. When parameterized by data from well-designed surveys, relevant predictors, and an appropriately identified model, SDMs can characterize the natural distributions of species and subsequently provide ecological insight and predict a species distribution across a seascape.

Coastal polynyas: Winter oases for subadult southern elephant seals in East Antarctica.

Antarctic coastal polynyas are regions of persistent open water and are thought to be key bio-physical features within the sea-ice zone. However, their use by the upper trophic levels of ecosystems remains unclear. A unique bio-physical dataset recorded by southern elephant seals reveals that East Antarctic polynyas are a key winter foraging habitat for male seals. During their post-moult trips from Isles Kerguelen to the Antarctic continental shelf, a total of 18 out of 23 seals visited 9 different polynyas, spending on average 25 ± 20% (up to 75%) of their total trip time inside polynyas. Changes in seal foraging and diving behaviours are observed inside polynyas as compared to outside polynyas. Two polynya usages by seals are observed for the

inactive and active polynya phases, pointing to different seasonal peaks in prey abundance. During the active polynya phase, we link seal foraging behaviour to changes in the physical stability of the water-column, which likely impact the seasonal biological dynamics within polynyas.

Manatee chat — a combination of citizen science and deep learning for identification of manatee calls and mastication sounds

Lace, Natalija
Cetalingua Research Project, Tampa, Florida
Corresponding Author: kodzaks@yahoo.com

Identification of biological sounds in large acoustic data sets can be difficult and time-consuming. Deep Convolutional Learning Networks have been used for sound identification and classification, but they require a substantial amount of labeled data. Manatee Chat, a citizen-science project currently housed on the Zooniverse platform, allows participants to easily label sound files.

Over 2,000 citizen scientists inspected 9,259 audio files by listening to the sounds and visually examining the spectrogram. Each 10-second file was rated 15 times by different citizen scientists. Three identification categories were used: manatee calls, mastication sounds and nothing — resulting in 138,885 classifications. The obtained Fleiss' Kappa (multi-raters reliability) was 0.48, indicating moderate strength of agreement.

Next, 2,523 sound files that had at least 80% agreement among raters were selected to train and test the Deep Convolutional Neural Network model. The training set included 1,697 labeled spectrograms, and the validation set included 726 labeled spectrograms. The trained model achieved 97% accuracy on a validation set. The model was tested on 100 new spectrograms that were not a part of the testing or validation set and achieved 85% accuracy.

Data augmentation could further improve model accuracy and the ability to generalize. A number of citizen scientists doing the initial data labeling and subsequent training of Deep Convolutional Neural Networks could provide effective and accurate tracking and identification of manatee calls and mastication events in large acoustic data sets.

Fantastic Beasts and Where to Find Them: Modelling the distribution of deep diving cetaceans in the eastern North Atlantic.

As Governments increasingly seek sources of clean renewable energy, the search is turning increasingly to deeper waters further offshore. These habitats are relatively undisturbed compared to some of the more coastal environments, and as such, conservation of both the habitats and the species that rely on them is a pressing issue. Beaked whales, and other deep diving cetacean species such as sperm whales and pilot whales are some of these species. They are challenging to study at sea due to their long dive times and relatively short periods of time at the surface between dives. This makes them difficult to detect on conventional sightings surveys. As a result, there are typically only very low numbers of detections from large scale surveys resulting in insufficient data to model the spatial distribution of these animals in their offshore habitat. However, combining data collected from many different platforms of opportunity with those from specific cetacean surveys can maximise the data available for analysis, allowing investigations that would not otherwise be possible.

This study combines deep diving cetacean data collected on the SCANS-III, ObSERVE and NASS cetacean surveys with equivalent data collected on more than 30 years of seabird surveys carried out throughout the North Sea and European Atlantic. Data were modelled using GAMs to find the relationships that best explained variability in distribution as a function of a variety of static (e.g. depth, slope) physical (e.g. SST) and biological (e.g. chlorophyll a) oceanographic variables, based on a rigorous model selection framework. Preliminary results highlight the importance of depth and slope to these deep-diving species, emphasising the need for further research as their primary habitat becomes increasingly targetted for exploitation.

Patterns of cranial directional asymmetry among Odontocete species and families

Bilateral directional asymmetry in odontocete skulls has been described in extant species as well as fossils, with different degrees of intensity. This asymmetric condition has widely been associated with biosonar and communication. This study used 2-dimensional geometric morphometrics to analyse and compare the cranial asymmetry of five odontocete families: Iniidae, Pontoporiidae, Delphinidae, Monodontidae and Phocoenidae. We used photographs of skulls in dorsal aspect from 150 specimens, without stratification by sex or age. Twenty-six homologous anatomical landmarks were selected to allow repeatability and reliability among different taxa. The configuration included landmarks along the central axis of the skull, and paired, corresponding landmarks at each side of the skull. Procrustes ANOVA demonstrated the presence of significant directional asymmetry with a higher variance than fluctuating asymmetry. Principal component analysis of the asymmetric shape component presented a general leftward shift of the dorsal midline in combination with increased dimensions of right-side bones. The first principal component presented torsion of the rostral tip and the brain case to the left side, whereas the nasal bones and the premaxilla shifted to the right. Meanwhile, the second component represented opposite torsions, and also demonstrated greater magnitude in these distortions. Analysis of vectors describing species-specific deviation from symmetry revealed that the patterns of asymmetry were largely similar among species and families. Comparisons of species-specific magnitudes of asymmetry revealed the both monodontids were among the most asymmetric species. *Pontoporia* had the most symmetric skulls, followed by first *Inia* and then phocoenids. Delphinidae were the most diverse family and demonstrated a remarkable spectrum of lower and higher magnitudes of asymmetry, independent of size and the skull shape.

Locating ship strike risk hotspots for fin whale (Balaenoptera physalus) and sperm whale (Physeter catodon) along main shipping lanes in the North-western Mediterranean Sea

Lahaye, Elise[1]; Borroni, Anna[2]; Tepsich, Paola[3]; Rosso, Massimiliano; Moulins, Aurelie

For the two Mediterranean subpopulations, the "vulnerable" fin whale and "endangered" sperm whale, ship strikes with large vessels are one of main causes of decline. For both, the North-western Mediterranean Sea, and especially the Pelagos Sanctuary (PS) is a regular feeding ground crossed by a large amount of shipping lanes intensively used. The mapping of ship strike risk hotspots is an urgent conservation measure tool. A 10years dataset (2009-2018) collected in central PS along 3 North–South and 1 East–West long-distance ferry lanes was used to identify the species-hotspots. Data were collected weekly by MMOs aboard ferries from June to September. Over the 79,048km surveyed, we collected 1'237 sightings of fin whale and 133 sightings of sperm whale (respectively 1'653 and 160 whales). The effort intensity was computed using a buffer around the on-effort transects. The buffer size was defined analysing the distance sampling data obtained specifically for the two species. Similarly, for each species, a buffer was applied around each sighting in order to represent the whale sighting area. Then, the SPUE values were calculated and normalized by lane and by year, to overcome the differences in survey effort among transects. Yearly spatial distribution as well as persistence of risk-hotspots through years have been examined in order to identify priority areas of conservation. For each year, we highlighted at least 1 risk-hotspot per lane (i.e. normalized SPUE > 0.5) and through years, few persistent risk-hotspots. These risk-hotspots are consistent with species habitat preferences but not only; some are surprisingly also in coastal areas, in particular, at the entrance of few main ports. This result establishes priority areas for conservation measures to minimize ship strike risk.

The decrease in the occurrence of cancers in St. Lawrence estuary beluga (Delphinapterus leucas) supports a causal relationship with polycyclic aromatic hydrocarbon exposure.

Over the last 36 years, we have monitored the causes of death in the endangered population of St. Lawrence beluga (*Delphinapterus leucas*). During this period, cancers have been documented in 18% of the 193 stranded adult beluga (≥8 years old) examined. Direct exposure to sediments containing carcinogenic contaminants, such as Polycyclic Aromatic Hydrocarbons (PAHs), was proposed as the main risk factor to explain this unusual occurrence of cancers. A marked decrease in the reported cancers has been documented over the years in this population: the last case of cancer was diagnosed in 2011, whereas gastrointestinal tract cancers were not documented over the past 14 years. The occurrence of cancers is significantly lower (0% vs 23%; p=0.0012) in adult belugas born after 1976 (n=41) than in those born during or before the period of relatively high industrial PAHs dumping, between 1950 and 1976 (n=152). We calculated a theoretical PAHs exposure index for each examined adult beluga based on their estimated age and historical contamination data for the Saguenay River. The likelihood of an animal being affected by at least one type of cancer significantly increased with the increase of the PAHs exposition index ($p<0.0001$). This relationship was also statistically significant for gastrointestinal tract and mammary gland cancers ($p\leq0.003$). These observations, as well as recently published work on intestinal PAH-DNA adducts in belugas, strongly support the proposed causal relationship between the development of cancers in this population and its exposure to industrial contaminants. Neoplastic conditions seem no longer to be a conservation issue for this population.

Cholangiocarcinoma in a harbour porpoise from the North Sea.

Lakemeyer, Jan[1]; Wohlsein, Peter[2]; Siebert, Prof. Dr., Ursula[3]

The harbour porpoise (*Phocoena phocoena*) is the only native cetacean species in the German North and Baltic Seas and classified as least concern in the North Sea, whereas critically endangered in the Baltic Sea. Anthropogenic impacts like fishery, offshore windfarm construction and pollution are its main threats. Persistent organic pollutants (POPs) may impair immune and endocrine systems but also induce tumours known from Saint Lawrence Estuary belugas. Cetaceans rarely display neoplasia. Few cases are described in harbour porpoises, especially in the gastrointestinal and reproductive tracts. Hereby, we report a cholangiocarcinoma as new case. In 2018, a male, adult harbour porpoise with dyspnoea and moderate nutritional status stranded alive and died on Amrum, Germany. In the necropsy, the liver displayed diffuse, whitish, firm, up to 3 cm large nodules and a ventral bile duct cyst, potentially caused by trematodes (*Campula oblonga*), although none were located macroscopically. The abdominal lymph nodes near the aorta showed whitish foci on the cut surface. An infiltrative, poorly differentiated adenocarcinoma was determined histologically, originating from the bile duct epithelium. Infiltrative metastases were located in the abdominal lymph nodes and right adrenal gland. Furthermore, inflammations associated with parasitic infections were detected in the liver, lung, stomach, intestine and right ear. The tumourigenesis is uncertain. Genetic predisposition, pollutants or infectious agents may be responsible. The liver is an important POP metabolising organ and accumulates a higher amount of certain POPs than blubber. PCBs are cancer promotors and immunosuppressors. Chronic bile duct inflammation caused by flukes generates hyperplasia and proliferative epithelium alterations, being potential tumour precursors. Cholangitis, bile duct cysts and trematode infection are described as human cholangiocarcinoma risk factors, which can also be found in harbour porpoises. A connection between the tumours and POPs as well as liver fluke infections in this case needs to be further investigated.

Direct reprograming of dermal fibroblasts derived from Northern elephant seals into muscle cells

Ex vivo tissue culture is a powerful technique that allows the study of complex cellular mechanisms that are relevant to physiological responses in animals while overcoming the challenges presented

by studying animals that are not tractable. In a primary cell culture system, certain proliferating cells can be functionally reprogrammed into other cell types via overexpression of key genes. Dermal fibroblasts can be reprogramed into muscle progenitor cells (myoblasts), which are often challenging to obtain but offer a unique system to study metabolic responses, by overexpression of the myogenic transcription factor MyoD. We isolated dermal cells from Northern elephant seal (NES) skin samples using enzymatic digestion and propagated them in primary culture. NES dermal cells stained positive for the fibroblast marker Platelet-derived growth factor receptor. Primary NES fibroblasts were amenable to eGFP transfection by both, lipofection and electroporation. Maximal transfection efficiency was achieved using the Neon Electroporation system and corresponded to 55% of living cells. We overexpressed MyoD in NES fibroblasts and conducted antibiotic selection of MyoD-expressing cells with 2 ug/mL puromycin for 3 days. As expected, expression of MyoD was significantly higher (17-fold) in overexpressing cells according to RT-qPCR analysis (t-test $p < 0.05$). We are currently evaluating the capacity of MyoD-expressing dermal fibroblasts to differentiate into muscle fibers and comparing differentiation and metabolic profiles with fibers differentiated from primary NES myoblasts. Establishing differentiated muscle fibers from other mature cell types such as fibroblasts could provide a unique platform to conduct mechanistic studies in marine mammal species where muscle biopsies cannot be obtained from live animals.

The Sea Mammals and Sonar Safety (3S) project: 13 years of Behavioral Response Studies investigating the impact of naval sonar on marine mammals.

For 13 years the 3S-project (Sea Mammals, Sonar and Safety) has been studying the effects of military sonar on cetaceans in Norwegian waters. We have focused on 6 species' behavioral responses to different sound levels. Currently we are aiming to extend our results using an operational sonar in at-sea experiments, and looking at the effects of higher duty cycle sources (Continuous Active Sonar, CAS). In this paper we will present an overview of key results obtained thus far, emphasizing recent results.

The most striking results we have achieved in the project are:

- Clear indications of behavioral responses to sonar were documented for all species.

- Dose response curves for four different species: killer/long-finned/pilot/sperm/humpback whales, showing large variation in response thresholds

- Type and severity of responses varied significantly across species, and also between individuals of the same species.

- Bottlenose whales (a beaked whale) were demonstrated to be most responsive, with strong responses at large distances (>20km) from the source. Killer whales were (surprisingly) responsive to sonar in some experiments. Sperm and pilot whales were less responsive.

- Frequency specificity of response is not explained by hearing ability

- Ramp up or soft start reduces risk of hearing impairment – but only for responsive animals

- Responses to continuous sonar are similar to responses to pulsed sonar at the same SEL level in sperm whales.

- The nature and severity of behavioral responses to sonar can match the anti-predator response template depending on the studied species and sonar exposure types.

- Herring, an important prey item for many cetaceans (e.g. killer whales), did not respond to naval sonar. Hence, responses like feeding cessation cannot be explained directly by prey movement.

Implications for management and directions for future research will be discussed.

Beyond Maui: Humpback whale occurrence across the Hawaiian archipelago revealed through the prevalence of song.

The Hawaiian archipelago is the principal breeding ground of north Pacific humpback whales (Megaptera novaeangliae), hosting approximately half of the population during winter and spring months. Historical data suggest that the main Hawaiian Islands (MHI), and specifically the four-island region of Maui-Molokai-Lanai-Kahoolawe, serve as the primary wintering habitat of the Hawaii distinct population segment (DPS) of the north Pacific stock. However, beginning in 2015, commercial operators, researchers, and citizen-science counts began reporting unusually low numbers of whales in the MHI, leading to speculation that whales may be migrating in smaller numbers or possibly using more remote parts of the archipelago. As a result, there is increased need to better understand the occurrence and distribution of humpback whales across the archipelago, including on the banks and atolls of the Northwestern Hawaiian Islands (NWHI), which have remained largely unsurveyed. To address this need, both historical and contemporary data from bottom-moored acoustic recorders deployed throughout the MHI and NWHI were analyzed for the occurrence and abundance of humpback whale song, which is produced by males during the breeding season. The data reveal that humpback whale singing is common throughout the archipelago, including in remote parts of the NWHI. This indicates that nearly the entire Hawaiian archipelago is used as breeding habitat, not only the MHI. However, differences in whale song prevalence among locations suggest that parts of the archipelago are likely used preferentially. In light of these findings, a re-distribution of whales to other parts of the archipelago is at least a plausible explanation for the changes recently observed in the MHI. In addition, the documented presence of whales across more than 1000 nautical miles raises the possibility that whales from the western Pacific DPS may also use parts of the archipelago, which would imply a more complex stock structure than previously assumed.

How to remotely assess body condition on Antillean manatees: The DIY (drone it yourself) alternative.

Body condition index (BCI) is an important morphometric measure for monitoring the health status of sirenians. The capture and handling of wild manatees enables accurate body measurements but are invasive, expensive and logistically challenging. We tested the use of small drones to remotely collect morphometric data from captive Antillean manatees at Dolphin Discovery facilities in Quintana Roo, Mexico. The manatees (n = 12) were considered healthy at the time of the experiment and were previously measured according to standard protocols to obtain standard length (SL^M) and umbilical girth (UG^M). We conducted 15-min flights (n = 11) with a DJI Phantom 4 Pro drone at altitudes between 10–100 m and obtained 173 minutes of video recordings the manatees. A polystyrene white block (1m x 0.25 m) was placed at water level as a reference object of known size to scale images. We selected 308 images of manatees oriented horizontally near the water's surface and assessed their standard body length (SL^D) and maximum width (MW^D) from the drone images using *ImageJ* software. The umbilical girth was calculated by the formula $UG^D = MW^D \times \pi$. Mean values (± SE) of SL^D and UG^D were obtained for adults (253.8 ± 1.7 cm; 191.3 ±1.5 cm), juveniles (210.6 ± 1.2 cm; 151.5 ± 1.0 cm) and calves (162.2 ± 1.6 cm; 125.2 ± 2.2 cm). No significant differences were found among SL^D and SL^M ($U=54$, $p=0.31$), suggesting that measurements obtained by drones can offer a good

proxy of the 'real' manatee size. The relative error (%) of SL^D was 8.1 ± 3.8% (Mean ± SD). The average of BCI (UG^D/SL^D) was 0.75 ± 0.05 (Mean ± SD). Our results highlight the potential of drones to conduct body assessments of free-ranging manatees in order to monitor the health status of their populations.

Towards a sustainable whale watching in Reunion island in the South-west Indian Ocean: Assessing and mitigating humpback whale (Megaptera novaeangliae) tourism disturbance.

The whale watching industry has grown rapidly worldwide over the last decade. Reunion Island is no exception to the rule, its coasts attract a growing number of humpback whales (HW) during the austral winter breeding season, few nautical miles away from seaside resorts. This recent industry has raised concerns about the behavioral responses of HW to whale watching (WW) and swim-with whales (SW) disturbances. A responsible observation of cetaceans was recently encouraged through a charter and a label. In 2017, a team "Quietude" was committed to monitor and sensitize whale watchers at sea to ensure compliance with this charter. We assessed WW and SW activities in Reunion Island during three HW breeding seasons from June 2017 to October 2019. Until now, a total of 411 hours was spent collecting data, 105 hours of which occurred with HW behavioral recording. Observed groups were mostly composed of mother/calf pairs spending most of their time resting and nursing. Vessels were present in 85% of sightings with recreative vessels accounting for 68.4% of vessels and SW activities observed in 42% of sightings. General compliance with the charter is high (71.2%) but low with the specific recommendations on SW activities (< 38%). Swimmers were reported on active groups and some agonistic behaviors were revealed, leading to challenging safety issues. Resting along with nursing behaviors of HW were disrupted to a level that raises concern. HW tend avoid vessels and SW encounters, especially when the behaviors of whale watchers were not compliant with the charter. Our results advocate for reinforcing tourism education, management and control with an emphasis on SW activities. This could be efficiently achieved by engaging all stakeholders with the charter concomitant with the permanent team at sea to enhance dissemination of best practices and to sensitize on the sustainable values of implemented regulations.

Factors influencing the duration of implantable satellite tags in humpback (Megaptera novaeangliae) and right whales (Eubalaena spp.).

Implantable satellite tags have provided new information on movements, migration, distribution and behavior of large whales. These tags are designed to provide long-term tracking and currently remain attached for several weeks to several months. In this study, factor influencing implantable tag duration were evaluated for humpback whales (Megaptera novaeangliae) and right whales (Eubalaena sp.). Data were extracted from published papers and reports or from unpublished tag deployments. Generalized linear mixed-effect models were used to assess whether a series of explanatory variables (sex, tag model, species and deployment location) influenced duration. Non-collinearity was verified between variables using chi-square Test of Independence ($p \leq 0.5$). The results were evaluated considering the most parsimonious model and also the lowest Akaike's Information Criterion (AIC). Mean duration for tags deployed in humpback whales was 33 ± 38.5 days, for the Eubalaena australis mean was 69.1 ± 61.2; for Eubalaena japonica mean was 40.7 ± 15.3 and for Eubalaena glacialis mean was 22.9 ± 13.7. The most supported model indicated that sex and models of trasmitters were the variables to significantly influence the tag duration. The tag model could be influence on the durability due to constantly improving in the attachments of tags to whales to ensure long-term retention. The differences on the attachments must be evaluated. The influence of sex suggests that differences of behavior between males and females is an important factor in the duration of both species. Further analysis should include other factors (e.g., social role) and other species to further understand retention of implantable tags on large whales.

Analysis of plastic bioaccumulation in stranded marine mammals and correlation to diet through stable isotope analysis.

Langford, Christina
University of Californa Santa Cruz

Plastics are pervasive in marine ecosystems, which can lead to bioaccumulation of those plastics in marine predators. This ingestion of plastics can occur through direct consumption as well as through trophic transfer. While these mechanisms are known to occur, patterns of accumulation across species and geographic areas are only starting to be explored. Marine mammals offer an opportunity to analyze this, as they feed on lower taxa. This study aims to look at plastic bioaccumulation directly through stomach content analysis of newly stranded marine mammals. Carcasses that wash ashore at Año Nuevo state park in Pescadero, Ca will be analyzed for levels of plastic ingestion. While the sample size and species studied will be dependent upon what washes ashore, it is predicted that species of pinnipeds such as the northern elephant seal (Mirounga angustirostris), the stellar sea lion (Eumetopias jubatus) and the California sea lion (Zalophus californianus) will be among the most common as these species haul out in and around Año Nuevo. Through direct observations of plastics in the stomach, the study seeks to correlate the amount and type of plastic to carcass demographics such as species, sex, age class, and size. Plastic analysis will be done by visual inspection of gut content, using the naked eye for macro plastics and microscopy for micro plastics. The other goal of this study is to test for a correlation between the observed plastic accumulation and diet, through stable isotope analysis of pinniped vibrissae. The vibrissae will be analyzed for δ13C (carbon 13 isotope), which will provide an indication as to where in the water column the animal was feeding. While not a direct analysis of diet, if a correlation is found, it could suggest a link between feeding ranges and plastic bioaccumulation, which has not been widely studied

Site use and connectivity of adult female grey seals (Halichoerus grypus) in Wales and the Celtic Sea

The grey seal (*Halichoerus grypus*) is listed in Annex II of the EU Habitats Directive and is a qualifying feature of three Special Areas of Conservation (SAC) in Wales. Since 1992, Natural Resources Wales and its collaborators have maintained a photographic identification (photo-ID) database, surveying seal breeding and haul-out sites around the Celtic and Irish Seas. Here, we investigated site use and connectivity of female grey seals within the Celtic and Irish Sea database. A total of 2,857 individual females were identified from left heads and 2,789 from right heads (there were few opportunities to link left and right sides) within the computer-aided pattern recognition software *ExtractCompare*. In comparison, pup production in Wales was 1,650 in 2017. Capture histories were generated for uniquely identifiable individuals using a spatially-explicit capture-recapture algorithm. Most recorded individuals were only seen once (77% left heads, 78% right heads). For individuals seen more than once, 12% from left heads and 13% from right heads were recorded twice, and <1% were recorded seven times or more. One individual first identified at Skomer Island was "recaptured" 12 times between 1993 and 2016 at locations around Skomer and Ramsey Island. For individuals seen more than once, transition probabilities were calculated to investigate connections (implied movements) of seals between main locations. The highest transition probability was Bardsey Island:Lleyn Peninsula (0.7) which are both within Lleyn Peninsular and the Sarnau SAC. Transitions occurred between locations within an SAC (e.g. Bardsey:Cardigan Bay, 0.09) and between locations within and outside of SACs (e.g. Bardsey:Anglesey, 0.06). There was a high transition probability (0.5) between the Dee Estuary and Anglesey, but neither of these haul-out sites are included in a SAC. This shows that female grey seals move throughout the Celtic and Irish Seas and are not limited to the site at which they breed.

Metabolic rate determination in wild dugongs

Little is known about the metabolism, energetics, and food requirements of dugongs (*Dugong dugon*). The related manatees have low metabolic

rates (only 25-30% of predicted values for large mammals) and based on phylogeny, it has been assumed that dugongs have comparably low rates. However, measured rates of water turnover have indirectly suggested that dugongs may either have relatively high metabolic rates or that dugongs practise mariposia (voluntary drinking of seawater). This project, conducted in Australia in the first week of austral spring, measured oxygen consumption in a total of five resting non-gravid adult dugongs held at thermal neutrality in a metabolism chamber. Oxygen consumption expressed in terms of absolute body mass was converted to resting metabolic rate (RMR), and energy expenditure at rest was also calculated. Mean O_2 consumption ranged from 2.12 to 2.9 mL $kg^{-1}min^{-1}$, RMR from 29,943 to 40,799 kJ day^{-1}, and energy expenditure at rest from 0.81 to 0.99 W kg^{-1}. RMRs for these five dugongs were higher than those reported for the related West Indian manatee, but are comparable to rates for similarly-sized marine and terrestrial mammals. We suggest that the higher RMR of dugongs compared to manatees may explain discrepancies between their behavior, growth and reproductive rates. A higher rate of metabolism may account for dugongs' more active pelagic habits and may help clarify why growth and reproduction are slow. Whilst metabolism and energy expenditure are relatively high, grazing on a low-nutrient, low-energy seagrass diet means that dugongs use a high proportion of the energy extracted from their diet to power metabolism, and thus allocate a lower proportion to growth and reproduction. Future work will explore the effect of seasonal water temperatures on RMR of dugongs.

Let it grow: Ontogenetic growth of the minke whale skull and implications for the teeth-to-baleen transition in Mysticeti (Cetacea).

Lanzetti, Agnese
San Diego State University, El Cajon, CA
Corresponding Author: agnese.lanzetti@gmail.com

Baleen whales (Mysticeti) have an extraordinary fossil record documenting the transition from toothed raptorial taxa to modern species that employ baleen plates for filter feeding. However, while adults bear baleen plates, tooth germs still develop unerupted *in utero*. Ontogenetic data, combined with present knowledge of modern and fossil mysticete skull anatomy, provide a better understanding of the mechanisms of this unique macroevolutionary transition. Though, currently little information is available on prenatal development of baleen whales, especially regarding tooth resorption and baleen development. Here, I present the first comprehensive description of the ontogenetic sequence of minke whales (*Balaenoptera acutorostrata* and *B. bonaerensis*), focused on the skull internal anatomy and tooth germ development, resorption, and baleen growth. The anatomy was analyzed using traditional and iodine-enhanced computed tomography (CT and diceCT) scanning of 10 specimens of both minke whale species, spanning from the earliest fetal stages to full term. Using these non-invasive methods allowed reconstruction of virtual 3D models of the specimens and geometric morphometric (GM) analyses, in addition to providing traditional qualitative descriptions. Tooth germs appear to resorb completely just before eruption of the of the baleen from the gums, and they are still present for a brief period along with baleen rudiments. GM analyses show that the rostrum progressively grows in length relative to the braincase, and that the supraoccipital shield elongates anteriorly during gestation. Both changes contribute to a defining feature of cetaceans, telescoped skull. This information aid in the interpretation of fossil morphologies that exhibit intermediate traits between modern filter feeders and raptorial feeders, but caution is needed when comparing prenatal extant specimens to adult fossils. This new data greatly enhances our understanding of baleen whale ontogeny and of the role of developmental transformation in the evolution of mysticetes.

Sea otter (Enhydra lutris) seasonal diet composition in southern Southeast Alaska

Until translocation efforts in the 1960s, sea otters (*Enhydra lutris*) were absent from Southeast Alaska due to extirpation from the fur trade in the 18th and 19th centuries. About 400 sea otters were reintroduced to six Southeast Alaska locations with consistent population growth to date. Previous foraging studies throughout the sea otter range have shown that sea otters will reduce invertebrate prey biomass when recolonizing an area. By quantifying sea otter diets and caloric intake according to recolonization patterns, we can better understand the ecosystem impacts of sea otter population increase and range expansion. We hypothesized that sea otter diet will vary according to age, reproductive class, seasonality, and time since recolonization. Foraging data were collected

around Prince of Wales Island to determine diet composition during the summer. Sea otter vibrissae were obtained from subsistence hunters to assess seasonal changes in sea otter diets by using bulk stable isotope analysis. Sea otter prey items were collected in three seasons (spring, summer, and winter) to measure caloric value and stable isotopes of carbon ($d^{13}C$) and nitrogen ($d^{15}N$). Overall population-level diet composition consisted of 69% of the biomass derived from clams, with butter clams (*Saxidomus gigantea*) as the main clam species in this mixed-bottom habitat. This study aids in the future management of shellfisheries, subsistence hunting, and co-management of a protected species by providing quantitative diet composition data for stakeholders. This work is a part of a large-scale project examining how the recovery of sea otters structures nearshore marine ecosystems, provides ecosystem services and affects community sustainability.

After 12 years of knowledge gap: New data on franciscana bycatch in the artisanal gillnet of Torres and Passo de Torres, southern Brazil, assessed through onboard observers.

The franciscana (Pontoporia blainvillei) is endemic of coastal waters from Brazil (18°25'S) to Argentina (42°10'S). The species is considered the most threatened cetacean in the western South Atlantic due to high bycatch mortality in gillnets fisheries. Four Franciscana Management Areas (FMAs) are recognized. Bycatch levels in FMA-III (Brazil/27º37'S- Uruguay/34º34'S) are the highest among all FMAs, but since the middle 2000s fishery monitoring have been interrupted. This study reports preliminary results of resuming efforts to estimate franciscana bycatch in artisanal gillnets fisheries with onboard observers at Torres/Passo de Torres, southern Brazil (29°19'S/49°42'W, north FMA-III). From June/2018 to April/2019, 27 one-day fishing trips of two vessels were accompanied by observers. Location of fishing grounds, gear type, target species, fishing effort, and the number of franciscanas incidentally caught were recorded for each fishing trip. Fishing occurred within an area of 164km^2, ranging in depths of 15-28m. The drift (surface) gillnets used had (mean±SD) 818±151m in length, 11m in height and mesh sizes of 8.2±0.25cm. A total of 50 surface sets were accompanied with soaking time of 0.7±0.24h, resulting in the capture of 1,106kg of target species (*Pomatomus saltatrix*) and none franciscana. Bottom trammel nets used had 3,728±1,265m in length, 1.95±0.09m in height and mesh sizes of 20±0.0cm (inner panel) and 60±0.0cm (outer panels). A total of 21 bottom sets were accompanied with soaking time of 27.5±9.7h, resulting in 1,234kg of target species (mainly *Micropogonias furnieri* and *Paralichthys orbignyanus*) and six franciscanas by-caught (Catch-per-unit-effort [CPUE] = 0.000003franciscanas/m/h). Our preliminary results indicate higher CPUE values for franciscanas in bottom gillnets than those reported for the same area in the 2000s (CPUE=0.000002franciscanas/m/h). Continuity of the fishery monitoring is essential to estimate annual mortality and assess its seasonality, as well as to understand the effects of the current bycatch on the long-term viability of franciscanas.

Spatial haul-out dynamics of three sympatric Alaskan pinnipeds

Larsen, Gregory[1]; Moreland, Erin[2]; Seymour, Alexander[1]; Newton, Everette; Johnston, David[3]

Many pinniped species haul out in terrestrial habitats to enact critical behaviors and life history events. High-resolution remote sensing reveals how such behaviors interface with a physical environment to structure pinniped haul-outs. In the Pribilof Islands of Alaska, three pinniped species regularly use terrestrial habitats to haul out; these haul-outs can overlap in time and they describe unique, though not necessarily discontiguous spatial habitat associations. In October 2018, a survey using unoccupied aircraft systems (UASs) mapped simultaneous, sympatric haul-outs of three species on Otter Island: the northern fur seal (*Callorhinus ursinus*), the harbor seal (*Phoca vitulina*) and the Steller sea lion (*Eumetopias*

jubatus). A synoptic dual-UAS flight survey captured simultaneous visible-light and thermal imagery of these haul-outs. Photogrammetric image processing with Pix4D software yielded high-resolution othomosaics in visible light (2.6 cm/pixel resolution) and thermal infrared (17 cm/pixel resolution), and derived a digital surface model (2.6 cm/pixel resolution) of the study region. Spatial analyses of these products reveal species-specific behavioral affinities toward distinct physical environments and between animals. Conspecific clustering is discernible in preliminary products and is quantifiable as spatial autocorrelation among pinniped locations, but it is ambiguous whether this reflects conspecific attraction or convergence on limited suitable terrestrial habitat. Here we apply fine-scale habitat suitability modeling to describe, for each species, spatial autocorrelation of haul-out locations amid suitability models of landcover type and surface topography. The presence (or absence) of alternative but unoccupied habitats for a given species discounts (or fails to discount) the hypothesis that clustering reflects a convergence on limited suitable habitat. Such insights into haul-out structural dynamics can inform future monitoring, research and conservation efforts in the Pribilof Islands and other terrestrial pinniped habitats.

Whose pregnant? Parsing out postpartum and parturient Pacific walruses using endocrine profiles.

Larsen, Jenell; Atkinson DeMaster, Shannon
University of Alaska Fairbanks
Corresponding Author: jtlarsen@alaska.edu

The reproductive cycle of female Pacific walruses (*Odobenus rosmarus divergens*) is characterized by breeding in winter, an embryonic diapause from conception until summer and parturition the following spring. Like other pinnipeds, female walruses likely undergo a postpartum estrus, but the function for this is unknown as males are thought to be infertile outside of the breeding window. In this study we assessed the reproductive statuses of female walruses categorized as postpartum, embryonic diapause, full-term pregnant and unbred. Ovarian tissues and reproductive status were provided by Alaska Native hunters from animals taken in Alaska in May of 2011, 2015 and 2016. Progesterone was measured using enzyme immunoassays and total estrogen concentrations were determined using radioimmunoassays in corpora lutea (CL) of ovaries. For progesterone, CL of postpartum females (n=11) had the lowest concentrations (77.31 ± 58.21 ng/g) whereas CL from unbred females (not pregnant or postpartum) (n=3) had the highest progesterone concentrations (2170.01 ± 246.29 ng/g). One CL was present from a female known to be near full-term pregnancy (62.92 ng/g), as well as one CL from a female known to be in embryonic diapause (108.48 ng/g). For total estrogens, CL from postpartum females had the lowest concentrations (n=8; 15.38 ± 10.17 ng/g). Total estrogens of CL were similar among females that were unbred (n=2; 693.19 ± 467.30), full-term pregnant (n=1; 313.58 ng/g), and in embryonic diapause (n=1; 551.14 ng/g). In this study neither CL progesterone nor estrogen profiles alone were able to differentiate between states of pregnancy in female walruses, with such low sample sizes. To our knowledge, this is the first time that these reproductive hormones have been measured in ovarian tissues for this species.
