Physiological reference intervals are useful when assessing the health status of individual animals. Few zoos or aquariums care for enough cetaceans within their facility to develop functional reference intervals given high inter-individual variability in physiological biomarkers in cetaceans. Further, previously published intervals are limited in their functionality as differing sample collection procedures, analysis methods and inter-laboratory variation render results not directly comparable. To develop functional reference intervals for traditional and novel physiological biomarkers of welfare applicable across facilities, data were collated from cetaceans housed at 43 locations in seven countries. Blood and fecal samples were collected from common bottlenose dolphins (*Tursiops truncatus*), Indo-Pacific bottlenose dolphins (*Tursiops aduncus*), Pacific white-sided dolphins (*Lagenorhynchus obliquidens*), and beluga whales (*Delphinapterus leucus*). Samples collected from clinically healthy animals between July 2018 and March 2019 and analyzed with respect to species, age, sex, pregnancy (females) and month of the year. Reference intervals were generated for 40 hematologic, serum, and plasma biochemical variables, three hormone biomarkers, and one antibody. After establishing reference

intervals for the physiological parameters, intervals were made available in the new iOS mobile software applications, ZooPhysioTrak. Reference intervals in ZooPhysioTrak represent zoo and aquarium cetaceans at the population-level and serve as a frame of reference for future development of community-wide health protocols. For the species with smaller sample sizes, prior baseline physiological biomarker values are extremely limited and our results establish a protocol for collecting comparable samples in the future. ZooPhysioTrak will enable animal care and veterinary staff to enhance clinical care by quickly accessing the expected intervals for a given physiological biomarker on an individual level.

Combining multiple surveys increases precision and provides more reliable mapping of marine mammals distribution.

Species distribution is a key indicator to inform conservation status of marine mammals, cetaceans in particular, and to predict possibly problematic interactions with human activities. However, the distribution of cetaceans is difficult to assess because they are highly mobile species occurring at low densities and across wide areas.

Here, we propose a formal statistical framework to combine multiple cetacean surveys to overcome these issues. We illustrate our approach considering two aerial and at-sea monitoring programs to estimate the distribution of bottlenose dolphins (*Tursiops truncatus*) in the North-Western Mediterranean Sea. Aerial surveys were designed to monitor marine megafauna across 24,624 km of line-transect over coastal and pelagic North-Western Mediterranean (including the Pelagos Sanctuary). At-sea photo-identification was carried out across 21,646 km of transects performed over the French continental shelf (including Gulf of Lion and Corsica). We modeled the proportion of area used by bottlenose dolphins using occupancy models to account for imperfect and heterogeneous detection between the two surveys. We also considered occupancy models with a single visit per spatial sampling unit.

We found that combining the two monitoring programs greatly improved the precision estimates of the proportion of area used. Also, considering the two surveys jointly in the analysis provided a much better coverage of the ecological gradient, which in turn translated in a more representative map of the proportion of area used by bottlenose dolphins. Last, single-visit occupancy models produced similar estimates to occupancy models with repeated visits, which opens the perspective for a better optimization of the sampling effort.

Overall, our approach allows making the best of marine mammals monitoring programs by borrowing strength of the different surveys (aerial and at-sea) for a reliable assessment of species distribution.

Movements and diving behaviour of Ross Sea Killer Whale (Orcinus orca), along the Ross Sea Region MPA, Antarctica

The Ross Sea Killer Whale is a fish-eating ecotype (type - C) regularly occurring around pack ice in the Ross Sea, Antarctica. Increasing knowledge on this ecotype's foraging habitats and movement patterns is listed amongst the research priorities recommended under the framework of the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR). In Terra Nova Bay (TNB) during the austral summer 2015 ten type - C killer whales were equipped with Smart Position Only (SPOT) and depth-recording satellite transmitters (SPLASH) in the Low Impact Minimally Percutaneous External-electronic Transmitters (LIMPET) configuration. Hierarchical switching state-space models (hSSSM) were applied to Argos satellite tracking data to characterize the horizontal behaviour of tagged whales. The behaviour log from SPLASH transmitters returned the maximum depth reached in each recorded dive as well as the dive durations and surface intervals between dives. Tags transmitted on the whales for 19 - 44 d (mean=28.6 d; SD=8.79). Overall, 8,803 Argos locations were available to fit the hSSSM. The Bayesian state-space model revealed discrete, largely non-overlapping Areas of Restricted Search (ARS) along the coast line, as well as transit behaviour in the open ocean outside Antarctic

waters, with no evidence of foraging activity. ARS behaviour infered by the hSSSM matched the pattern of deeper dives, which were typically to depths in excess of 150 m and reached a maximum value of 452 m, thus indicating possible feeding grounds along the Ross Sea coast. Considering the recent institution of the Ross Sea Region Marine Protected Area (RSR MPA), these findings might well contribute to finalizing the research and monitoring programme required by the MPA and furthering conservation measures in the exiting Antarctic Special Protected Area (ASPA).

Tool use increases foraging success in southern sea otters.

Tool use is a behavioral innovation that allows individuals to obtain otherwise inaccessible food resources including novel prey items. Although researchers have investigated variation in tool use between sea otter populations, they do not elucidate how variation in tool use frequency contributes to differences in foraging success (both biomechanically and energetically) and fitness between individuals. Along the central California coast, southern sea otters (*Enhydra lutris nereis*) exhibit individual dietary specialization and variation in percussion tool use frequency; while some individuals use rocks and shells as anvils or hammers to break open hard-shelled prey, others do not yet still feed on hard-shelled prey. Although recent work revealed that an individual's diet is the best predictor of an individual otter's tool use frequency, little is known about how variation in tool use frequency contributes to differences in prey acquisition, caloric income, and fitness between individual otters. In this study, we tested hypotheses that individual otters with different tool use frequency will vary in their (1) consumption of hard prey items, (2) acquisition of calories, and (3) tooth damage. We analyzed foraging data from 197 tagged individual otters and quantified the fracture forces and caloric energy of different prey items across their respective size classes. We used Bayesian generalized linear mixed effect models to examine each of our hypotheses. Our preliminary results suggest that individuals with greater tool use frequency feed on relatively harder prey items and obtain an increase in caloric income. Increases in tool use frequency, however, do not result in a reduction in tooth damage; rather, age, irrespective of tool use, is the best predictor of tooth damage. These findings suggest that individuals that frequent tool users exhibit greater foraging success by gaining access to relatively harder prey, resulting in greater caloric intake.

Significant improvement of habitat-based distribution models for cetaceans in atlantic canada facilitated by a novel amalgamation of biotic and abiotic data

Lawson, Jack[1]; Goulet, Pierre[2]; Sheppard, Lee[3]

Recent cetacean modelling efforts in Atlantic Canada have employed MaxEnt models, with relatively few abiotic inputs and using chlorophyll α concentration persistance and magnitude as a proxy for prey for all species. For apex predators like the killer whale the use of chlorophyll is a poor prey substitute, and the MaxEnt approach itself relies on several subjective choices by the modeller. DFO has spent more than six years cataloguing a variety of georeferenced data strata, including abiotic (such as BPI, distance to shelf edge, dynamic oceanographic features) and biotic variables (such as distribution of higher trophic level forage fish and seabirds with diets similar to the cetaceans of interest). In addition, DFO has conducted recent broad-scale cetacean surveys and continues to expand its autonomous acoustic monitoring programme.

In this study we used habitat-based distribution models to integrate these data for a varied niche spectrum of small and large cetaceans. We then used the survey and monitoring data to assess the performance of the models with several approaches (such as binomial testing).

These models performed better than previous MaxEnt-based assessments when challenged with the systematic survey/acoustic data. With their richer range of data inputs, the improved habitat models will better predict where cetaceans in Atlantic Canada might occur in

response to climate-related prey changes. Moreover, they will allow researchers to implement superior monitoring in the future by focussing on areas with a higher probability that species of interest will be present.

Atlas, frequency and pathology of skin lesions in beluga whales (Delphinapterus leucas) from the St. Lawrence estuary, Quebec, Canada.

Le Net, Rozenn[1]; Larrat, Sylvain[2]; Michaud, Robert[3]; Lair, Stéphane[4]
(1) Université de Montréal, Lyon, France

Our knowledge on the diversity, frequency, and causes of skin lesions in free-ranging belugas (*Delphinapterus leucas*) is limited. The objectives of this study were 1) to establish a classification system of skin lesions in belugas from the St. Lawrence Estuary based on macroscopic appearance, 2) to estimate the frequency of skin lesions categories (SLC) observed during photographic surveys of this population and 3) to explore the causes of SLC in this population. A list of 18 SLC was suggested and their frequency on St. Lawrence Estuary belugas was assessed using 26,020 photographs, representing 5,388 randomly selected individual sightings, collected from 2003 to 2014 as part of a photo-identification program. Images of individual sightings of sufficient quality were screened by one observer for the presence of SLC. In individual sightings of gray and white belugas, “rake marks” (gray: 77.2%; white: 69.5%), “single linear scars” (gray: 55.1%; white: 55.0%), and “circular depressions” (gray: 39.9%; white: 34.9%) were most often observed, while “single linear fissures” (21.9%), “single linear scars” (19.2%) and “ulcer-like lesions” (17.1%) were most frequent in individual sightings of neonates. In addition, cutaneous lesions from 111 St. Lawrence Estuary belugas stranded between 1983 and 2017 were characterized microscopically. Needle-like foreign bodies were found within some “pinhole erosions” and a gamma-herpesvirus was detected by PCR in a wound. The potential cause and significance of most SLC observed in this study remain largely undetermined. “Yellow patches”, “circular depressions” and “map depressions” may be partly associated with seasonal molting in gray and white belugas. Postnatal molting could partly account for “ulcer-like lesions” and “single linear fissures” in neonates. This is the first study which investigates skin conditions in belugas in the St. Lawrence Estuary.

Assessing pinniped response to diadromous fish conservation efforts in the Penobscot River estuary

Leach, Lauri[1]; Stevens, Justin[2]; Lipsky, Christine[2]; Cammen, Kristina[3]

Following historical overexploitation across the North Atlantic, seal populations have increased in the Gulf of Maine since federal legislation aimed at their conservation was passed in 1972. More recently, reports of seals in the Penobscot River Estuary have increased. The Penobscot River Estuary in Maine, USA is the site of almost a decade of collaborative diadromous fish conservation and habitat recovery efforts. Successful conservation efforts have resulted in the growth of some populations of forage fish that use the river and estuary as spawning habitat. The objectives of this research are to evaluate trends in abundance and distribution of seals in the Penobscot River and assess their overlap with changes in the biomass of diadromous fish. A feasibility assessment of using photo-identification techniques to study individual patterns of seal spatial distribution and seasonal use will also be presented. To achieve these objectives, pinniped abundance and distribution data will be compared to hydroacoustic fish density data, both of which have been collected since 2012. Between 2012-2018, 11-18 surveys were conducted each year. Following an initial drop from peak observations in 2013 (47.7 sightings/survey), seal sightings in the river have generally increased since 2014. Seal sightings are typically highest from mid-April through May, partially overlapping with the peaks of several diadromous fish runs. This study provides an opportunity to assess pinniped ecology in a recovering system. This research will also evaluate the impacts of conservation efforts on predator-prey dynamics, which could inform future management decisions on how to best reconcile the competing objectives of marine mammal protection and fish restoration. This insight could be applicable to other systems involving protected species, as well as systems that are recovering from habitat loss and overexploitation.

Sexually diagnostic morphometrics enable photogrammetric monitoring of size structure and group composition for common dolphins

Common dolphins are an abundant upper trophic level predator in the California current, and as such can constitute a key indicator of environmental change. However, their abundance, large school sizes and pelagic ranges make individual re-identifications impossible. Instead, we are developing aerial photogrammetry measurements of length and body proportions as a tool for determining age and sex composition of groups. To validate this approach, we examined morphometrics of stranded and by-caught short-beaked (*Delphinus delphis*, n =359) and long-beaked common dolphins (*Delphinus capensis*, n=259) from the California current. Adult males were significantly longer for both species (average 186cm vs 178cm for *D. delphis* and 219cm vs 207cm for *D. capensis*). This sexual dimorphism was not significant in the measurement from snout to anterior insertion of the dorsal fin, but driven mostly by males having significantly longer tails: the measurement from the anterior insertion of the dorsal fin to the fluke notch as on average 7cm longer for males of *D. delphis* (representing 87% of the average length dimorphism) and 10cm longer for males of *D. capensis* (81%). We demonstrate how these sexually diagnostic morphometrics can be used in aerial photogrammetry studies to determine if adult males are present within schools, particularly when high-resolution images are available from low-altitude drone flights. This information is being used to examine ecological covariates for common dolphin group composition and size structure, and to investigate underlying sensitivities of certain group compositions to sonar, as part of controlled exposure experiments.

Applying the CAF-mapping algorithms to marine bioacoustics.

This presentation will discuss the adaptation of the Cross Ambiguity Function Mapping (CAF Map) algorithm and adaptations developed to use it in acoustics. The CAF Map algorithm provides a useful means of generating a geographic visualization of acoustic data when the acoustic sources are moving. It can be used to develop tracks of acoustic energy without first detecting and classifying the signal or used as a temporal/spatial filter to detect specific types of target movement. The algorithm is also able to provide discrimination between multiple signals when they are broadcasting in a partially synchronized manner. This may make the algorithm useful to detect, visualize, and track multiple marine mammal sources and observe acoustic interactions. Application to multiple sound sources will be presented, including possible blue whale (*Balaenoptera musculus*), right whales (*Eubalaena australis*) data and simulated humpback whale (*Megaptera novaeangliae*) calls.

Reproductive parameters of Indo-pacific humpback dolphin (Sousa chinensis taiwanensis) in Taiwan

Corresponding Author: jasperleeearth@gmail.com

Female reproductive parameters are important for understanding population dynamics and helpful for conserving small or declined population, i.e., the Indo-Pacific humpback dolphins (*Sousa chinensis taiwanensis*) population in Taiwan. In total of 25 breeding females and 33 different mother-calf pairs were identified from 359,452 photographs, which collected though 1056 boat surveys from Miaoli to Tainan county between 2008 to 2017. Overall, female dolphins gave birth all year around, and higher in spring and summer (May to September). The average crude birth rate was 0.032 with calving interval 5.01 years. Comparing the calf survivorship from age 1 to age 3, both calf survival rates and age-specific survival rates decreased in recent years. In average 1.2 independent calves were recruited into population each year, indicating the population were in slow growth rate. Our results indicate an emergency sign for this small population and active conservation management are immediately requested.

How do noise measurements made with seismic streamers compare to those made using marine autonomous recording units (ARUs)?

Lee, Robert[1]; Milner, Emma[2]
(1) Gardline, Tobermory, United Kingdom

(2) Gardline, Great Yarmouth, United Kingdom
Corresponding Author: robert.lee@gardline.com

Measuring the source levels of anthropogenically produced underwater noise and its subsequent propagation is often a pre-requisite for geophysical surveys or marine construction projects, such as wind farms. Regulators rely upon these source level measurements to ensure mitigation zones for marine mammals are adequate, to keep track of incidental harassment of animals throughout a project's lifespan, and to confirm the accuracy of predictive models used during the planning stages. However, for optimal recordings to be made, additional personnel and specialist equipment are required including at times the inclusion of an additional vessel. Along with delays to the start of a project, this can add significantly to a project's cost and carbon footprint, and to the cumulative sound exposure levels from having an additional vessel on site.

On many geophysical surveys a seismic streamer will be towed behind the vessel. It will be made up of many hydrophones and often exceed a length of 10 km. This has been proposed as a method to measure the source level and propagation loss *in situ* without use of additional equipment, staff, or vessels. In this study we compared the recordings from seabed moored ARUs to those taken using a single seismic streamer. Using a range of predictive models, we aimed to ascertain if the highest quality recordings could be obtained using the streamer method as opposed to the increased investment needed using ARUs.

Killer whale (Orcinus orca) dive behaviour in the eastern Canadian Arctic

Lefort, Kyle[1]; Matthews, Cory[2]; Ferguson, Steven[3]
(1) University of Manitoba
(2) Fisheries and Oceans Canada, Winnipeg, Manitoba, Canada
(3) Fisheries and Oceans Canada, Winnipeg
Corresponding Author: klefort@unb.ca

Climate-mediated decreases in summer sea ice have provided killer whales (Orcinus orca) longer access to a more extensive open-water season in the Canadian Arctic. Recent findings have suggested that killer whale occurrence in the Canadian Arctic is increasing, and photographic capture-mark-recapture studies have indicated that ~93 individuals visit the Canadian Arctic's Lancaster Sound ecoregion seasonally. According to local Inuit knowledge, killer whales prey on narwhal (Monodon monoceros) and energetic modelling indicates that this predation may have population-level effects; this is unfavourable for Inuit communities who rely on narwhal for sustenance. However, stable isotope studies and analysis of tooth wear have suggested that killer whales may subsidize their energetic requirements with Greenland sharks (Somniosus microcephalus), lessening the consumptive effects on narwhal accompanying increases in killer whale occurrence. The objectives of this study, which is the first to characterize killer whale dive behaviour in the Canadian Arctic, were to use satellite transmitters to better understand killer whale vertical habitat-use, and in particular, to investigate if killer whales are diving to the seafloor, which would support predation on benthic Greenland sharks. In September 2018, a multi-sensor satellite transmitter, which recorded depth at 75 s intervals, was surface-mounted on the dorsal fin of an adult male killer whale near Pond Inlet, Nunavut. During the ten-day deployment, the killer whale's maximum-recorded depth was 352m, although comparison with the region's bathymetry indicated that none of the animal's dives were benthic. While this suggests that feeding on Greenland sharks is unlikely, deep dives (>50m) occurred almost exclusively at night, which may represent the pursuit of pelagic marine fishes undergoing a diurnal vertical migration. An improved understanding of killer whale dive behaviour and possible feeding on Greenland sharks is necessary to assess the effects of predation on culturally, economically, and ecologically valuable marine mammals in the Canadian Arctic.

Reduced cytokine expression and lymphocyte proliferative capacity in diseased harbor porpoises (Phocoena phocoena) – biomarkers for health assessment in wildlife cetaceans

Lehnert, Kristina[1]; Siebert, Prof. Dr., Ursula[2]; Reißmann, Kristina; Bruhn, Regina; McLachlan, Michael S.[3]; Müller, Gundi; Van Elk, Cornelis E.; Ciurkiewicz, Malgorzata; Baumgärtner, Wolfgang; Beineke, Andreas

Harbor porpoises are the only reproducing cetacean species in the North and Baltic Seas and exposed to anthropogenic influences including acoustic stress and environmental contaminants. Organochlorine compounds can have detrimental effects on the

health and physiology of odontocetes and recent studies show that the effects of PCB pollution continue to affect cetaceans in European waters.

In order to evaluate immune responses in healthy and diseased harbor porpoise cells, lymphocyte proliferation assays and cytokine expression together with toxicological analyses were performed in stranded and bycaught harbor porpoises as well as in animals kept in permanent human care. EDTA blood samples were taken from the epidural vein of 9 porpoises in human care, 11 free-ranging animals, and 4 stranded harbor porpoises found diseased. Lymphocyte proliferation assays were performed and blood contaminant levels measured. Immuno-relevant cell mediators (cytokines TGF-β & TNF-α) were analysed by real time RT-qPCR.

PCB concentrations were highest in the investigated harbor porpoise blood samples, followed by DDE and DDT concentrations. All compounds were correlated, indicating co-accumulation of investigated xenobiotics. Severely diseased harbor porpoises showed a reduced proliferative capacity of peripheral blood lymphocytes together with diminished transcription of transforming growth factor- β and tumor necrosis factor- α compared to healthy controls. mRNA expression levels were significantly higher in porpoises from human care compared to bycaught ($p=0.004$) and stranded animals. In addition bycaught animals showed significantly higher expression levels than stranded animals. Correlation analyses between lymphocyte proliferation data and cytokine mRNA levels revealed that both TGF-β ($p=0.028$; $r_s=0.448$) and TNF-α levels ($p=0.038$; $rs=0.0425$) significantly correlate with ConA-induced lymphocyte proliferation. Results reveal an impaired function of peripheral blood leukocytes in severely diseased harbor porpoises, indicating immune exhaustion and increased disease susceptibility. The development of novel approaches in marine mammal immunology will help to better understand anthropogenic impacts upon cetaceans in the future.

Detection of the distribution of the Yangtze finless porpoises between the mainstream of the Yangtze River and Poyang Lake via passive acoustic monitoring

Lei, Peiyu; Li, Weilun; Wang, Zhitao; Wang, Kexiong; Wang, Ding
Institute of Hydrobiology, Chinese Academy of Sciences, Wuhan, China
Corresponding Author: lei_py@ihb.ac.cn

As the confluence of the mainstream of Yangtze River and Poyang Lake, the mouth area of Poyang Lake is a significant place reflecting the present status of the dynamic communication and possibly-existing isolation of the Yangtze finless porpoises (*Neophocaena asiaeorientalis asiaeorientalis*) between the River and the Lake. However, there is lack of elaborate information of the distribution patterns of the YFP in the area and impacts from anthropogenic activities, which is urgently needed for informing better conservation actions. In this research, a monthly and appropriately space-extended monitoring of the YFP population in the area has been carried out for the last whole year. Passive acoustic monitoring methods deployed on a moving platform—with two compact self-contained underwater sound recorders towed in tandem behind a boat on one rope, are used to detect the acoustic signals of the YFP. In the meantime, the ship courses were recorded by a GPS to acquire the distribution patterns of the YFP in the study area. 12-month data have been collected and a custom-made YFP acoustic signals detecting program based on MATLAB 2014a has been developed to obtain the time and frequency of the signals. Combined with the data of GPS, 12 pictures of the distribution patterns of YFP for each month in a whole year would be presented. In the next phase, the influence of the water level, shipping as well as two transcurrent bridges near the mouth area would be taken into consideration and analyzed with the distribution of YFP. We expect to get knowledge of and also present at the conference the temporal and spatial variation of the distribution of YFP during the experiment and the impacts of possibly related factors, through which we could have better understanding of the population status and inform better conservation initiatives for the Yangtze finless porpoises.

Diel and seasonal variation in feeding calls of humpback whales in the Kitimat fjord system, BC, Canada.

Corresponding Author: leloegoliath92@gmail.com

Humpback whales Megaptera novaeangliae, known for their songs, produce other sounds on their feeding grounds, whose functions are not fully understood. In South-East Alaska and Northern British Columbia, Canada, the production of a series of 'feeding calls' are associated with bubble-net feeding, a cooperative and coordinated feeding strategy where a group of humpback

whales feed on a prey school corralled by a spiral of bubbles. These call sequences can last more than one minute and comprise single calls that are mainly tonal in their frequency and are centered around 500 Hz. In the present study the diel and seasonal production of feeding calls was investigated for a population of humpback whales in the Kitimat fjord system, British Columbia, Western Canada. Continuous recordings were analysed from May to October 2015 and the occurrence and rate of the calls was recorded for every hour and analysed using GEE and GAM models. Calls were recorded in all months with very few calls recorded in May and a peak in calls recorded in July. Feeding calls were recorded only during daylight hours from May to July and also during night-time from August to October. The intensity of the calls was greater during daylight hours than night, when it was absent or low. The consistent presence of calls from June to October suggests this feeding strategy is an important component for the ecology of the species and the strong diurnal component strengthens the hypothesis that whales, aided by sound as an additional corralling tool, rely heavily on sight for prey detection. Annual variations in the patterns of vocalizations when using this bubble-net prey capture strategy could be used to provide further insights into the ecology of this species and the status of the ecosystem and provide insights into the culture of this species.

Stressed and slim or relaxed and chubby? A simultaneous assessment of gray whale body condition and hormone variability.

Linking disturbance events with long-term or population level impacts on cetacean populations is challenging. Cetacean body condition and hormone variability mayindicatephysiological responses to natural and anthropogenic stress events. Feasible application of these metrics to measure and monitor cetacean health requires a robust understanding of how these values vary over time, by demographics, and in relation to each other. We undertook a non-invasive study on gray whale foraging along the Oregon coast (USA) to simultaneously evaluate fecal hormone variability and body condition assessed through drone photogrammetry. We also gathered remote sensing data to explore associations between oceanography and body condition. We identified 171 individuals between June and October 2016-2018, from which we collected 164 fecal samples, and conducted 289 drone overflights to collect images for photogrammetric assessments. Immunoassays were performed for progesterone, testosterone, cortisol and thyroid (T3) hormone quantificationin the fecal samples. Hormone validations were also conducted. We observed (1) improvement in Body Area Index (BAI: body condition indicator) over time, at population and individual levels, indicating energetic gain over a feeding season, (2) BAI variation according to demographics, where calves and pregnant individuals displayed higher BAIs, followed by resting females, mature males and, finally, lactating females, (3) higher population BAIs in 2016, correlated tolower sea surface temperature and higher upwelling indices, (4) high hormone level variability (cortisol: 0.078-70.221 $ng.g^{-1}$; progesterone: 0.008-609.106 ng.g-^{1}; testosterone: 0.004-1478.041 $ng.g^{-1}$; T3: 0.039-1592.125 $ng.g^{-1}$), and (4) pregnancy detection through body condition and hormonal assessments. Associations between BAI and hormone variability are also being explored. This is the first study to simultaneously explore the variation in hormone levels and body condition relative to demographics and environmental conditions for any cetacean. Hence, results from our gray whale study system will inform multiple management efforts regarding cetacean physiological health in response to human disturbances.

The IWC at 75 years: Evolving with the challenges.

The International Whaling Commission (IWC) is one of the world's oldest environmental organizations (est. 1946). The Convention's objective remains to *'provide for the proper conservation of whale stocks and thus make possible the orderly development of the whaling industry.'* This vital post-war mandate to ensure food supply has evolved in response to its ever-

changing global context. Today's IWC addresses a growing number of population-level threats from activities other than direct harvest, reflecting how the world has changed over the lifespan of the IWC with a tripling of global human population (2.5 to 8 billion) and extensive environmental impacts of industrialization. While some cetaceans have made remarkable progress and even recovery (eastern North Pacific gray whales) due in large part to the 1986 commercial whaling moratorium, the IWC now faces considerable, complex obstacles in making progress on these emerging sources of population decline, as evidenced in a recent extinction (baiji) and another on the brink (vaquita). The IWC has stepped up to these challenges through scientific research and more recently through engagement in design and implementation of monitoring and mitigation. The globally recognized science and stewardship programs of the IWC provide evidence of the impacts of these new threats and options for action, including: bycatch and entanglement in active and ghost fishing gear (killing over 300,000 cetaceans each year); underwater noise, marine debris and other habitat pollutants; and climate change and its impact on range, feeding, and reproductive activities. The IWC's work program now features expert groups, coordinators, training and guidelines on issues such as bycatch, stranding events, entanglement response and whale watching. This helps explain why, in 75 years the Commission has grown from 15 whaling nations to 89 member governments and a large body of observers and contributors reflecting the broad stakeholder interest in cetaceans, their conservation and management.

Assessing respiratory microbiome of small- and medium-sized cetaceans using unmanned aerial systems: Breath sampling humpbacks is so 2016.

Despite the increased use of unmanned aerial systems (UAS) in marine research, there have been no documented attempts to use drones to collect samples to examine respiratory microbiome in small and medium-sized cetaceans. Remote methods of breath sampling for assessment of the respiratory microbiome, including pathogens, has the potential to minimize harassment of individuals, reduce biases in sampling associated with reactions to vessels, and maximize sampling at reduced economic costs. In 2018 and 2019 we carried out UAS breath sampling feasibility assessments with two species of medium-sized odontocetes off Hawai'i Island. UAS sampling was undertaken with short-finned pilot whales and false killer whales at an altitude of approximately 2 m above the surfacing animal. Three different drones (DJI Inspire 2, Phantom 4 Pro, Mavic 2 Pro) were used to collect nine animal samples (two from false killer whales, seven from short-finned pilot whales) from a total of thirteen attempts. No reactions were detected for nine attempts; for three, reactions were minimal (e.g., individual rolling to look at drone). During an attempt on a logging pilot whale the individual rolled on its side and associated non-target individuals responded and abruptly dove, although all returned to pre-attempt behavior within two minutes. From 2018 sampling, two of four breath and three of four control samples yielded sufficient DNA for ribosomal DNA sequencing. Preliminary results revealed common seawater microbes (SAR11 and *Prochlorococcus*, ≥98% nucleotide match) from control samples while the best breath sequence was *Methylobacterium*sp. (99% nucleotide match), a facultative methylotrophic bacterium that could be environmentally derived. These proof-of-concept studies demonstrate the ability to use drones to breath sample medium-sized odontocetes that may not be readily approachable by boat for traditional pole-based sampling. The operational system and protocols in development will increase the reliability of sample collection while minimizing reactions in future efforts.

Passive acoustics identifies a new blue whale population in the Indian Ocean

Blue whales were brought to the edge of extinction by 20th Century's commercial whaling. While some populations are increasing, the recovery rate of blue whales in the Southern Hemisphere has been slow, and they remain classified as endangered by the IUCN Red list. Ironically, although the blue whale is the largest animal on Earth, they have been difficult to study in the Southern Hemisphere; thus our knowledge about their population structure, distribution and migration, remains sparse. Blue whales within a

population produce highly stereotyped songs allowing us to distinguish, and monitor different 'acoustic populations'. We examined whether a blue whale call (the 'DGD-call') that had been described as a call-variant of a known population, was in fact produced by a different, and as yet, unknown blue whale population. Using a signal processing algorithm we identified the prevalence of the DGD-call in 17-years of continuous hydroacoustic data recorded at two North Indian Ocean sites. We show that rather than being a variant call, that across the 17 years the DGD-call dominates the underwater soundscape recorded at these sites. Seasonal differences in call detections between our recording sites shows that a large part of the DGD-whale population remains year-round in these tropical waters, and that the whales may migrate from West-to-East annually, instead of the classical North-to-South migration. We argue that the DGD-producing blue whales are an entirely different population, which questions the usual belief of a single blue whale stock in the Northern Indian Ocean. This study highlights the use of passive acoustic monitoring, and shows that for the blue whales of the Southern Hemisphere, this is an efficient approach to study this cryptic species.

The climate vulnerability of U.S. marine mammal stocks in the western North Atlantic, Gulf of Mexico, and Caribbean.

Changing ocean conditions and extreme weather events associated with climate change may be especially detrimental for marine species that are already experiencing acute human impacts (e.g., fisheries interactions, vessel strikes, habitat degradation, chemical and/or acoustic pollution). A systematic approach for assessing climate vulnerability of marine mammals is needed to identify vulnerable species and stocks and help incorporate climate change vulnerability into management decisions. We developed a trait-based climate

vulnerability assessment framework to characterize the relative vulnerability of marine mammals in the western North Atlantic, Gulf of Mexico, and Caribbean. Forty-one subject matter experts scored climate sensitivity/adaptive capacity and climate exposure for 108 U.S. marine mammal stocks and stock groups. To score sensitivity/adaptive capacity, experts used species and/or stock life history characteristics. To score climate exposure, they used projected change in climate and ocean conditions compared to historical conditions within current stock distributions. The sensitivity/adaptive capacity and exposure scores were combined to calculate a climate vulnerability index. Of the marine mammal stocks scored, 33% had very high sensitivity to climate change, 18% had high sensitivity, 34% had moderate sensitivity, and 15% had low sensitivity. The majority of stocks scored (72%) had very high exposure to climate change, whereas 24% had high exposure, approximately 4% had moderate exposure, and no stocks had low exposure. When these factors were combined, the climate vulnerability index score was very high for 44% of the stocks, high for 29%, moderate for 20%, and low for 7%. Factors including temperature, ocean pH, and dissolved oxygen were the primary drivers of high climate exposure, with effects mediated through prey. These results can inform management decisions related to statutory mandates, seed hypotheses for further research, and identify potentially vulnerable stocks as candidates for advanced modeling, monitoring, research, and conservation.

A preliminary investigation of cetacean occurrence and diversity around Hainan Island in the South China Sea.

Li, Songhai; Lin, Mingli; Liu, Mingming
INSTITUTE OF DEEP-SEA SCIENCE AND ENGINEERING, CHINESE ACADEMY OF SCI, SANYA, China
Corresponding Author: lish@idsse.ac.cn

1. The South China Sea (SCS) is known to support diverse wildlife, yet the cetacean fauna is poorly investigated. To fill this knowledge gap, we used multiple ways to conduct a pilot investigation around Hainan Island in the SCS.

2. First, we reviewed available records on cetacean stranding around Hainan from 1978 to 2016. Second, a local ecological knowledge (LEK) dataset was obtained through large-scale questionnaire-based interviews with 510 fishermen around Hainan. Lastly, we yearly carried out boat-based surveys in this region since 2014.

3. *In total, we obtained 112 stranding records, which involved 17 cetacean species, (5 baleen whale species and 12 toothed whale species). We established the Database of Cetacean Stranding Records around Hainan Island (DCSRHI, http://www.cetacean.csdb.cn/) and a cetacean rescue network in this region. Our LEK dataset served as conservation-valuable information source to investigate by-catch of cetacean in this region, and also provided insights into effective community-based conservation through understanding fishers' experiences and perceptions of cetaceans. Combined with stranding records, our LEK dataset obtained meaningful information on coastal cetacean diversity.*

4. During ~300 boat-based survey days, we sighted 5 toothed whale species for ~50 times, with the majority of sightings involving Indo-Pacific humpback dolphins (*Sousa chinensis*). A resident population of Indo-Pacific humpback dolphins was recorded in coastal waters southwest off Hainan, which expanded the known southernmost distribution range of this species in Chinese waters by more than 300 km. Besides, we also sighted Indo-Pacific finless porpoises (*Neophocaena phocaenoides*), pantropical spotted dolphins (*Stenella attenuata*), false killer whales (*Pseudorca crassidens*) and Indo-Pacific bottlenose dolphins (*Tursiops aduncus*) around Hainan.

5. To conclude, our multiple-source data indicate a high species diversity of cetacean around Hainan. More in-depth studies using novel techniques and collaborative approaches around Hainan are needed to provide baseline data for effective research, conservation and management.

Effect of whale-watching vessels on Risso's dolphins' behaviour off Pico Island (Azores).

Whale-watching is a growing worldwide industry, with potential benefits both for cetacean conservation and sustainability of local

communities. Off Pico Island, in the Azores Archipelago, whale-watching is conducted in a critical area for Risso's dolphins (Grampus griseus). We investigated the effect of whale-watching vessels on the proportion of time that dolphins spend in different behavioural states within the categories activity state, group formation, heading, and speed of travel. These were estimated for before, during and after whale-watching interactions (i.e. whale-watching vessel approached the focal group within 200m and stayed for at least 10 minutes). We calculated the transition probability between states within each category, using a first-order Markov chain model, and used these to simulate the behaviour of the dolphins over time. From the resulting time series, we calculated the proportion of time that dolphins spend in different states. Whale-watching interactions had an effect on Risso's dolphin behaviour. During interactions with the vessels, the proportion of time dolphins spent travelling increased, whereas the proportion of time spent resting decreased, leading to an overall increase in activity levels. Dolphins also increased the time spent in very tight formation, which is a common anti-predator behaviour employed by dolphins. Moreover, observed changes in heading suggest that Risso's dolphins tend to avoid the whale-watching area during interactions with whale-watching vessels. After interactions, dolphin groups spent more time in very slow swimming speed, potentially recovering from the interaction. In light of these results, we strongly recommend the use of best available science to develop whale-watching guidance, and the inclusion of a process to improve compliance, especially considering the current interest in revising the existing local regulations. Well-designed coastal management policies, including appropriate regulations, will not only protect cetaceans, but will also positively impact tourist satisfaction, increasing the probability of tourist repeating and recommending the experience.

Proposed mechanism by which retia mirabilia dampen pulsatility in the cranial circulation of the fin whale.

Retia are vascular plexuses found in the thorax, vertebral canal and cranium of cetaceans. Nagel and coworkers (*Science* 161: 898, 1968) demonstrated that retia dampen pressure pulses to the cerebral circulation, but they identified no dampening mechanism nor any source of potentially damaging pressure pulses. We hypothesize that each fluke downstroke generates a venous pressure pulse in the abdomen that travels towards the brain via the extradural spinal veins, and that the retia protect the brain from these pulses. In terrestrial mammals, because cranial volume is fixed, dampening cardiac pulsatility is closely linked to intracranial compliance: Arterial pulsatility is shunted into veins and cerebrospinal fluid (CSF) and then out of the cranium through compensating venous or CSF outflow, effectively bypassing the cerebral circulation. In cetaceans, we propose a similar mechanism dampens fluking pulses in cranial veins: a pulse in venous volume is balanced by a loss (hindered inflow) of arterial blood, made possible by the enlarged retial compliances. We tested this hypothesis using a mathematical lumped-parameter model of cranial hemodynamics. Retial blood volumes were obtained from dissection of six fin whales and compliances from inflation tests of fresh retial arteries. Flow was calculated from measured brain weight. Simulations showed that venous pulsatility was transmitted into the CSF and arteries. Increasing compliance of the spino-cranial rete reduced pulsatility in its flow by inhibiting arterial inflow. This inhibition effectively transferred pulsatility out of the cranium and into the thoracic rete upstream. Increasing thoracic rete compliance reduced its pressure pulses, but flow there remained pulsatile**.** These simulations show how the spino-cranial rete could redirect and dampen pulsatility from cranial veins, and the thoracic rete could absorb pulsatile energy to limit further propagation. The complementary function of two retial beds—one inside rigid bone and one outside—could protect the cerebral circulation from fluking-generated pulsatility.

Seasonal, ontogenetic and sexual variation in South American fur seal (Arctocephalus australis) diet: Insights from stable isotope analysis of whiskers and teeth.

The South American fur seal is commonly found along the coasts of southern Brazil, Uruguay and Argentina. Main reproductive activity occurs in the Uruguayan coast in spring/summer. Males disperse to foraging grounds in autumn/winter, while females tend to remain closer to the breeding colonies. The goal of this study was to evaluate the ontogenetic, seasonal and sexual variation in resource use through stable isotope analysis. Teeth (n=22) and whiskers (n=20) obtained from stranded adult animals in southern Brazil (31-33°S) were longitudinally sampled and had their $\delta^{15}N$ and $\delta^{13}C$ values analyzed. Dentin powder was extracted from each Growth Layer Group (GLG) with a 300µ micro drill and data were attributed to age-classes according to sexes different life histories (Males: adults ≥9yr, subadults 6-8yr, juvenile 2-5yr; Females: adults ≥4yr, juvenile 2-3yr). Whiskers were sectioned every 3mm and data were attributed to seasons according to available growth-rates. Isotope mixing models (SIMMR package) were used for estimating ontogenetic (teeth) prey contribution using published isotopic data. Sex was an important factor for whisker $\delta^{15}N$ and $\delta^{13}C$ values (Two-Way-ANOVA $p<0.05$), while season was not ($p=0.5$). According to teeth GLGs data, adult and subadult male diets were diverse, with almost even contribution of demersal-benthic, demersal-pelagic, pelagic-fish and squid (17-21% each). For juvenile males, crustaceans (14%), squid (20%) and pelagic-fish (21%) were the most important. A high contribution of squid (53%) to adult female diet was found, while for juveniles, demersal-benthic fish showed almost half of total relative contribution. Our analysis showed that fur seals have sexual and ontogenetic variation in feeding preferences, which is probably related to differential energetic requirements of each sex and age-class. Both males and females seem to have a steady diet throughout the year. Males showed a much more diverse diet, which is probably a result of their dispersive nature.

The relationship between estuary ecosystem and behavior of Indo-Pacific humpback dolphin (Sousa chinensis taiwanensis) in Yunlin, Taiwan.

The Indo-Pacific humpback dolphins inhabit near shore along the western coast of Taiwan. This species has been claimed to be associate with estuary habitat. This study is aimed to explore the association between dolphin sighting rates and estuary environmental factors, including physical factors (i.e. rainfall, runoff, turbidity…) as well as biological factors (net primary production, $chlorophyll_a$). We collected physical factors in estuary area and dolphin data collected through 45 transect-line boat surveys between 2017 to 2018. Dolphin sighting rate is positively correlated with $chlorophyll_a$ while it is negatively correlated with runoff and rainfall. Behavioral analysis indicates feeding behavior is negatively correlated with low turbidity while traveling behavior is positively correlated with high concentration of $chlorophyll_a$. High turbidity can decrease photosynthesis of algae and thus reduces productivity and further influence the dolphin activity through food web. Overall, the environment factors affect the dolphin activity through food web in estuary.

Food-risk trade-off in the Indo-Pacific humpback dolphin: An exploratory case study.

Based on the optimal-foraging theory, animals are expected to maximize foraging benefits whilst minimizing risks. Despite being highly subjected to anthropogenic impacts such as water contamination, marine traffic and underwater noise, estuaries have been identified as the preferred habitat of Indo-Pacific humpback dolphin (*Sousa chinensis*, IPHD). However, it still remains unclear why this endangered species favour such risky habitats. Here, we conducted an exploratory case study in Zhanjiang estuary (China) to test the assumption that IPHD select estuaries habitats as a trade-off that maximizes foraging opportunities whilst minimizing mortality risk. We showed that IPHD accept greater mortality risks for higher food reward, but select habitats with lower risks when food rewards are similar between two locations. Although this type of data is important to underpin

individual based models for dolphins, its principle role is to show environmental protection agencies why IPHD favours estuaries despite increased mortality risks. Habitat Conservation Plan should carefully consider prey stocks, possibly through the presence of marine protected areas near estuaries, as local overfishing may lead vulnerable cetacean populations to take greater risks.

Quantifying ringed seal lair habitat and emergence timing in the eastern Bering and Chukchi Seas

Lindsay, Jessica[1]; Laidre, Kristin[2]; Conn, Paul[3]; Boveng, Peter[3]

Climate warming presents considerable challenges for Arctic marine mammals that have evolved a strong dependence on snow and sea ice. Ringed seals *(Phoca hispida)* are ice-associated Arctic pinnipeds that are a vital resource for Arctic indigenous peoples, and are ecologically important as the primary prey for polar bears. These seals rely on snow-covered lairs in the spring to protect their pups from hypothermia and predation when they are young and vulnerable. There is a paucity of information on the amount and duration of snow required for pupping, and the timing of seal emergence from snow lairs. In this study, we use observations of ringed seals during the spring denning period from two extensive aerial surveys conducted in the Bering (2012-2013) and Chukchi Seas (2016). In total, these surveys covered 116,000 km of survey track and detected 8,449 ringed seals. Both surveys were a product of U.S.-Russian collaboration, and used a combination of thermal and color cameras to detect ringed seals on sea ice and categorize them by age class. We use generalized additive models to describe increases in the number of ringed seal detections (pups and adults) over the spring denning period (April-May) as they emerged from snow lairs. This time series of emergence provides information on the optimal timing for future aerial surveys, information sorely needed to quantify trends in abundance. We further relate trends in emergence to environmental covariates that are expected to shift under climate change, including snow depth, melt onset, temperature, and precipitation derived from satellite passive microwave data and regional reanalysis. This study thereby provides valuable information on the importance of snow and sea ice to ringed seal reproductive ecology, with implications for the species' future in a warming Arctic, and will inform successful monitoring and management.

Will conservation translocations play a critical role in maintaining future marine mammal biodiversity and are we ready for Ii?

Littnan, Charles[1]; Baker, Jason[2]
(1) Hawaiian Monk Seal Research Program, Honolulu

Corresponding Author: charles.littnan@noaa.gov

Continued anthropogenic and natural threats have pressed several marine mammal species and populations to the brink of extinction and beyond, and many more are on course for the same fate. As these conventional threats intensify, the reality of climate change as both a direct threat and driver of secondary pressures is becoming increasingly apparent. Conservation translocation encompasses a suite of tools to conserve species and populations, and effective application of these techniques to terrestrial plants and animals has seen explosive growth in recent decades. However, for marine mammals their application is relatively uncommon. These highly manipulative techniques, which foster species' recovery, are rarely considered in the marine mammal community for several reasons. Individuals may object philosophically to the notion that translocations amount to "playing god". For others, the risks and consequences of failure may seem intolerable, especially given that marine mammals present a unique set of challenges that may increase dangers associated with translocation. For many species, significant gaps in our knowledge regarding their habitat needs, physiological/stress limitations, social dynamics, population genetics, and a myriad of other variables erode confidence in our ability to successfully design and execute translocation programs. This presentation will review past and ongoing marine mammal translocation efforts, their justifications and lessons learned; discuss institutional hurdles our Society needs to overcome to normalize these techniques; and introduce IUCN and marine mammal specific guidelines and other tools to help inform translocation planning. As we face increasing threats to marine mammal biodiversity, conservationists should shift from reactive thinking and interventions to being more predictive and consider all potentially beneficial interventions, including conservation translocations. This will require changes in attitudes, policies, and foci of attention to overcome obstacles that cause scientists, managers, and others to avoid considering translocation until it is too late to reverse species' decline.

Media coverage on cetacean stranding in Chinese waters, 2007-2018: A source of

information for a nationwide stranding recording network.

Liu, Xin[1]; Zhigang, Mei[2]; Hao, Yujiang[3]
(1) Institute of Hydrobiology Chinese Academy of Science, Wuhan, China

Systematic recording of cetacean stranding provides lots of significant information and valuable basic data for conservation actions, yet an effective nationwide stranding recording system is still lacking in Chinese waters. Media coverage, serve as an important approach to obtain information, providing us with an economical method of collecting data to establish the national network. In the present study, 1083 media reports were collected and analyzed on cetacean stranding from 2007 to 2018. A total of 1,334 individuals were recorded in these reports, which could be identified at least 7 species of Mysticeti (n=54) and 22 species of Odontoceti (n=1280). Among them, Finless porpoises (*Neophocaena phocaenoides*), Indo-Pacific humpback dolphins (*Sousa chinensis*) and bottlenose dolphins (*Tursiops truncatus*) were the most common species, consisting of 49.18%, 8.77% and 3.52%, respectively. With the highest number of reported stranding in Taiwan Province (n=179), followed by Guangdong Province (n=154), Hong Kong (n=127) and Fujian Province (n=111). The diversity of stranded cetaceans was highest in Fujian Province, with 20 species involved. Cetacean stranding occurred in all months, but most frequently recorded from March to May (35.83%). In the recent decade, the annual numbers of media coverage on cetacean stranding in Chinese waters increased significantly ($t=6.16$, $p<0.01$), which might not only due to the increasing individual of stranding, but also reflect an increasing public response and conservation awareness on such events. Although the growing social attention, some problems are still existing on media coverage, such as the lack of comprehensive and detailed, which limits a great knowledge of the status of cetaceans. Hence the standardization of media reporting is recommended to providing accurate information source, and the establishment of an effective nationwide stranding recording network to promoting the scientific management and effective conservation of Chinese cetaceans.

Trade-offs between age-related reproductive improvement and survival senescence in highly polygynous elephant seals: Dominant males always do better.

Lloyd, Kyle John
Marion Island Marine Mammal Programme, Mammal Research Institute, Department of Zoology and Entomology, University of Pretoria, Hatfield, Gauteng, South Africa
Corresponding Author: kyle.john.lloyd@gmail.com

Life history trade-off theory predicts that current reproduction negatively affects survival and future reproduction. Few studies have assessed reproductive costs for males of polygynous species compared to females, despite substantial variation in reproductive success among individual males (e.g. subordinate *cf*. dominant breeders). Specifically, differentiating between the costs of attending a breeding season and the additional costs of successfully mating females is lacking. We investigated whether trade-offs are present in the highly polygynous male southern elephant seal (*Mirounga leonina*) using 34-years of individual-level data. We compare age-specific survival and reproductive probabilities of breeders (subordinate and dominant) and pre-breeders (males yet to recruit) using multievent models. Pre-breeders and breeders of overlapping ages had similar survival probabilities, suggesting that there was no attendance cost for early recruits. In addition, the probability of recruiting as a dominant breeder never exceeded recruitment as a subordinate breeder of the same age, but chances were much improved by the oldest age class. When comparing subordinate and dominant breeders, we found clear evidence for survival senescence, with subordinate breeders having a higher baseline mortality. In contrast, age-specific reproductive success (measured as social rank) increased with age, with dominant breeders maintaining higher subsequent reproductive success. These opposite trends in breeder survival and reproductive success may indicate a lifetime, population-level trade-off. However, we found no evidence to suggest that being a dominant breeder consecutively (and having a higher accumulated reproductive cost) accelerated the rate of senescence when compared to individuals that were previously subordinate. Thus, breeders experienced actuarial senescence regardless of mating success, with dominant (and possibly high quality) breeders reducing the trade-off between survival and reproductive success. We make several novel contributions to understanding polygynous male life histories and southern elephant seal demography.

Foraging-site fidelity and behavioural consistency in female Australian fur seals

Individual specialization has profound implications for population dynamics and how species adapt to environmental variability and, therefore, understanding the degree of inter- and intra-individual variation within populations is important for predicting how species may respond to future changes in their ecosystem. The Australian fur seal (*Arctocephalus pusillus doriferus*, AUFS) represents the largest marine predator biomass in south-eastern Australia, currently one of the fastest warming oceanic regions in the world, and is expected to experience significant changes to the distribution and abundance of prey. While numerous studies have investigated the at-sea movements and diving behaviour of female AUFS, revealing they forage almost exclusively on the sea floor of the shallow continental shelf of Bass Strait, little is known of the degree of individual behavioural consistency within the species. The present study investigated foraging site fidelity and behavioural consistency in female AUFS provisioning pups from Kanowna Island (northern Bass Strait). Matched data from females instrumented with GPS and dive behaviour data loggers conducting ≥2 foraging trips (4.7 ± 0.5) were obtained from a total of 36 individuals. Bhattacharyya's Affinity Index on the overlap of 95% foraging area utilization distributions within individuals ranged from 0.004 - 0.85 (0.21 ± 0.17), suggesting a generally low degree of foraging site fidelity. However, Variance Components Analysis indicated that individuals accounted for moderate-high (40-60%) proportions of the variation in foraging behaviour metrics. Using the co-efficient of variation in foraging metrics as a measure of consistency within individuals revealed substantial differences in specialization between individuals. Of the intrinsic variables investigated, linear models indicated relationships only for Standard Length and the degree of consistency in dive duration and dive depth (both positive). The observed variability of foraging specializations and low fidelity to foraging sites, provides insight into the adaptability of AUFS under the constraints of future environmental variation.

Structure and mechanical properties of Southern Right and Pygmy Right whale baleen.

Baleen is a resilient and keratinised filter-feeding structure attached to the maxilla of mysticete whales. It withstands extreme pressures in the oral cavity during feeding, making it a strong and tough, yet pliant and resilient material. We investigated the structure, water content, wettability and mechanical properties of baleen of the Southern Right *Eubalaena australis* (SRW) and Pygmy Right whale *Caperea marginata* (PRW), in order to understand the effects of hydration on the physical and mechanical properties of baleen. Sixty 25x15mm baleen specimens of each species were prepared: half were hydrated in circulated natural seawater for 21 days and half were dry. Water content analysis showed that SRW baleen was 21.2% water weight and the PRW was 26.1%. Wettability testing indicated that the surfaces of both hydrated and dried SRW and PRW baleen were hydrophilic, with hydrated samples of both species having lower contact angle values. For the SRW, the average contact angle of hydrated baleen was 40° ± 13.2 and 73° ± 6 for dried samples. Hydrated PRW baleen had an average contact angle of 44° ± 15.3, which was lower than in dried samples (74° ± 2.9). Three-point bending mechanical tests showed that the average maximum flexural stiffness of dried SRW (134.1 ± 34.3 MPa) and PRW samples (117.8 ± 22.3 MPa) were significantly higher than those of hydrated SRW (25.7 ± 6.3MPa) and PRW (19.7 ± 4.8 MPa) baleen. Scanning electron microscope images showed the stratification of the outer cortical layer, with cross-linked keratin fibres observed within and between baleen keratin sheets. Hydrated baleen, similar to its natural and functional behaviour, has greater flexibility and strength, attributes necessary for the complex filter feeding mechanism characteristic of whales. The effects of hydration must be considered in studies addressing the physical and mechanical properties of baleen, especially those using dried museum specimens.

Genetic assignment of humpback whales, Megaptera novaeangliae, from feeding grounds in the eastern North Pacific to Distinct Population Segments.

Humpback whales undertake a seasonal migration from warm-water, winter breeding grounds to high-latitude summer feeding areas. During this annual migration population segments overlap on migration corridors and in shared feeding destinations, creating a mix of multiple breeding stocks or distinct population segments (DPS). At least two breeding stocks overlap on the feeding grounds along the coasts of California, Oregon and Washington: the Mexican DPS and the Central American DPS, listed as threatened and endangered respectively under the US Endangered Species Act. Entanglement rates of humpback whales on these eastern North Pacific feeding grounds have recently increased due to interactions with fisheries activity. This increase in entanglement rates has raised concern about exceeding limits of Potential Biological Removal (PBR) allowed under the US Marine Mammal Protection Act for these management stocks. Here we present genetic differences between feeding aggregations and assignment to DPS for n = 864 samples of humpback whales sampled in the eastern North Pacific, using a standard DNA profile of genetic sex, mtDNA haplotype and 10 microsatellite loci. Preliminary analyses indicate mtDNA haplotype frequencies differ by latitude for humpback whales feeding in California, Oregon, and Washington, representing different proportions of individuals from each DPS in mixed-stock feeding aggregations. Population assignment procedures using microsatellite genotypes allow a probabilistic assignment of individuals to DPS and an alternate estimate of mixing proportions. Greater confidence in assigning individuals to DPS through genome-wide analysis (ddRADseq) is pending. Inclusion of genomic markers and improved analysis of breeding ground samples provides data necessary for informed management decisions, as fisheries closures could be imposed to reduce incidental mortality exceeding the allowed PBR of either DPS.

Using data collected from opportunistic platforms to assess marine mammal abundance and distribution in Cardigan Bay, West Wales

Collecting scientific data from opportunistic platforms is becoming increasingly common due to the financial burden of line transect surveys. Opportunistic platforms provide not only the opportunity for inexpensive data collection, but also the prospect to enhance public attitudes and awareness towards the marine environment. However, the scientific robustness of such data is often questioned. Data were collected by trained Sea Watch volunteers participating and completing both dedicated surveys and observations aboard opportunistic platforms between the years of 2014-17 inclusive within the Cardigan Bay Special Area of Conservation in West Wales. Data collected from opportunistic platforms and dedicated surveys were compared to assess the potential of using the former to accurately estimate population abundance and sighting rates and for visualising potential marine mammal hot spots. Opportunistic and line transect data showed similar trends and gave an insight into sighting hot spots. Although dedicated line transect data can yield absolute abundance estimates with much improved confidence levels compared to data collected from opportunistic platforms, this study highlights that data collected from opportunistic platforms such as wildlife trip boats should not be disregarded as they may provide a broad understanding of distribution and trends at lower cost and pinpoint areas that may benefit from further more refined study.

Seal and polar bear behavioral response to an icebreaker vessel in Petermann Fjord, Northwest Greenland.

Icebreaker vessels are important scientific tools, enabling access and research within the polar regions of the world. These vessels have the potential to overlap with marine mammal habitats in infrequently studied areas. Marine mammal

behavioral responses to icebreaker vessel presence and distance are not well documented or understood. During the Petermann 2015 Expedition on icebreaker *Oden*, seal and polar bear (*Ursus maritimus*) data were collected in Petermann Fjord (Northwest Greenland), adjacent Nares Strait region, and transit to/from Thule, Greenland July 30 – August 30, 2015. We examined behavioral responses from four seal species: bearded (*Erignathus barbatus*), ringed (*Pusa hispida*), harp (*Pagophilus groenlandicus*), and hooded (*Crystophora cristata*) and the polar bear to an icebreaker vessel in a rarely studied region. We investigated rate of flush response, entering the water from a previously hauled out location on ice, in relation to seal distance to icebreaker. Our results showed significant difference (independent t-test, $P \leq 0.001$) between seal distance to vessel when a flush response occurred (mean = 467.1 m, SD = 212.39 m) and when no flush response occurred (mean = 1334.0 m, SD = 433.89 m). There were fewer flush responses by seals at distances > 600 m and no flush responses by seals at distances > 800 m. We used a logistic model to describe the relationship between the proportion of seals that flushed and distance from the icebreaker; estimated distance at which 50% of the seals flushed was 709.45 m (SE = 9.24, $t = 76.8$, $P < 0.0001$). Three polar bears were recorded during transit and a behavioral response (e.g. look, approach, move away) was recorded for all three sightings. Our preliminary findings are relevant to assess potential impacts of increasing vessel activity in the Arctic and to assist in the development of effective monitoring and mitigation strategies.

Investigating growth layer group deposition in the earbones of old Florida manatees via tetracycline marking

Tetracycline is an injectable antibiotic commonly used for validating animal age estimation methods because it gets incorporated into bone during active mineralization, fluoresces under ultraviolet light, and persists in samples for many years. Tetracycline was used previously to determine the annual rate of growth layer group (GLG) deposition in earbones of Florida manatees (*Trichechus manatus latirostris*), but sample size was limited (n=3) for manatees >15 years old. GLG counts in earbones from manatees >15 years old often underestimate age, a finding attributed to increased resorption (bone turnover) in older animals. An alternative hypothesis is that earbone GLG deposition rate varies with age. To investigate GLG deposition in older manatees, we analyzed earbones from 11 manatees that were injected with tetracycline and were recovered dead 6–37 years later. Cross-sections of earbones were photographed under ultraviolet light to document the location of tetracycline mark(s) and then processed to visualize GLGs. Individual case histories were compared to blind GLG age estimates and estimated years since injection, based on the location of the tetracycline mark(s) relative to GLGs. Nine manatees had at least one earbone that fluoresced. Age was underestimated for the five manatees that were known the longest (>26 years). Years since injection was underestimated for five manatees and overestimated for two manatees. Heavy resorption was present in only three of these seven inaccurate cases, suggesting that there may be other reasons for error. These could include time in managed care, exposure to different environmental stressors, and changes in somatic growth with age, which all might affect bone growth and GLG deposition. Ultimately, GLG deposition may be more variable in manatee earbones than expected, particularly for older individuals, which influences the accuracy of age estimates. The growth dynamics of tissues should be considered when validating age estimation methods for marine mammals.

Haul-out behavior and detectability of bearded, ribbon, and spotted seals in the Bering and Chukchi sea

Ice-associated seals rely on sea ice for a variety of activities, including breeding, molting, pupping, and rest. In the Arctic, many of these activities occur in spring and early summer as sea ice begins to melt and retreat northward. Rapid acceleration of climate change in Arctic ecosystems is thus of concern, as the quantity and quality of suitable habitat is forecast to decrease. Here, we use data collected from bio-loggers deployed

between 2005 and 2017 to investigate the seasonal timing and environmental factors affecting sea ice use by bearded, ribbon, and spotted seals in the Bering, Chukchi, and Beaufort Seas. In addition to providing baseline data on phenology, these data also allow us to refine availability estimates needed to accurately estimate abundance from aerial survey counts of seals basking on ice. Using generalized linear mixed pseudo-models to properly account for temporal autocorrelation, we fit models with a variety of covariates (e.g., day-of-year, solar hour, age-sex class, wind speed, barometric pressure, temperature, precipitation) to explain variation in haul-out records. We found evidence for strong diurnal and seasonal patterns in haul-out behavior, as well as strong weather effects (particularly wind and temperature). In general, seals were more likely to bask on ice mid-day and when wind speed was low and temperatures were higher. Haul-out propensity increased through March and April, peaking in May and early June before declining again. The timing and frequency of haul-out events also varied based on species and age-sex class. For ribbon and spotted seals, models with year effects were highly supported, indicating that the timing and magnitude of haul-out behavior varied among years. This analysis suggested a large degree of plasticity in the timing of annual haul-out peaks, indicating they may have the ability to adapt breeding, molting, and pupping to environmental conditions.

Monitoring acoustic labels to determine abundance and individual movement of coastal bottlenose dolphins, Tursiops truncatus

Mark-recapture is commonly used for studying abundance, survival and movements of wild animals. For cetaceans, photographic mark-recapture is widely used but it is limited to day-light hours and good weather conditions, is expensive, time consuming and causes some level of disturbance. Fixed hydrophones offer a non-invasive alternative to capture individuals using acoustic labels – individually unique signature whistle types (SWTs). Over 50 years of research into signature whistles indicate a high degree of uniqueness and stability, making them ideal 'marks' for mark-recapture. We investigated the potential to use static acoustic monitoring (SAM) to detect individual bottlenose dolphins using their SWTs and analysed the data within a mark-recapture framework. Data were collected from four moored hydrophones located in Walvis Bay, Namibia. We investigated the influence of location and duration on SWT detection, by comparing data from 22 synchronised recording days at 4 sites; and 124 days of data from one high-use site. SWTs were identified using a bout analysis approach (SIGID, Janik et al., 2013). There was high variability in SWT capture rates between sites (range 0 to 13 SWTs detected). This variation may be partly explained by differences in background noise, detection ranges and/or differences in behaviour at each site (e.g. travelling/socialising). At the high-use site, 47 SWTs were captured over six months. Boat-based surveys (n= 29) carried out across the bay identified 54 animals photographically during this time. Discovery curves showed an initial increase in newly detected SWTs, approaching asymptote around 100 days. A Huggins closed capture model using months as capture occasions calculated 78 individuals (71 to 92 95% CI) which overlaps with the known population size (Elwen et al. 2019). This study indicates the potential power of using acoustic labels as proxies for individual occurrence but also highlights some potential sources of bias that may occur.

Distribution, abundance and residency time of humpback whale mother/calf pairs off NW Boa Vista or why to protect the Bay of Sal-Rei and adjacent waters

The Cabo Verde Islands constitutes the only known breeding ground for humpback whales in the eastern North Atlantic. Research activities of this population began in 1991. Since 2008, whale watching boats have been used as platforms of opportunity to monitor the population off the west coast of Boa Vista. The breeding season occurs between February and May. Fluke matches have been found between Cabo Verde and high latitude feeding grounds off Norway, Iceland and Ireland. The Bay of Sal-Rei has been identified as the single most important habitat for winter breeding, calving and nursing whales in the eastern North Atlantic. Cabo Verde Islands/Northwest Africa is regarded as one of the four humpback whale distinct population segments listed as endangered. Based on photo-identification, the small Cabo Verde humpback whale population (<300 individuals) has relatively high inter-annual re-sighting rate (ca. 50%) that suggests strong site fidelity to this breeding ground. Here we present inter-annual fluctuations in the spatial and temporal distribution, numbers and residency time of mom/calf pairs in Sal-Rei Bay and adjacent waters (<70 m deep) over the last three breeding seasons (2017, 2018 and 2019). Residency time has been defined as the minimum number of days that individuals remained in the same area. Results were quite consistent in 2017 and 2018, in terms of number of MC pairs (14 and 16, respectively), maximum residency time (ca. 30-35 days) and average residency time (ca. 8 days).Preliminary results for 2019 breeding season are pending analysis but does include a minimum of 14 mom/calf pairs.These results may have important implications for conservation and management measures that could contribute to the recovery of this endangered population, including the delimitation of a marine protected area and the regulations of human activities that could have a detrimental impact to these animals.

Impact of past climate changes on narwhal population structure and demographic history.

Climate warming is currently happening at an unprecedented pace on our planet. However, Earth has experienced severe climatic oscillations in the past. Understanding the responses of species to past climatic perturbations can provide useful insight into their resilience to on-going and future climatic shifts. The Arctic is experiencing warming at 2-3 times the rate of the rest of the planet and has already undergone major changes in the last few decades in terms of sea ice cover (declines) and air and ocean temperatures (increases). However, predicting how these changes are likely to impact endemic Arctic marine mammals is challenging due to a lack of information regarding how past climatic shifts have impacted the populations of these top trophic animals in the Arctic. The narwhal is considered to be one of the most vulnerable Arctic marine mammals to sea ice losses because of its limited distribution and narrow ecological niche. Here, we present complete mitogenomes and low-coverage nuclear genomes from narwhal samples (n=121) collected across the present distribution range of the species. We find low levels of genetic differentiation and a lack of geographic structuring of mitochondrial haplotypes. Demographic history analyses indicate that narwhal effective population size increased threefold after the Last Glacial Maximum (LGM), from ~9,000 years BP. This expansion is correlated with a drastic post-glacial increase in the amount of suitable habitat available for narwhals, as inferred from species-distribution models. The response of narwhals to post-LGM deglaciation is in marked contrast to the patterns seen for Arctic terrestrial mammals, which showed population declines or extinctions. However, it mirrors the responses of several marine top predators in the Southern Ocean, which experienced population expansions following the release of new breeding and/or foraging habitats. Our analyses suggest the amount of available habitat has been critical to the success of the narwhal.

Behavioral effects of sound from marine geophysical surveys on marine mammals: A literature review.

There are numerous recent reviews of marine mammal behavioral responses to underwater sound. However, these reviews fail to characterize biases in both literature selection and within and between reviewers. We have quantified inconsistency and bias, both in the literature and the subsequent review. We evaluated original sources on behavioral effects of anthropogenic sound, emphasizing sound sources used in geophysical surveys.

An initial review by five independent reviewers determined the most impactful and relevant literature for inclusion in the review. Reviews were assigned using a modified Gellerman series to balance the number of reviews and combinations of reviewers. A double-blind control process was implemented in the analysis of the results. A subset of references, including references for which there was disagreement among reviewers and those for which agreement was unanimous during the initial review, was then re-reviewed using the same design, providing a robust basis for quantifying inter- and intra-reviewer variability.

This review demonstrated that the reported and utilized sound source are frequently inconsistent; for example, utilizing playback of a sound source inconsistent with actual usage parameters, especially for large specialized sources like military sonars and seismic survey arrays. It is often difficult to extrapolate results from these proxy sound sources to responses produced by the actual sources of concern. Additionally, many studies characterize only short-term changes in behaviors, but the extent to which the reported effects persist is unclear. Without a durational component it is impossible to determine the potential long-term impacts to the animals, leading to tendencies to speculate unscientifically about the potential long-term outcomes. Finally, this review confirmed that observer bias, even among experts, is an unavoidable outcome in any literature review and should be factored into any literature review process.

Marine mammals seeking for prey in tridimensional environments

Within pelagic domains, marine mammals exploit tridimensional environments seeking for prey. Understanding the drivers of predator-prey interaction is a long-lasting issue in ecology. Based on integrated ecosystem surveys that collected simultaneously multi-trophic information and oceanographic characteristics, we described the tridimensional environments of marine mammal species in the temperate ecosystem of the Bay of Biscay. For that, we combined estimation of prey biomass using acoustic methods and oceanographic characterisation based on a multidisciplinary approach to model marine mammal abundance during the 2013-2018 period. During early autumn, common Delphinus delphis and bottlenose dolphins Tursiops truncatus were observed on the continental shelf, while Cuvier's beaked whales Ziphius cavirostris and long-finned pilot whales Globicephala melas were observed on the continental slope and striped dolphins Stenella coeruleoalba and fin whales Balaenoptera physalus in the oceanic area. Predator-prey relationships were explored from a functional point of view by considering prey characteristics such as prey availability, depth, body size and energetic content. Pelagic prey considered were 6 species of fishes (European anchovy Engraulis encrasicolus, European pilchard Sardina pilchardus, European sprat Sprattus sprattus, Atlantic horse mackerel Trachurus trachurus, Atlantic Mackerel Scomber scombrus and Mueller's pearlside Maurolicus muelleri) and 1 crutacean (Krill Euphasia spp.). Based on Generalized Additive Models, we developed density surface models to disentangle the effects of the 3D ocean environment and preyscapes at different depth ranges, in addition to static variables, on driving the spatial abundance of marine mammals. We validated the development of 3D predictors that integrate the outputs of integrated ecosystem surveys by identifying the biologically meaningful depth ranges linked to the ecology of marine mammals. Our outcome allows us to frame predictions about the functional structure of the pelagic network of the Bay of Biscay in autumn, and exemplifies the value of annual monitoring schemes to advance ecosystem-based management.

A review of humpback whale strandings and human interaction in Virginia and North Carolina on the southern Mid-Atlantic coast of the United States.

The humpback whale (Megaptera novaeangliae) is the most commonly stranded baleen whale along the southern mid-Atlantic US coast. We investigated 93 stranding reports in Virginia and North Carolina, USA, from 2000 to 2019 to assess seasonality, demographics, and stranding cause. Strandings occurred in every month and every year, with significantly more (n=73) occurring in cooler months (Dec-May; W=466.5; p=0.0002). Twenty-five whales were initially sighted as floating carcasses, with 11 eventually beaching or being towed to shore. Nine events involved live strandings. Two live-stranded whales refloated independently and were not re-sighted; two died without assistance, and five were euthanized. Sex ratio was nearly equal (37 females, 34 males). Minimum and maximum lengths were 609 cm and 1,541 cm, respectively, and there was no difference in length by sex ($F_{2,82}$=0.786; p=0.459). Mean length was significantly different among 5-year periods (X^2=9.702; df=3; p=0.02;) and increased from a mean of 886 cm (±200 SD) from 2000-2004 to 972 cm (±131 SD) from 2015-2019. Fifty-six carcasses were fresh to moderately decomposed, all received an external examination, and 29 (52%) received a partial or complete necropsy. Half of those 56 (n=28) whales scored YES for human interaction (HI), three scored NO, while status HI could not be determined for 25. Twenty-two carcasses displayed lesions consistent with entanglement or vessel interaction, and two displayed both. Four cases scored YES, but the cases could not be reviewed further, and lesion/HI type was not determined. Of 13 carcasses with entanglement lesions, all but two had recent/healing lesions that were suspected to be associated with the stranding. Of the 13 with vessel interaction lesions, seven had lesions consistent with blunt trauma and six had propeller lesions. These results demonstrate that humpback whales are year-round visitors to the mid-Atlantic and that the leading cause of strandings are anthropogenic.

Antarctic fur seal males: Tourists, trouble makers or an appropriate sentinel of the Antarctic marine ecosystem?

In the Antarctic, seals and seabirds are used to monitor change in marine ecosystems arising from climate change or other anthropogenic impacts such as fishing. The logistical constraints imposed by the remote location and harsh climate of the Southern Ocean has resulted in monitoring programmes focusing on species that are accessible during the austral summer at land-based sites. For example, various species of seals and seabirds are monitored during breeding at colonies along the West Antarctic Peninsula (WAP) and Scotia Sea, the region of Antarctica experiencing the most rapid warming and the primary area for Antarctic krill fishing. Foraging and breeding indices of these predators have been used to infer changes in krill availability in this region. However, adults that provide parental care must return regularly to land to feed dependent offspring, restricting how much time can be spent at sea. Consequently, breeding and foraging indices derived from parents will only integrate information over restricted parts of the marine environment and inferring changes in prey variability from such predator indices may be flawed. To highlight this limitation, we use data from an unmonitored and unconstrained life history stage of a monitored species; adult male Antarctic fur seals. We present data collected from 18 individuals instrumented with electronic tags on the South Orkney Islands shortly after breeding. Using telemetry data in addition to biogeochemical markers from whiskers, we demonstrate that the pattern of foraging is consistent over years, overlaps in time and three-dimensional space with breeding chinstrap penguins (a monitored species) and that they use the same areas as the krill fishery. We suggest that indices collected from unconstrained predators may be more informative regarding ecosystem change than those currently used, which do not integrate information across

large areas and may be subject to interference competition from unmonitored species.

Amino acid nitrogen isotope values as new tool for identifying fasting events in free-ranging marine mammals

Bulk tissue stable isotope values measured chronologically along the length of metabolically inert but continuously growing whiskers collected from adult females or pups can be used as a nutritional biomarker to retrospectively reconstruct the diet of the mother during gestation. Yet, it is increasingly recognized that physiological factors associated with fasting or reproduction may confound this interpretation. To quantify the effects of fasting and gestation on nitrogen isotope (δ^{15}N) values, we measured δ^{15}N of both bulk keratin tissue and its constituent amino acids along the length of whiskers sampled from adult female southern elephant seals (*Mirounga leonina*) captured on Marion Island in the Southern Ocean. The significant δ^{15}N enrichment (~2–6‰) of most glucogenic amino acids and simultaneous depletion (~2–3‰) of the alanine δ^{15}N values observed during known periods of fasting enabled us to accurately predict (74%) whether animals were in a catabolic (fasting) or anabolic (feeding) state during the period when the whisker growth occurred. The mechanism by which fasting affects the δ^{15}N values is explained with reference to the glucose-alanine cycle. In addition, we assessed the use of isotope values measured in tissues from paired mothers and pups (n = 15) to hindcast the foraging ecology of breeding females during gestation and assess the accuracy of isotope-based dietary reconstructions. Contrary to expectations, the mother-pup whisker isotope values were not linearly correlated, and δ^{15}N discrimination between moms and pups changed as gestation progressed. It is evident that physiological factors have an under-appreciated influence on δ^{15}N values, which can lead to erroneous isotope-based dietary reconstructions. This study also provides proof-of-concept that an isotope-based approach can be used as a nutritional biomarker for assessing the state of nitrogen-balance of an individual.

Standardization of protocols for quantifying GST activity and CYP1A levels in integument biopsies of Tursiops truncatus, Stenella longirostris and Balaenoptera brydei

Lüchmann, Karim Hahn; Righetti, Barbara P.H.; Mattos, Jaco J.; Lima, Daína; Lanzarin, Lígia H.; Rodrigues, Luiza M.; Bôas, Luiz O.B.V.; Bainy, Afonso C.D.

The widespread occurrence of xenobiotics in marine waters has prompted the development of pollution monitoring programs to guide the conservation of marine mammals, focused on determining contaminant levels and evaluating the biological related-effects on biota through the analysis of biomarkers. Nonetheless, their use may be limited due to the absence of standardized methods specific to integument of cetacean species. Thus, this study aimed to standardize the protocol of two classic biomarkers: glutathione *S*-transferase (GST) activity and cytochrome P450 1A (CYP1A) immunodetection in integument of *Tursiops truncatus*, *Stenella longirostris* and *Balaenoptera brydei*. The samples were collected during the Cetacean Monitoring Project (PMC-BS), required by Brazil's federal environmental agency for the environmental licensing process of oil production and transport by Petrobras at the Santos Basin pre-salt province. For the GST activity, kinetic curves were constructed for the substrates 2,4-dinitrochlorobenzene (CDNB) and reduced glutathione (GSH), and fitted to Michaelis-Menten non-linear regression. For CYP1A immunodetection, microssomal protein loads and antibody (primary – ABCAM 126887 and secondary – ABCAM 205723) dilutions were tested for each species, and optimal parameters were established by chemiluminescence. For GST activity, optimal CDNB and GSH concentrations were: 12.4-24.9 mM and 3.5-7.0 mM for *T. truncatus*, 12-24 mM and 2.1-4.3 mM for *B. brydei*, and 12.5-25 mM and 2.1-4.3 mM for *S. longirostris*, respectively. Regarding CYP1A, 10 µg was the optimal protein load, and primary and secondary antibodies dilutions were established at 0,1 µg/mL and 0,15 µg/mL, respectively, for *T. truncatus* and *S. longirostris*, and the secondary antibody at 0,3 µg/mL for *B. brydei*. Results indicate similarity among species, suggesting that tissue features might be more important than species for analytical standardization. Nonetheless, optimal substrate concentrations obtained for GST are higher than those described in standardized protocols and reinforce the need of standardization of such methods to avoid any unbiased results.

Identifying novel predictors of bycatch of protected species in static net fisheries to better inform mitigation.

Bycatch of protected species in static net fisheries is a global conservation concern, and is currently considered the dominant anthropogenic threat to many marine mammal species worldwide. Effective bycatch mitigation remains challenging, contingent on an understanding of the underlying mechanisms that cause individuals to become entangled. We combined data collected by scientific observers and fishers to identify the strongest drivers of seal bycatch in static net fisheries along the west, southwest, and south coasts of Ireland. We included in our analysis factors relating to the type of net used (mesh size) and the environment in which they were set (distance to major seal colony, water turbidity, depth, and the occurrence of seal depredation of catch). Based on a negative binomial generalised linear model, the rate of seal bycatch significantly increased in nets with larger mesh size, when seal depredation occurred, and in waters that were more turbid. The effect of distance to major seal colonies on bycatch rates varied with season; increasing closer to colonies in spring, summer, and autumn. Our results identify reliable predictors of seal bycatch that can be used to identify future bycatch risk and target mitigation measures accordingly. This is the first study to identify the effect of water turbidity on bycatch of protected marine species. Increasing net visibility in turbid waters may provide a novel approach to mitigating against protected species bycatch in static net fisheries.

Geo-spatial analysis on oil-spill risks for marine mammals in Peru: In need of an action plan.

Corresponding Author: luckow@orca.org.pe

Oil spills are a worldwide concern when it comes to the long-term effects that impact the marine ecosystem. Oil can be toxic through contact with skin, inhalation and ingestion. There is currently no formal oil spill response plan for Peru, yet the Peruvian coast is home to 30+ marine mammal species that are at risk or endangered. We analyzed the risks of a potential oil-spill considering the geo-spatial distribution of marine mammals to produce an efficient proposal of an oil-spill action plan. Geo-positional system coordinates were taken for fixed rockeries for three pinniped species, as well as frequency of coastal sightings and strandings of ten cetacean species. Overlap mapping of these coordinates was confronted with the physical distribution of current oil platforms and gas plants. Geospatial analysis helped us to identify the areas where oil production is high: Over 40 platforms in Tumbes and Piura states in the northern coast; six oil distribution plants in Lima and Ica in the central coast, and thirteen distribution platforms are projected in Moquegua state in the south. Amazingly, these states are of ecological significance and most of the platforms are within the range of Natural Reserves, carrying >80% of at-risk species, including the endangered marine otter. Several lessons have been learned following past oil-spill events, and it is clear that prevention plans, buffer zones and safety guidelines must be developed in Peru. In the event of an oil spill, only ORCA's South Pacific Marine Mammal Center in Lima can provide medical assistance. In consequence, we found that the overall result today would be that of a high risk and a severe impact. This further proves our need to advocate for an oil spill action plan for marine mammals as the next step in the conservation and protection of coastal Peru.

Geographic variation in the acoustic repertoires of common bottlenose dolphins in the Atlantic Ocean and the Mediterranean Sea

Intraspecific variability in acoustic repertoires is common in widely distributed species, and geographic variation in this trait has been used to distinguish populations of marine mammals. Acoustic divergence in cetaceans has been linked to ecological factors, geographical barriers, and social processes. In the case of common bottlenose dolphins (*Tursiops truncatus*) most studies of geographic variation focus on a single sound category: whistles. Here, we study the acoustic repertoires of nine bottlenose dolphin populations across the Atlantic Ocean and the Mediterranean Sea, and identify divergence patterns of shared acoustic signal elements and acoustic variants. Repertoire composition was defined based on the occurrence of different signal types and sub-types, both pulsed and tonal sounds. A similarity index derived from Dice's coefficient of association was used to assess repertoires' (dis)similarity. Our results show multi-regional richness in the acoustic repertoire of these dolphin populations, with a total of 21 nominal signal sub-types including: whistles, creaks, squawks, brays and bangs. Acoustic divergence was observed only in social signals reported as information-rich calls, namely whistles and the elements of bray sequences (e.g. squeaks, grunts and gulps). The repertoire dissimilarity values were remarkably low (from 0.08 to 0.4) and support previous work showing that signal repertoire does not mirror geographic distances among dolphin populations. The highest repertoire similarity was found between the Sado estuary, Portugal and the Adriatic Sea dolphins, which live in very similar environments. The lowest similarity was found between the neighboring populations of Gandoca-Manzanillo, Costa Rica and Bocas del Toro, Panamá that live in contrasting habitats. Our results support the 'environmental adaptation hypothesis' - geographic variations in animal acoustic repertoire may reflect local adaptations to specific environmental contexts. Geographic variation on acoustic repertoires may clarify the boundaries between neighboring populations, and shed light into vocal learning and cultural transmission in bottlenose dolphin societies.

A classification scheme for external injuries of dolphins: Towards objective quantification and comparison across space and time.

Dolphins are impacted by a variety of threats but little is known about spatial, temporal and inter-species variation in injuries. Our review of studies which quantified the prevalence of injuries in dolphin populations shows that different criteria are being used for classifying injury types and that injuries are reported using different methods. We argue that the cause of injuries is often speculative and therefore unsuitable as the primary basis for a classification system. The lack of a universal method for reporting the prevalence of injuries in marine mammals hampers comparative studies of geographic, temporal, and inter- and intra-specific variation in the prevalence of injuries. To remedy these problems we propose a classification system for quantifying external injury types in marine mammals which defines injury types on the basis of their external morphology. We will test the proposed classification system with several photo databases. We review current knowledge about the cause(s) of these injury types and identify topics for further study. Standardized reporting of injuries will hopefully deepen our understanding of factors that affect the health and survival of marine mammal populations worldwide.

Quantifying habitat use of killer whales in Vestmannaeyjar, Iceland.

Corresponding Author: realyal91@gmail.com

Animal movements largely depend on the proximate (immediate) or ultimate (long term) requirements of the animal, and whether the habitat resources can meet those requirements. *Orcinus orca* are a globally distributed species, but tend to occur in higher numbers in temperate and polar regions. In Iceland, killer whales are annually sighted in the summer months on the spawning grounds of the Icelandic Summer-Spawning (ISS) herring stock, located on the gravel beds around the Vestmannaeyjar archipelago, south Iceland. To understand if killer whales occur in this region to feed on spawning herring we used ArcGIS to investigate killer whale habitat use based on data collected in July for six years, and environmental data (substrate type and depth) from the European Marine Observation Data Network (EMODnet). The location of sightings was obtained from the GPS locations of killer whale images collected during surveys. Data layers were built upon a 170m² grid, firstly intersected with survey vessel tracks, the presence or absence of orca per surveyed cell, and lastly the environmental data layers, resulting in maps of orca habitat use around Vestmannaeyjar (556 km²). A generalised linear

model tested the effect of the explanatory variables (substrate type and depth) on killer whale presence. The results showed coarse sediment, which accounted for approximately 40% of the total study area and is the material most suitable for herring spawning, was the strongest determinant of orca presence ($p < 0.0005$). Sightings' depth was also more strongly correlated with habitat suitable for herring spawning than not. This study suggests that within this region, killer whales are choosing areas suitable for herring and targeting this prey, but further research will be necessary to investigate if there are temporal or individual/group-specific variations in habitat use.

Are recent population level changes in the central North Pacific humpback whales, Megaptera novaeangliae, affecting entanglement threat and reporting rate?

Entanglement in fishing gear and marine debris is considered a principal anthropogenic threat to large whales. Over a hundred whales are reported entangled in the North Pacific annually. In some regions scar studies have indicated that approximately 50% of the animals have been non-lethally entangled. Entanglement threat is influenced by many dynamic factors, such as gear type, the co-occurrence of animals and gear/debris, and lack of familiarity (e.g. changes in habitat use and/or fishing effort) and/or inexperience of animals (e.g. age class considerations). Changes in effort may also influence reporting. Starting in 2013, significant population-level changes (e.g. sighting rates, habitat usage, animal condition) began to be documented in the Hawaii distinct population segment. These changes likely influenced entanglement threat. While confirmed entanglement cases reported on the feeding grounds off Alaska have decreased the last 2 years, they generally have remained constant over the long-term. However, reports off British Columbia have shown a general increase since 2015. Entanglement reporting on the breeding/calving ground off Hawaii varied less, perhaps in part due to an increase in reports originating from British Columbia. Reports of subadults entangled off Hawaii have decreased, possibly as a result of greater energetic costs of entanglement and a changing environment (e.g. limited resources) on subadults. However, the rate of non-lethal entanglements, as determined through scar analysis in Hawaii, has not changed significantly over the period. The percentage of reports from Alaska feeding grounds involving nearshore-set gear, as well as, involving the mouth have tripled and doubled, respectively, perhaps a result of differences in local habitat use by whales. Information gained by evaluating entanglement risk remains our best strategy for reducing entanglement threat. However, broad-based changes, such as environmental trends and cycles, may provide additional challenges to understanding an already dynamic threat – entanglement, affecting humpback whales and other species.

Rethinking the process of whale entanglement through first person observations.

Whale entanglement in fishing gear has been extensively studied along the East Coast of North America. Considerable work has been done to

determine when and where whales overlap with gear, but relatively little is known about the events leading up to an entanglement. Efforts have been made to model those interactions, but require data and entanglements are rarely witnessed in progress. Over the past decade, through tens of thousands of routine whale sightings, we witnessed eleven whales come into physical contact with fishing gear, including rope-based gear and monofilament from rod and reel fisheries. In all of these cases, there is at least one example of each major body area making first contact with gear and all strongly changed their behavior, exhibiting strong arches, changes in direction, surging, rolling, and/or tail flicks. Five individuals did not ultimately become entangled and returned to prior behaviors within minutes of contact and no observable injuries detected. However, more than half of the individuals became entangled (three in rope and three in monofilament). The behavioral state of all of these individuals remained altered for the duration of the observations, up to 2.75 hours. In the rope-based cases, there were multiple changes in gear configuration, including whales becoming mobile with heavy gear and the formation and loss of wraps of line to more body areas following initial contact, as a result of this behavioral response. Our observations suggest, that the configuration of gear on the body when typically viewed (days or weeks after the event) may not reflect exactly how the individual first contacted the gear. Although data remain limited, detailed study of the behavior of whales at the initial gear encounter is critical for understanding entanglements and for making effective changes to fishing practices to reduce this serious threat.

From here to there: Distance reproduction in a harbor seal.

Harbor seals and other marine mammals regularly commute between haul-out places and feeding grounds. Mostly it was speculated that the seals' orientation and navigation abilities are based on cues derived from external sensory systems. However, at first glance the open ocean does not seem to provide many external cues for orientation. Therefore, we propose that seals might rely on information that can solely be derived from internal cues, if necessary. These internal cues could help the animal to continuously document distances travelled as a parameter for spatial orientation.

Here, we tested a harbor seal in a distance reproduction task along a 43 m long stretched belt system in the water. The seal was familiarized with a standard distance interval, which it immediately had to replicate by keeping the same swimming direction. The seal was able to reproduce a given distance very accurately and independently from its absolute position. Furthermore, it could decrease its error of replication to less than 10% when asked to replicate specific distances repeatedly. We could also show that the seal did not learn specific endpoints during the reproduction and might have focused on motor cues by swimming specific motion patterns for each given distance. Its performance was also almost unimpaired in the absence of optical cues. Thus, we conclude that distance estimation and reproduction could assist spatial orientation in the seals' natural environment, even when external information is missing.

Using whale alert in southeast Alaska: Creating safe waters for both mariners and whales.

After discussions among stakeholders about whale strike avoidance in Southeast Alaska, the maritime community sought the ability to avoid whales and take proactive measures (i.e. reducing their speed) in areas where whale aggregation

s occur. In response, NMFS Alaska Region and National Park Service (NPS) biologists have worked together since 2011 to produce weekly whale sightings maps that improve situational awareness for bridge teams on cruise ships and the Alaska Marine Highway state ferries. Cruise ships and state ferries are the target audience because their prior experience with whale strikes motivates them to improve situational awareness and avoid collisions. These weekly maps helped to inform mariners' whale avoidance and proactive measures, however the sightings were up to a week old when delivered in this format. Real-time whale sightings were a mutual goal realized in May 2016, when mariners and biologists were able to share sightings in the Whale Alert online mapping system and smart phone applications. After the first 3 seasons of digitally capturing and reporting sightings, we'll present lessons learned and a path forward for continued conservation.

Tracking harbour porpoises around static fishing nets using PAM

Static nets are by far the largest cause of anthropogenic mortality in harbour porpoises in UK coastal waters, with best estimates indicating

bycatch levels between 587 and 2615 individuals in 2017. Despite this, very little is known about how wild animals behave in the vicinity of nets and what the mechanism leading to entanglement is. This represents a significant barrier to the development of new bycatch mitigation strategies. Single-channel passive acoustic monitoring (PAM) devices have been previously used to record cetacean activity around static nets. These devices are generally limited to monitoring presence/absence and basic behavioural cues such as foraging buzzes. We have developed a recording system (SoundNet) which can track the fine scale three-dimensional movements of harbour porpoises (or any echolocating odontocete) around nets. The system consists of two compact four-channel recorders (SoundTraps) which record 384 kHz data for 5 days (the upper end of a typical static net soak time). Each recorder has a sample synchronised sensor package which uses 3D motion tracking technology to accurately log orientation, depth, temperature and light. Recorders are used in pairs, attached directly to the net floatline and can be deployed by hand during normal fishing operations by a trained researcher or experienced fisheries observer. Recordings are subsequently analysed in PAMGuard and the positions of animals calculated using acoustic localisation methods. We present findings from two static net deployments (each circa 2.5 days soak time) during which 10 separate porpoise encounters were recorded, two of which producing enough detected clicks to effectively track their movements. Tracks show a porpoise approaching the net and turning away when within 10 m. It is expected that continued deployments will yield a sufficiently large dataset to investigate porpoise behaviour near actively fishing static nets. This open source technology could be applied to other species and locations.

Does Guina dolphin repertoire change over time? 20 years of recording data.

Acoustic repertoires may change in temporal and spatial scale, which can result from new social alliances, by changes in the acoustic soundscape or geographic variation. Considering the increase of the anthropogenic impacts in Sepetiba Bay (Rio de Janeiro, Brazil) over the years and the movements of Guiana dolphins (*Sotalia guianensis*) between Sepetiba and Ilha Grande bays (Rio de Janeiro, Brazil), the goals of this study are: 1) to evaluate the temporal changes in whistles of Guiana dolphins in the last 20 years in the Sepetiba bay; 2) spatially compare the acoustic repertoire between Sepetiba and Ilha Grande bays. We divided our database of acoustic recordings in two settings: "past time" (Sepetiba Bay between 1998 and 2002) and "present time" (Sepetiba and Ilha Grande bays 2015 to 2018). In order to compare whistles in temporal and spatial scale, we compared frequency contours over tow time series and between bays. We compared 200 frequency contours in each population using the ARTwarp method. For this comparison, we used a 96% vigilance with contours re-sampled at 10ms. We identify a total of 74 contour types in Sepetiba bay and 114 in Ilha Grande bay. The temporal comparison indicated 63 contour types only in the past, 4 in the only in the present and 8 in both time series. The spatial comparison indicated a total of 10 whistles shared among populations. Previews studies point to an increase of anthropic impact in Sepetiba bay and indicate that Guiana dolphins are changing their acoustic behavior over time. Thus, the observed temporal changes may indicate acoustic changes due to anthropic impacts in the bay. In addition, spatial changes indicate that even spatial separation between Guiana dolphins in this bays, they may remain social connection.

Capturing fishermen's knowledge to understand the scale and impacts of marine animal entanglement in Scottish waters from a conservation, welfare and economic perspective.

Marine animal entanglement in fishing gear is a growing problem worldwide, considered by many to be the single most significant marine mammal welfare issue of our time. In Scottish waters the reported prevalence of entanglements over the last 20 years has remained low, but based on data

collected by the Scottish Marine Animal Stranding Scheme (SMASS) the incidence and range of affected species appears to be increasing. Entanglement in static gear has now been identified as the largest cause of non-natural mortality in Scottish baleen whales, however a thorough scientific understanding of the impacts of these incidents remains limited due to underreporting, constraints of post-mortem examinations, and the low likelihood of retrieving carcasses. In a bid to address this, the Scottish Entanglement Alliance (SEA) was established in June 2018. A partnership between six marine research, industry and conservation and welfare bodies, SEA is working closely with small-scale static fishermen to provide a co-ordinated, comprehensive monitoring and engagement programme to better understand the scale and impacts of marine animal entanglements from various perspectives. To achieve this, inshore creel fishermen have been participating in anonymous interviews regarding their fishing practices, wildlife encounters and experiences and knowledge of entanglements. To date 109 interviewed have been completed and 105 separate and previously unreported entanglement incidents involving cetaceans and other species have been recorded. This is the first time this type of research has been conducted in the UK and feedback from fishers so far is highlighting several technical, policy and social challenges surrounding entanglement in small-scale fisheries. However over 80% of those interviewed have expressed an interest in engaging in measures to reduce the risks of future entanglements. This demonstrates the potential to develop practical, industry-led solutions to this issue in Scottish waters, which will form the next stage of this work.

The impact of spatial scale on the scale of impact: Harbour porpoise Phocoena phocoena bycatch in the Celtic Seas.

Understanding the impact of activities on populations is fundamental to conservation efforts. Impact assessments are required at a variety of spatial scales, often predefined by legislative or administrative boundaries. The use of such boundaries for impact assessments, could give rise to misleading outcomes and potentially put species at conservation risk. We used harbour porpoise (*Phocoena phocoena*) bycatch data collated by the International Council of the Seas (ICES) working group on bycatch of protected species (WGBYC) to demonstrate this issue. WGBYC supports ICES advice to the European Commission on the wider ecosystem impacts of fishing activities. ICES has undertaken several ecosystem reviews within ecoregions and WGBYC has been encouraged to conduct its assessments within ecoregions to facilitate this process. Using 2015 - 2017 data, we estimated the bycatch of harbour porpoise in gillnets in the ICES Celtic Seas ecoregion to be 230 - 471 animals per year or 0.28-0.58% of the best available abundance estimate for this ecoregion. This is less than the 1.7% threshold that ASCOBANS uses to define an unacceptable level of interaction. However, the Celtic Seas ecoregion was not based on evidence of population sub-structuring for harbour porpoise and it likely extends over two subpopulations. Therefore, we repeated the analysis within a recently defined Celtic Sea Assessment Unit (AU) that was delineated from biological information on the northeast Atlantic harbour porpoise. These results highlight a potentially more pressing bycatch problem, with an estimated 2- 6% of the unit's population taken annually. Recent survey data from this area, also show a much lower density of porpoises in parts of this AU compared to estimates from 10 years ago. Impact assessments must be carried out at biologically meaningful spatial scales if the magnitude of population-level impacts is to be understood and the need for conservation action prioritised.

Examining patterns in human interaction with bottlenose dolphins (Tursiops truncatus) and assessment of public awareness of policy: A multiple regression model provides a dual approach for understanding a conservation issue in Tampa Bay.

It is well documented that human interaction (HI) with cetaceans can have detrimental population level effects. To mitigate this stress, the National Marine Fisheries Service has established the Southeast U. S. Marine Mammal and Sea Turtle Viewing Guidelines (henceforth, Wildlife Viewing Guidelines, WVG) to promote responsible use of bottlenose dolphin stocks in Florida; however, little work has been focused on determining the efficacy of these policies. The Eckerd College Dolphin

Project documented HI encounters opportunistically from 2009-2018, providing a long-term dataset for which boater compliance to the WVG could be analyzed. We assigned a compliance code to each HI encounter (n = 151) in our dataset for a range of compliance from non-compliant and negligent (3) to compliant (0). We then performed a stepwise multiple regression as a function of vessel characteristics, such as vessel type, in order to identify key explanatory factors for encounter compliance in the study area. Vessel activity was the key explanatory variable identified by the model for HI encounters, where vessels engaged in wildlife viewing tended toward a greater degree of non-compliance. We assessed baseline public awareness of the WVG by distributing a survey to beachgoers. We calculated a policy awareness score for each respondent (n = 225) determined by the number of questions specifically addressing the WVG answered correctly. Then we performed a stepwise multiple regression as a function of demographic data, highlighting key predictors for policy awareness. This preliminary survey provides insight on potential targets for increased public education measures as gender, education level, and age were the most important predictors of policy awareness. Thus, this study provides a dual approach for analyzing boater compliance to the WVG and public awareness of these conservation policies. Managers could use such information to better target allocation of enforcement and education resources.

Harbour porpoises modify biosonar behaviour in different environmental contexts

Toothed whales use biosonar for foraging and navigation in a wide range of habitats from shallow rivers to coastal waters and open oceans. The ambient noise, clutter and reverberation levels that limit biosonar operation may vary widely between and within these aquatic habitats. Toothed whales must therefore cope with dynamically changing masking levels while extracting the echo information of interest. Dynamic biosonar adjustments have mainly been studied in relation to range to the main target(s) of interest, however, the influence of the context in which echolocation tasks are solved is largely unknown. Here we test the hypothesis that toothed whales use context-dependent biosonar adjustments. We did this by training two captive harbour porpoises to actively approach the same sound recording target (SoundTrap), while blindfolded and wearing a sound recording tag (DTAG-4), over the same 8 m approach distance in two highly different environments; a PVC-lined pool and a semi-natural net pen in a harbour. We show that the porpoises used significantly longer interclick intervals (ICIs) in the net pen than in the pool except during the buzz phase where the porpoises used slightly shorter ICIs in the net pen. The reverberation level, quantified as the median 128 kHz third-octave level, was more than 10 dB higher in the pool than the net pen. We also demonstrate stronger range-dependent ICI and source level adjustments in the pool compared to the net pen environment. We conclude that context is an important factor to consider in addition to target range in studies of biosonar dynamics, and adds another layer of complexity to understanding toothed whale biosonar operation. Importantly, passive acoustic monitoring (PAM) studies should therefore consider context and species-specific ICI distributions across widely different habitats.

Morphological and molecular identification of gastrointestinal parasites in free-living striped dolphin (Stenella coeruleoalba) of the Gulf of Taranto (Northern Ionian Sea, Central Mediterranean Sea)

The striped dolphin *Stenella coeruleolba* has been reported to be host of several gastrointestinal parasites as protozoa, nematoda, cestoda, trematoda and acanthocephalan, some of them considered to be highly pathogenic and cause of death for this small odontocetes. Generally, parasitological investigations on the gastrointestinal parasites have been carried out on stranded and dead dolphins and only occasionally the necropsy provided information on death cause. Conversely, data on gastrointestinal parasites in free-living dolphins are still limited due to the difficulty in collecting samples and the cost effort in performing experimental studies. The present study provides results on the gastrointestinal parasites fauna infecting *S. coeruleolba* free living in the Gulf of Taranto, by using non minimally invasive methods to collect fecal samples. Standardized vessel-based surveys targeting the striped dolphins was carried out from September 2018 in the study area, and

GPS position, depth (m) and number of observed striped dolphins were recorded during sightings. Each fecal sample was subjected to coprological examinations and molecular techniques in order to identify/characterize the parasites. Analysis revealed that *S. coeruleolba* harboured 3 parasites species (2 protozoa and 1 nematode) with some of them bearing zoonotic and/or pathogenic potential. Although preliminary, this study represents the first parasitological monitoring in free living dolphins within the Mediterranean Sea providing a baseline for studies on dolphin's health as well as a contribution towards the development of effective conservation plan for species in this biogeographic region.

The International Impulsive Noise Register for the Mediterranean Sea Region (INR-MED)

Maglio, Alessio[1]; Sanchez, Marta[2]; SALIVAS, Maylis[3]; Ben Nakhla, Lobna[4]
(1) SINAY, Valbonne - Sophia Antipolis, France

(4) SPA/RAC, Tunis, Tunisia
Corresponding Author: alessio.maglio@sinay.fr

The QUIETMED project, funded by the EC-DG Environment, aims to enhance cooperation among Member States (MS) in the Mediterranean Sea to implement the Second Cycle of the Marine Directive through: i) promoting a common approach at Mediterranean level to update GES and Environmental targets related to Descriptor 11 on underwater noise; ii) development of methodological aspects for the implementation of ambient noise monitoring programs; iii) development of an impulsive noise joint monitoring program based on a common register, including gathering and processing available data on underwater noise. The project was developed by a consortium composed of 10 entities coordinated by CTN. It ended in December 2018, after 24 months of duration.

In this framework, a common register for the Mediterranean basin for the monitoring of impulsive noise was developed in line with the European Commission Decision 2017/848 and following technical recommendations from the TG-Noise. The conception is based on the first demonstration tool developed by ACCOBAMS in 2016. The development also took advantage of similar initiatives on Descriptor 11 in European seas (OSPAR, HELCOM and ICES).

This Impulsive Noise Register in the Mediterranean region (INR-MED) facilitates the assessment of pressure levels for D11 in the process relative to the MSFD or to the Ecosystem Approach led by Barcelona Convention (for EU and non-EU Mediterranean Countries). Indeed, once data are uploaded, the reported noise events are displayed in a map interface and calculation of Criterion 1 of D11 (Anthropogenic impulsive sound in water) is automatically provided, facilitating the interpretation.

For moving forward with future combined risk and impact analysis, the project QUIETMED2, also funded by the DG Environment, will facilitate the assessment through the establishment of a link between the pressure and the associated environmental risk.

Interactions between cetaceans and purse seine fisheries in the Madeira archipelago (NE Atlantic)

The waters off Madeira archipelago present a large diversity of marine mammals. Of the 38 species that can be encountered in the Atlantic Ocean, 29 have been recorded here. Despite this great abundance, this study provides the first assessment of the range and impact of cetacean interactions with fisheries for this region. One observer collected data aboard three artisanal purse seine fishing vessels small targeting small pelagic fish species, covering 100% of the fleet, during 13 months. Data collected covered cetacean sightings, fishing event parameters and interactions. Thirty-six sightings were registered on 21 trips, from a total of 72 trips monitored. The common bottlenose dolphin (Tursiops truncatus) was the main cetacean species sighted and seen interacting, followed by the short-beaked common dolphin (Delphinus delphis). From the several variables analysed, only the association of sardine (Sardina pilchardus) total catch biomass and cetacean presence was found to be statistically significant (P value = 0.0333) . In Madeira, sardines have low commercial value, thus there is no pressure from fishermen to take action or to implement measures in order to decrease this interaction. However, some negative reactions, including one by-catch event with mortality, were observed, suggesting that mitigation measures may be needed to protect cetaceans. The fact that all the fishing trips occurred at night, with limited

visibility, made the correct identification of cetacean species difficult, and a relatively low percentage of trips was surveyed. This might have influenced the data analysis and conclusions towards good local stock availability, and little or no competition between fishermen and top predators. These results should be regarded with caution as further studies covering more trips and other types of fishery should be undertaken to lead to a more complete assessment of the range and impact of fisheries on cetaceans, in this important oceanic region.

Subarctic winter whales: An overwintering strategy of humpback whales in Icelandic waters.

Corresponding Author: eddaem@hi.is

Humpback whales (*Megaptera novaeangliae*) were near depletion during the mid-20th century, but for the last two decades they have been recovering rapidly, particularly in polar regions for the last few years. The humpback is a migrating baleen whale whose behaviour is believed to be largely discrete between their winter breeding and summer feeding grounds. Recent research on the migration behaviour of humpbacks in the North Atlantic has shown a delayed winter migration and even overwintering of humpbacks in the subarctic. Recent findings by the author showed how males engage in active singing (a male breeding display) during their reported breeding season in the subarctic, indicating a trade-off between growth and reproduction on a high latitude feeding ground; a strategy which may have assisted these populations' recovery.

The aim of this study is to investigate the occurrence, habitat use, sex ratio and physical state of humpback whales in an Icelandic subarctic feeding ground during the breeding season (January–March) in comparison to the more traditional May–October feeding season. The physical state observed is sexual receptivity, based on sex hormone levels (testosterone, oestradiol and progesterone), and stress based on cortisol levels. Such measurements will allow for an investigation of mating opportunities in the subarctic, pregnancy rate and whether humpbacks experience more stress during the subarctic winter months compared to other seasons. Such information provides insight into the trade-off strategy between overwintering and migrating. The biopsy samples are collected from free roaming humpback whales during the winter (November-February), late spring (April-May), late summer (August) and fall (October). The preliminary results from the first year, i.e. 2018-2019, of a three years study will be presented. The findings could provide a new global perspective of the life history dynamics of this species and their possible response to the rapidly changing climate of the Polar Regions.

Long-term mom/calf associations in rough-toothed dolphins (Steno bredanensis) off the island of Hawai'i: Evidence of a stable matrilineal social structure in a deep-water dolphin?

Mahaffy, Sabre[1]; Baird, Robin[2]

Corresponding Author:
mahaffys@cascadiaresearch.org

Documenting long-term mother/calf associations in cetaceans is often challenging due to the inconspicuous nature of calves. For rough-toothed dolphins however, individuals can be identified using pigmentation patterns visible from birth, allowing for assessing the associations of calves. Using photo-identification data from Hawai'i Island (2003-2018), associations between moms (n=5) and their calves (n=16) were assessed for pairs initially seen in close, constant association and demonstrating synchronous surfacing. Mothers selected were first sighted with calves in 2003/2004, allowing sufficient time to document calf association. Mothers were re-sighted over periods of 4.0-13.7 years (median=11.5). The number of calves per mom ranged from 3-4 (median=3) and calves remained associated up to 9.9 years (median=4.2). Older calves typically remained in association with the mother, occasionally into adulthood, even after new calves were observed, often traveling with the new calf between them. In fact, three of the moms were seen traveling with three different calves, with older calves either surfacing on the fringe of the group or with new associates. All offspring considered sub-adults or younger (n=9) when last sighted (with the exception of one juvenile not re-sighted past 2006 and assumed to have died) remained with the mother for the duration of the study. One adult male remained with the mother for 7.6 years and either left following arrival of a new calf, or died, and one presumed adult female was last sighted

with the mom two years after reaching maturity. Inter-calf intervals, estimated using the date each new calf was first observed, ranged from 3.7-5.0 years; median=3.8, n=6. Despite sample size limitations, this study provides evidence of long-term associations between mothers and calves, suggesting that if dispersal occurs, it is likely at attainment of sexual maturity. More research is needed to determine whether calves eventually disperse or remain in the natal group for life.

Impacts of bridge construction on the Indo-Pacific humpback dolphins (Sousa chinensis) in Hong Kong's waters

Corresponding Author: vienamak@gmail.com

Coastal development is a major threat to the Indo-Pacific humpback dolphins that inhabit Hong Kong's waters. Since 2012, the impacts on the local dolphins caused by the construction of an artificial island and extensive pier structure for several connecting bridges to the artificial island, were revealed by line-transect boat-based surveys, individual photo-identification work and shore-based theodolite tracking. This development project is part of an expansive bridge alignment of the Hong Kong-Zhuhai-Macau Bridge, which is the world's longest sea-crossing bridge connecting three major cities across the Pearl River Estuary, and was undertaken over dolphin habitat around Lantau Island. Line-transect data revealed a dramatic decline in dolphin abundance in northeast Lantau (from 11 in 2011 to 0 in 2018) where the artificial island is situated and also in nearby northwest Lantau (from 39 in 2011 to 6 in 2018). Dolphin densities calculated in a grid system indicated consistently lower dolphin usage in the west Lantau area that overlapped with the bridge alignment while their habitat use became much more confined in north Lantau. Furthermore, individuals' ranges have shifted from north Lantau to west Lantau since the construction commenced. There was also a marked decline in individual movements between northwest and west Lantau through what is believed to be an important traveling corridor for the dolphins and which may now be obstructed by the physical presence of bridge piers. Even though a series of mitigation measures has been adopted during the bridge construction, dolphins were evidently displaced from their once prime habitat (in north Lantau). Given the decreasing trend in dolphin abundance and the ever-increasing threats in the waters surrounding Lantau Island, other conservation measures are urgently needed because the current mitigation actions taken do not appear to be effective at stopping the continuing decline in dolphin numbers using Hong Kong's waters.

Towards ecologically-based management for recreational whale watching.

Current guidelines for recreational whale watching have little scientific foundation and are largely used because they provide an enforceable regulatory procedure. In light of the growth of cetacean-based tourism and the increase in the breadth and depth of research, we advocate for a stronger ecological and life history grounding to enhance the efficacy of these codes of conduct in reducing whale disturbance. We provide four areas for consideration to refine whale watching management: adaptation to the ecological setting of whale aggregations; quantification of acoustic disturbance by vessels and aircraft; the exclusion of sensitive species, populations, or individuals at critical life stages from the tourism resource base; and the need to assess the cumulative effects of stressors on whales. In each case we draw on examples from our long-term research site on the west coast of Vancouver Island, where foraging gray whales (*Eschrichtius robustus*) are the focal species of tourist activities, but believe these elements are broadly applicable to other species. We suggest mitigation measures such as 'quiet zones', and time-area restrictions on viewing, including more stringent restrictions on encounter lengths, approach distance, and the viewing of animals most sensitive to human-derived stressors.

Kogia echolocation click source parameters measured with a deep water autonomous vertical array

Dwarf (*Kogia sima*) and pygmy (*Kogia breviceps*) sperm whales are small toothed whales that employ narrow band high frequency (NBHF) clicks for echolocation. Such NBHF clicks are normally found in small, shallow-water toothed whales, such as porpoises, that produce clicks at ~125 kHz. These high frequency clicks are subject to high levels of acoustic absorption and are in keeping with porpoises' short-range echolocation. Here we sought to address the problem of how the little studied Kogia, as deep-diving toothed whales, can find food with NBHF clicks in the deep. Specifically, we tested the hypotheses that Kogia use NBHF clicks with longer inter-click intervals (ICIs), higher directionality, and higher source levels (SLs) compared to shallow water NBHF species. We did this by deploying an autonomous deep-water vertical hydrophone array of 7 synchronized SoundTraps at 576 kHz, for 74.6 hours over 18 deployments in May-June 2018 in the Bahamas, where no other NBHF species are present. Depth/tilt sensors (Star-Oddi) next to the peripheral hydrophones measured array straightness and allowed for calculations of localisation errors arising from tilt. NBHF clicks were detected, classified, and localised (n=828), with 276 clicks deemed on-axis. Based on the calculated locations of clicking Kogia and known positions of each hydrophone, the apparent SL and half-power beamwidth were quantified. Apparent SLs (up to 197 dB re 1μPa_{p-p}) with a peak frequency of 129 kHz mean that Kogia could use their biosonar to inspect out to twice as far as porpoises, assuming the same prey target strength. This range agrees with the mode of their ICIs (245 ms). Their half-power (-3 dB) beamwidth of <10° confirmed our hypothesis of their narrow acoustic field of view. Thus, Kogia use a directional long-range echolocation system with high SLs to compensate for the considerable absorption losses of their NBHF clicks while hunting.

Epigenetic effects of environmental contaminants on the skin of the fin whale (Balenoptera physalus) in the Mediterranean basin.

Mancia, Annalaura[1]; Abelli, Luigi[2]; Baini, Matteo[3]; Maria Cristina, Fossi[4]; Panti, Cristina[3]

Corresponding Author: annalaura.mancia@unife.it

The phenotypic plasticity of many organisms is mediated in part by epigenetics, the heritable changes in gene activity that occur without any alterations to DNA sequence. A major mechanism is the DNA methylation (DNAm). Hypo- and hypermethylation are generalized responses to control gene expression but recent studies have demonstrated that classes of contaminants could mark specific DNAm signatures, therefore be used to assess prior environmental exposure.

We sampled skin and blubber from 6 fin whale (*Balenoptera physalus*) individuals living in the northern Mediterranean Sea. Blubber was analyzed for Organochlorines levels while genomic DNA extracted from the skin of the animals with the lowest (mean value = 19 µg/g lipid basis, l.b.) (group 1, n=3) and the highest (mean value = 53 µg/g l.b.) (group 2, n=3) levels of contaminants were used for DNAm profiling through reduced representation bisulfite sequencing (RRBS).

We tested the hypothesis that the differences in the methylation patterns observed comparing the 2 groups are linked to environmental contaminant exposure and load in the whale tissues.

While pronounced variations in CHH and CHG methylation (where H is any base except G) were not observed, the CpGs showed 32683 differentially methylated Cs in promoters and/or exon/intron regions of genes ($p < 0.05$, mean coverage = 8.5), accounting for 13% of the whole set.

Gene Ontology indicated that DNAm affected genes dealt with cell differentiation and function in nervous, endocrine, immune, circulatory and muscular systems.

qPCR on a larger set of skin samples with known contamination loads correlated differential expression of selected genes with DNAm changes.

Eco-epigenetics have extraordinary potential to advance our understanding of biological responses to environmental challenges, and yield sensitive tools for pollution biomonitoring and ecotoxicity assessment.

Introducing the Risso's dolphins of the Isle of Man

Manley, Bryony[1]; Felce, Tom[2]; Adams, Jennifer[1]
(1) Manx Whale and Dolphin Watch, Peel, Isle of Man

(2) Manx Whale and Dolphin Watch, Peel, United Kingdom
Corresponding Author: bryony@manley.org.uk

The Isle of Man is a small island situated in the middle of the shallow Irish Sea. There have been no dedicated publications addressing cetacean presence in Manx waters, only brief mention in other British Isles studies. Manx waters are one of the few places in the British Isles where Risso's dolphins (*Grampus griseus*) are seen regularly throughout the summer months very close to the coast. Manx Whale and Dolphin Watch have collected over a decade of public sightings, boat based, land based, and photo-identification data for Manx cetaceans including the Risso's dolphin. Presented here is an overview of these data to introduce the Isle of Man as what appears to be an important habitat for Risso's dolphins in this part of the world. These data highlight an area of consistent summer seasonal use by Risso's dolphins with good sighting numbers, and photo-ID catalogue size and re-sightings rates comparable to other published British Isle 'hot-spots' such as those in Wales and the Scottish Hebrides as well as regional photo-ID matches. Compared to regions such as the Azores, the British Isles shows lower re-sighting rates of Risso's dolphins, perhaps suggesting larger home ranges and a wider use of the region as a whole. As a central point in this region the Isle of Man may serve as an important 'mixing' location for Risso's dolphins from the north and the south which will only be evidenced by a greater focus on consistent photo-identification data and a strong collaboration between parties studying this fascinating species around this region.

Integrating demography and genetics to guide conservation: A case study of coastal dolphin populations.

The viability of populations depends on metapopulation dynamics: the combination of reproduction and mortality within populations, as well as dispersal between populations. Population viability is also dependent on genetic diversity, which is essential for populations to adapt to environmental change. This study focuses on an Indo-Pacific bottlenose dolphin (*Tursiops aduncus*) population in coastal waters near Bunbury, Western Australia. Population viability analysis on this population suggested that recent reproductive output was not sufficient to offset mortality. Migrants from adjacent populations might make up this deficit, so that Bunbury would act as a "sink," or net recipient population. We investigated historical dispersal in and out of Bunbury, using microsatellites and mitochondrial DNA of 193 dolphins across five study locations along the southwestern Australian coastline. Additionally, we assessed adaptive genetic diversity of the major histocompatibility complex (MHC) in the Bunbury population and compared that to a stable conspecific population. Our results indicated limited gene flow between Bunbury and adjacent populations. The data also indicated a net-dispersal from Bunbury to neighboring populations, with microsatellites showing that more than twice as many individuals per generation dispersed out of Bunbury than into Bunbury. Therefore, in historic times, Bunbury appears to have acted as a source population, supporting nearby populations. In combination with the prior finding that Bunbury is currently not producing surplus offspring to support adjacent populations, this potential reversal of source-sink dynamics, may have serious conservation implications for Bunbury and other populations nearby. The analysis of MHC genetic variation revealed that Bunbury exhibited lower MHC diversity compared to the stable population. The comparatively low MHC genetic variability may limit the Bunbury populations' adaptive potential to environmental change and could thus negatively influence population viability.

From birth to death: Life history strategies in wild bottlenose dolphins, Shark Bay, Australia.

Longitudinal study is invaluable for understanding life history strategies of wild animals. Here, we provide the first overview of life history strategies for a wild cetacean, studied from birth to death, including key tradeoffs for each developmental period. The calf period is characterized by relatively high mortality (~34% by age 3, N=795), intensive maternal investment (weaning 4.0 yrs., range=2.6-8.6), and development of basic hunting tactics and social bonds. Maternal socio-ecological strategies set the stage for their offspring, particularly daughters, with lifespan stability of some hunting and social behaviors. Although sex differences emerge in infancy, with females more focused on hunting, and males, on their social lives, this pattern becomes more exaggerated in the juvenile period. Mortality risk is still elevated (21% between the ages of 4-10, N=508), but higher for males than females, arguably because of male social competition. Females, closer to their mother's network, are focused on foraging tactics. At the onset of female reproduction (mean age of first birth=12.8 (SD=1.6), female mortality risk increases. Costs of reproduction are high, not only because of the energetic costs of pregnancy and lactation, but also allied sexual coercion. To date, females who failed to produce a surviving calf before age 25, never did (23% of 163 females with complete histories). Male mortality matches females again when they reach their late teens, when mating competition is high and males achieve their first paternities. Median lifespan is 34.5 for both sexes (N=665) if they survive the juvenile period, but some of the oldest individuals in our population are males (early 50s). While reproduction is costly to survival for both sexes, social bonds are also important. Loss of social position (closeness centrality) contributes mortality for males and females. The sex-specific selection pressures shaping life history strategies in dolphins are discussed.

Marine protected areas dedicated to marine mammals in the Caribbean

Mannaerts, Gérald
Agence française pour la biodiversité, Fort-de-France, Martinique, France
Corresponding Author: gerald.mannaerts@afbiodiversite.fr

The Caribbean Sea is a hot spot for marine mammals biodiversity with over 31 species suspected among the 80 identified worldwide. However the low coverage of marine protected areas of national and international waters in this region (well below the 10% of the Aichi Biodiversity Target of 2020) makes their conservation all the more difficult. To resolve this issue, several countries have created marine mammals' sanctuaries covering their entire EEZ or at least large zones of it.

Along with national and international policies dedicated to marine mammals, this may be one the best way to ensure protected areas large enough to encompass marine mammals' high mobility. However some of these sanctuaries aren't recognized by the IUCN's world database on protected areas and most of them don't have any management plan or enforcement in place.

In the direct line of the Sistership Sanctuary Network initiated by the Stellwagen Bank National Marine Sanctuary (NOAA), the European Project CARI'MAM, led by the Agoa Sanctuary (French Biodiversity Agency), aims to form a network of marine protected areas dedicated to marine mammal conservation in the Wider Caribbean region and beyond. Among the action led trough the project, emphasis is put on capacity-building for managers and development of common management tools. The Transatlantic MPA Network also initiated a twinning program specifically dedicated to marine mammals throughout the Ocean, which led during the last year to the development of tools specifically designed to answer marine mammals' management.

Together, these projects develop new opportunities to enhance the conservation of marine mammals in the Caribbean and their inclusion in national and international policies.

Cetacean-habitat relationships are poorly transferable across the North Atlantic Ocean

Mannocci, Laura[1]; Roberts, Jason[2]; Pedersen, Eric[3]; Halpin, Patrick[4]

Species distribution models rely on the strong, often untested, hypothesis that species-habitat relationships are transferable across geographic space. As large-scale conservation needs increasingly necessitate building species distribution models from data assembled from

multiple locations, it is critical to assess how species-habitat relationships vary across space. Our objective was to test if relationships between cetacean distributions and habitat covariates are transferable across the North Atlantic. We studied 12 cetacean taxa that occur on both sides of the Atlantic and 3 covariates commonly used in cetacean distribution models (depth, sea surface temperature and primary productivity). We related cetacean presence on survey transects to each habitat covariate using 2 types of models: (1) global models that assumed relationships are similar on both sides of the Atlantic and (2) region-specific models that assumed relationships vary between the two regions. Ten of the 12 taxa showed substantial differences in their depth relationship using the region-specific model (e.g., fin whale's presence decreasing with depth in the west but increasing in the east), while only beaked whales and bottlenose dolphin showed non-significant differences between regions. Ten taxa showed substantial differences in their sea surface temperature relationship (e.g., sei whale's presence peaking at 12.7°C in the west and 18.2°C in the east), while sperm whale and Atlantic white-sided dolphin showed non-significant differences between regions. Eight taxa showed important differences in their relationship with primary productivity between regions, e.g., Risso's dolphin, whose presence peaked around 1000 $mgC.m^{-2}.d^{-1}$ in the west and 1600 $mgC.m^{-2}.d^{-1}$ in the east. In contrast, beaked whales, pilot whales, Atlantic white-sided dolphin and bottlenose dolphin showed non-significant differences in their primary productivity relationship between regions. Our results suggest that cetacean-habitat relationships are poorly transferable across the North Atlantic and stress the need to consider between-region variability when modeling cetacean distributions as a function of habitat across ocean basins.

Social structure in a resident population of bottlenose dolphins (Tursiops truncatus) in NW Spain (Galicia)

Social network analysis is important for studying the evolution of social systems. The aim of this study is to describe the social structure of a resident population of common bottlenose dolphins (*Tursiops truncatus*). Data were collected between January and June 2017 onboard a research vessel in the Ria de Arousa (Galicia, North West of Spain). Dolphins were identified by the natural marks present on their dorsal fin with photo-identification analysis. The strength of the associations was measured using the Half Weight Index (HWI). Social structure and network analysis were carried out with SOCPROG. 111 sigthings were recorded and 118 individuals were identified. Analysis was restrictred to adult marked individuals observed on more than six differents days (n = 42 dolphins). On average, each individual was seen 12 times (se = 0.65). Permutation analysis showed preferred association between individuals. The average HWI was 0.29 (sd = 0.11), the sum HWI was 12.84 (sd = 4.53), and the max HWI was 0.65 (sd = 0.12). The affinity of this population was 12.86 (sd = 2.16), the strenght was 11.84 (sd = 4.53), the eigenvector centrality was 0.14 (sd = 0.06), the reach was 160.23 (sd = 68.66), and the clustering coefficient was 0.44 (sd = 0.07). Temporal analysis demonstrated that dolphins showed rapid dissociations and preferred companions. Modularity analysis reported a population divided in 5 different social groups. These findings report a social structure characterized by fission-fusion dynamics with preferred associations between individuals. Further studies are needed to understand the potential factors (e.g., sex and behaviour) determining the observed differences in association between individuals.

Microbial diversity in the intestine of stranded southern right whale calves (Eubalaena australis)

Over 725 southern right whale (*Eubalaena australis*) calves died at Península Valdés, Argentina during 2003-2018. No such mortality has occurred at other right whale calving grounds. While pathogenic microbes are often suggested to cause mortality in cetaceans, to date there is no evidence supporting bacterial infections as a leading cause of right whale calf deaths in Argentina. In this study we aimed to identify the bacterial community in the guts of stranded right whale calves and explore whether some of those bacteria were pathogenic and potentially linked to calf mortality. We used high-throughput sequencing and culture methods to characterize the bacterial communities from the small and large intestine of stranded calves (n=44) that died in 2005-2010. We found 108 bacterial genera, most identified as Firmicutes or Bacteroidetes, and 9 genera that have been previously implicated in diseases of marine mammals including *Mycoplasma*, *Streptococcus*, *Erysipelothrix* and *Clostridium*. *Clostridium perfringens* was present in all samples. Moreover, all *C. perfringens* isolates (n=38) were positive for alpha, 50% for beta 2 (n=19) and 47% for enterotoxin (CPE) genes (n=18). *Clostridium perfringens* is associated with food-poisoning and gastrointestinal diseases in humans and possibly other animals. The prevalence of the cpe gene found in the Valdés calves is unusually high compared with other mammals. However, insufficient histologic evidence of gastrointestinal lesions in the gut of stranded calves (possibly masked by autolysis), and absence of enterotoxins, precludes conclusions about the role of *C. perfringens* in calf deaths. This is the first reported characterization of the microbial community that lives within the intestines of baleen whale calves and one of the few to study potential pathogenic bacteria in stranded whale carcasses.

A new, multidisciplinary approach to monitor the health status of free-living fin (Balaenoptera physalus) and sperm (Physeter macrocephalus) whales in the Pelagos Sanctuary, Corsican-Ligurian-Provençal basin.

Fin and sperm whale Mediterranean populations are classified respectively as vulnerable and endangered in the International Union for Conservation of Nature Red List and potentially threatened by both infectious diseases and anthropogenic factors. Parasites, bacteria, as well as organic and inorganic pollutants, are considered among the main causes of whale's death or factors predisposing them to other pathologies. To date, most of the investigations on these species have been carried out on stranded and dead whales and performed by necropsy, occasionally providing information on the death causes. Nowadays, data on health status in free-living whales are limited, mainly due to both the difficulty and the high costs of sampling. In order to get information on the health status of fin and sperm whales living in the Pelagos Sanctuary, a preliminary, multidisciplinary study was carried out analysing three faecal samples (2 samples from fin whales and 1 sample from sperm whale) collected with a non-invasive sampling method in the framework of a 30-years long research project on the ecology of these two populations. Each faecal sample underwent parasitological, microbiological and chemical analysis. Results revealed that fin and sperm whales harbour *Blastocystis* sp., a protozoan parasite with an anthropozoonotic potential, which was never recorded before in these species. Furthermore, a more diverse bacterial community and a higher concentration of heavy metals (*i.e.,* As, Co, Hg) were found in the sperm whale sample compared to fin whale ones, while the concentration of 16 EPA PAHs and 21 PCBs was <2 ppb in all tested samples. This preliminary study represents the first report of a multidisciplinary approach in live whales investigation, and may provide a baseline for both future monitoring studies on the relationships between health status and anthropogenic pressure, and the development of effective conservation plan for these species in the Mediterranean Sea.

Improving evaluation of cetacean interactions with fisheries in a stakeholder participatory context: A running example in Southern Portugal (Algarve).

Marçalo, Ana[1]; Pires, Alexandra; Carvalho, Flávia[1]; Gregório, Rúben[2]; Ressurreição, Adriana[2]; Rangel, Mafalda[2]; Bentes, Luis[2]; Oliveira, Frederico[2]; Henriques, Nuno[2]; GOnçalves, Jorge[2]

The Algarve (southern Portugal) is an important fishing region in Portugal, with a high potential for cetacean-fishery interactions. Increasing interactions between fisheries and marine protected species (e.g. cetaceans) are a reality and occur worldwide in many forms. The negative aspects of these interactions for both fishermen (e.g. loss of

catch through depredation or gear damage) and for the animals (e.g. incidental capture leading in most cases to death) are of most concern. The only works available regarding this subject for the region, indicate that several cetacean species interact with many coastal fisheries in the area, with the purse seine fishery best documented. However, work is still needed to evaluate the level of the events and work towards mitigation strategies. We used face to face interviews (n~200) along the Algarve coast covering the most important fishing ports (n=11) to identify areas, fishing gears and cetacean species of most concern. We found that interactions occur mainly along the whole Algarve coast between the purse seine and common dolphins, *Delphinus delphis* with occasional bycatch. On the other hand, for set net fisheries (gill or trammel nets), interactions are frequent with bottlenose dolphins, *Tursiops truncatus,* and mainly in the leeward (eastern Algarve) side of the coast, where damage of catch and fishing gear were highly reported and bycatch levels are low. Minimizing cetacean–fishery interactions requires the implementation of case-specific management strategies with the active participation of fishers. Ongoing work using a participatory multi-actor approach involving various stakeholders is taking place to find the best mitigation approaches as also in a way to obtain better results in local marine management and conservation.

Morphological and molecular characterization of Pennella sp. (Copepoda: Pennellidae) isolated in sperm and fin whales from the Mediterranean Sea.

Pennella Oken, 1816 is a genus of mesoparasitic copepods, infecting cephalopods, teleost fishes and marine mammals. Two species are mainly reported in fish (P. instructa and P. filosa), while P. balaenopterae is the species described in cetaceans. The aim of this report is to characterize morphologically and molecularly adult and immature stages of Pennella sp. collected in sperm and fin whale stranded along Italian coastlines. Specimens of Pennella sp. were collected from skin-blubber of three sperm whale (Physeter macrocephalus) and six fin whale (Balaenoptera physalus) stranded along the Apulian, Sardinian and Tuscan coasts between 2008 and 2015. The samples were preserved in 70% ethanol and studied by stereomicroscopy, microscopy and environmental scanning electron microscope. The adult copepods (from sperm whale and fin whale) were identified as P. balaenopterae (Abaunza et al., Crustacean 74: 193-210, 2001), while the immature copepods were referred to Pennella filosa, according to the morphological features reported by Thompson (1905, Biol Bull 8 (5): 296-307). Portions of adult and immature specimens were also submitted to molecular analyses by a PCR, amplifying the mtDNA cox1 gene (using the primers LCO1490 and HCO2198 (Folmer et al., 1994; Mol Mar Biol Biotechnol. 3(5): 294–299)). The sequences were compared with those present in GenBank and previously obtained from specimens of P. filosa (from bluefin tuna) and P. instructa (from swordfish). Alignment of the sequences was performed using BioEdit and genetic analysis (MP, NJ) by MEGA6.0 was performed. The preliminary results of this study indicate a genetic similarity among all the different Pennella spp., suggesting that they could be morphotypes adapted to different hosts. This result would support the hypothesis that P. balaenopterae and P. filosa are conspecific (Fernandez et al., Dis Aquat Org, 128:249-258, 2018). Hereafter, the use of other markers will be also useful to clarify this aspect.

Vertebral morphology in partially sympatric dolphin species: A 3D approach.

In cetaceans, body flexibility is associated with swimming speed and foraging behavior. Greater

flexibility is associated with increased maneuverability. One factor affecting flexibility is the structure and interference of the vertebrae. We studied vertebral morphology in four closely related and partially sympatric dolphin species from the Southern Hemisphere: Commerson's dolphin (*Cephalorhynchus commersonii*), Peale's dolphin (*Lagenorhynchus australis*), dusky dolphin (*Lagenorhynchus obscurus*) and hourglass dolphin (*Lagenorhynchus cruciger*). The former two, are usually referred to as coastal. They are associated with complex habitats and foraging strategies that require greater maneuverability, showing plasticity in their prey preference. The latter two are cooperative feeders on pelagic prey with long distance displacements according to prey availability. We employed 3D geometric morphometrics to analyze differences in vertebral morphology and relate them with the preferred habitats and habits. We used a Microscribe G2X to obtain five original landmark configurations with 28 to 41 landmarks, depending on the functional region under analysis. We performed multivariate analyses for comparisons (PCA and CVA). Inferences about the biomechanical significance of the particular morphologies allowed us to establish links between morphology and behavioral patterns. PCA showed there is great differentiation among species along the vertebral column. This was especially evident in the mid area, except for the dusky and hourglass dolphin; that showed no difference in the mid-column. PCA results were confirmed by CVA. Features associated with greater flexibility were observed in species with complex habitats/behaviors whilst cooperative feeder species had features associated with greater stability. In these latter species, mid-column morphologies suggested a mechanical advantage of the swimming muscles. Even though these species are closely related, vertebral morphology is distinctive and it is related to each species foraging strategy and habitat. This reflects high plasticity and highlights the importance of habitat and behavioral complexity in the development of particular adaptations.

Just a miniature larynx? Unique laryngeal anatomy of humpback whale (Megaptera novaeangliae) calves may limit their acoustic production.

Strandings are dramatic events, but also significant opportunities to collect anatomical data as population monitoring cues. During the 2018 breeding season in Madagascar, two humpback whale calves (*Megaptera novaeangliae*) stranded. Necropsies were conducted on both extracting the larynx from the relatively fresh carcasses. Results were compared to an adult specimen from a 2016 stranding. We investigate anatomical features that could explain the surprising range of low to mid-frequency social calls produced by calves recently discovered. Findings revealed that the calf larynx had the same anatomical structure as an adult larynx, including a laryngeal sac and cartilages (epiglottic, thyroid, cricoid, corniculate, arytenoid). The arytenoids support the U-folds, and appear to generate sound from airflow between lungs and laryngeal sac. However, laryngeal structures showed more flexibility and cartilages had not reached their final thickness traits likely attributed to the calves' early age. The pliability of laryngeal structures may restrict calves to a narrow range of vocalization frequencies. This may be due to an unstable cartilaginous frame that compromises muscle actions. Muscles pulling against weak attachments may cause difficultly producing high frequency sounds. Specific sounds require the U-fold aperture to be held at certain angles (adduction or abduction) against ingressive or egressive airflow, requiring higher muscle tension. Additional muscular energy may be needed to maintain an effective posture of cartilaginous frame. Complete arytenoid adduction or abduction are probably easier to hold compared with intermediate positions. Calves may tire more easily from this muscle strain, perhaps accounting for their narrow vocal production range. Also, we explore new combined and non-invasive techniques to estimate with accuracy early calf age, observing the presence, and settlement spreading of a parasitic barnacle (Coronula) Encouraging preliminary result allowed a age class categorization of the two calves. Confirming this

potential estimation technique, will need further testing on known age specimens.

Lethal interaction of bottlenose dolphins with two other cetacean species in the Western Mediterranean

Attacks of bottlenose dolphins (*Tursiops truncatus*) to harbour porpoises (*Phocoena phocoena*) resulting in death have been previously reported in different populations around the world but reports of fatal interactions with other larger cetacean species are exceptional. Here we report on ten stripped dolphins (*Stenella coeruleoalba*) and two Risso´s dolphins (*Grampus griseus*) that were found stranded on the Mediterranean coast of Spain and presumably died as a consequence of interactions with bottlenose dolphins. Inference was based on specific rake marks and severe internal lesions of traumatic origin including skull and ribs fractures, brain haemorrhage, haemothorax or haemoabdomen. Presumptive diagnosis was reinforced by comprehensive complementary analysis of collected samples. Complete necropsy, histopathology, microbiology and molecular diagnosis ruled out other causes of death including by-catch. All twelve cases included significant number of identifiable rake marks, with inter-tooth spacing compatible with that display in bottlenose dolphins. Microscopically, the main findings were severe tissue haemorrhages with related secondary changes. Interspecific agonistic interactions between cetaceans are considered as part of the natural behavioural repertoire of species but have been interpreted differently depending on authors. Based on previous evidence drawn from the interactions between bottlenose dolphins and harbour porpoises, we put forward several hypotheses to account of the aggressive interactions observed in the study area, including territoriality, a poor defined behaviour in cetaceans, and/or influence of human activities such as fish farms. These data provide key information for a better understanding of dolphin behaviour and human–wildlife interactions.

Environmental factors driving cetacean distribution off the central Catalan coast

Marcos Ayala, Ricard[1]; Giralt Paradell, Oriol[2]; Rizo, Eva; Mas, Abraham

ricard_marcos@hotmail.com

Several species of cetaceans have been recorded off the Catalan coast. Previous studies and stranding records carried out since the 1970s suggest that cetaceans are present year round in the Northwestern Mediterranean Sea, however, there is a lack of information on cetacean distribution off the central Catalan coast. Understanding species distribution has proven to be a crucial factor in developing effective conservation measures and management plans. The present work aims to assess the factors that influence cetacean distribution off the central Catalan coast by using data collected as part of 2 different projects conducted by Associació Cetàcea since 2013. Data were collected year round in two periods (march 2013 – June 2014 and April 2016 – December 2018) during 79 days at sea, covering 2955 nautical miles. In total, 122 sightings of 6 different species, including fin whales (*Balaenoptera physalus*), bottlenose dolphins (*Tursiops truncatus*), striped dolphins (*Stenella coeruleoalba*), Risso's dolphins (*Grampus griseus*), sperm whales (*Physeter macrocephalus*) and common dolphins (*Delphinus delphis*) were recorded during that period. A presence/absence method was used to assess the distribution of the different species and to link it to a series of geographical and environmental factors. Preliminary results show that species distribution might be highly influenced by the characteristics of the seafloor, namely depth, slope, aspect and by the presence of geographical accidents such as underwater canyons. The study provides a better understanding of the cetacean distribution off the central Catalan coast, an area included in a recently developed Specially Protected Area of Mediterranean Importance, and will contribute to the development of effective conservation

measures as a valuable baseline information on cetacean distribution.

Evidence for fission-fusion grouping pattern in narwhal inferred from telemetry data

Marcoux, Marianne; Watt, Cortney
Fisheries and Oceans Canada, Winnipeg, Manitoba, Canada
Corresponding Author: Marianne.marcoux@dfo-mpo.gc.ca

Cetaceans are social animals that live in groups, which has important consequences for the fitness of individuals. Groups vary in stability from permanent groups that last for life, to fission-fusion groups that may only last for a few hours. During the ice-free season, narwhals form mixed sex and age-class clusters of up to 25 narwhals within proximity to one another. These small clusters are part of large herds of several hundred individuals. Although the snap-shot composition of narwhal clusters (i.e. sex and age-class composition) has been examined, the stability of narwhal clusters over time remains unknown. We equipped seven pairs of narwhals from seven different clusters with satellite transmitters to investigate the stability of clusters. During the ice-free season (August - October), pairs of narwhals spent on average 16.7 % (range: 1.1 to 44.4%) of their time within proximity to one another (5km). One pair of narwhals split at least 5 times and spent up to 12 days and 200 km apart before coming back together during the 80 day they were tagged. Another pair of narwhals spent more than a month up to 500 km apart during the fall migration and reunited on their wintering grounds in Davis Strait. This study suggests that narwhals show characteristics of a fission-fusion society in which group formation is highly dynamic, and group size and composition change frequently.

Intraspecific variation in social structure in female bottlenose dolphins is driven by a combination of ecological, genetic, and cultural aspects

The complexity of dolphin social structure can only be compared to that found in primates including humans. Although many dolphin populations are characterized by a fission fusion system, preferred associations between individuals can lead to community structure within populations. While male bottlenose dolphins (*Tursiops aduncus*) in Shark Bay, Western Australia, form persisting social bonds within multi-level alliances, drivers of association in female bottlenose dolphins are not well understood. We investigated association patterns and community structure of female Indo-Pacific Bottlenose Dolphins in the western part of the bay. We assessed the role of kinship, habitat similarity, and shared foraging techniques (culturally transmitted tool use) on female association patterns. Permutation-based Mantel tests suggested that association indices were best explained by individuals sharing the same habitat ($p < 0.001$), the same mtDNA haplotype ($p < 0.01$), and the same foraging technique ($p < 0.001$), suggesting the presence of homophily. We also implemented three different community detection algorithms to assess the underlying female community structure in Western Shark Bay. All three algorithms identified habitat to be an important driver of community structure. Our results indicate that intraspecific variation in social structure in this bottlenose dolphin population is driven by a complex combination of both ecological and genetic aspects, but that also cultural processes appear to shape dolphin social structure, similarly to what has been described in humans.

Cetaceans as a potential indicators of micro- and macroplastic impact in the marine environment: Trend topic and emerging gaps.

(1) Univerity of Siena, Siena, Italy
(2) University of Siena, Siena, Italy
Corresponding Author: fossi@unisi.it

How can 5 mm plastic debris (microplastics) affect filter feeder baleen whales? How can kilograms of plastic debris affect sperm whales? Here, we report the scientific evidence and the emerging gaps of the interaction between the charismatic megafauna (filter feeder baleen whales and deep divers) and micro- and macroplastics studying their impact and their related toxicological effects. We also propose these species as candidate indicators for micro- and macro-plastic pollution, respectively, at global scale. Regarding the interaction between whales and microplastics the first warning was reported for Mediterranean fin whales (*Balaenoptera physalus*) since 2012, and confirmed later (high concentrations of PBTs, plastic additives and specific biomarker responses, detected in skin biopsies) in the same species and for other filter feeders (basking and whale sharks). Filter-feeding megafauna are susceptible to high levels of microplastics ingestion and exposure to associated

toxic compounds due to their feeding strategies and for habitat overlap with microplastic hot spots. For these reasons, this whale species has been proposed as a candidate indicator of microplastics pollution in semi-enclosed basins. On the other hand, deep divers such as the sperm whale and the Cuvier's beaked whale, are exposed to the ingestion of marine litter (ML), including large plastic fragments, due to their feeding in marine canyons. High occurrence of ML (75%) has been reported in Mediterranean sperm whales. This species was recently proposed as a candidate indicator the presence of ML in the Mediterranean (IMAP indicator 24). As these megafauna species are charismatic and iconic indicators that serve as flagship species for marine conservation, this research field became recently a "trend topic". However, several gaps must be resolved, such as the investigations of new plastic tracers in the tissues and the identification (through omics techniques) of the toxicological effects caused to plastic debris ingestion in these species.

The role of sperm whales as benthopelagic predators.

Sperm whales (*Physeter macrocephalus*) produce powerful clicks that allow them to echolocate prey at long ranges in the darkness of the deep ocean. They use information gleaned by echolocation to choose dynamically the foraging habitat targeted in each dive. At high latitudes they exploit epi-, meso-, and benthopelagic prey with highly variable diving patterns. This contrasts with their stereotyped diving behavior at low latitudes, where whales do not feed on epipelagic prey and maintain a typical maximum dive depth of 600-800 m. These differences have been interpreted as behavioural adaptations to geographical variation in prey resources rather than as sex-driven choice of foraging strategies. Here we aim to uncover how the dependence of benthic resources of sperm whales in low latitudes differ between two areas where this species has genetically distinct populations: the Gulf of Mexico (GOM) and the Mediterranean Sea (Med). We used data gathered with sound and movement recording DTAGs from 16 sperm whales (8 GOM, 8 Med) summing some 117 deep dives in 125 tag-hours. Clicks were identified with a supervised automatic detector and echograms were formed to locate seafloor echoes generated by the clicks. All sperm whales fed within the mesopelagic realm, but approximately 50% of deep dives entered the Benthic Boundary Layer (BBL, 0-200 m altitude above the seafloor). Sperm whales have an important role as top-predators in offshore waters, where they consume a large biomass and contribute to the recirculation of nutrients, and potentially pollutants, from deep to shallow waters. Understanding their trophic ecology and their dependence on different niches is essential for trophic web modeling and to assess the vulnerability of the species to human resource exploitation.

Bottlenose dolphin social sounds during interaction with bottom-trawl fishery in the Mediterranean Sea

Acoustic communication signals play an important role in mediating different relations in social animals. Bottlenose dolphins (*Tursiops truncatus*) produce whistles as social sounds, and each individual develops its own distinctive signature whistle encoding identity information. We assessed social sounds by bottlenose dolphins while interacting with bottom-trawl fishery in the central Tyrrhenian Sea and in the Sicily Channel (Italy). Both stationary and towed hydrophones were used to collect acoustic data by group of dolphins following trawling vessels to exploit anthropogenic food patches. The frequencies of different whistle types (upsweep, down sweep, concave, convex, flat, modulated), as well as their acoustic parameters (initial, final, maximum and minimum frequencies; number of steps and inflection points; duration) were measured. We found a varied whistle repertoire when animals interact with

fishing vessels, with the presence of some distinctive signature whistles mainly when groups included mother-calf pairs. This kind of whistles help to promote social cohesion among members of the group but are also recorded in stressful situations. This was dramatically evident in a recording collected when a mother-calf pair remained entangled and then died inside the net. Modulated and ascending were the most common whistle types, suggesting they play an important role in the bottlenose dolphin repertoire possibly transmitting specific information among individuals related to this particular feeding strategy. Interacting with trawling vessels requires group coordination and these complex signals may either facilitate individuals to associate with or distinguish those who implement the same foraging tactics.

New urban habitat for humpback whales: Foraging for fish in San Francisco bay.

Although humpback whale (*Megaptera novaeangliae*) populations in the Eastern North Pacific have mostly recovered, the Mexican Distinct Population Segment (DPS) remains threatened, and mortality from ship strikes and entanglements along the California coast have increased in recent years. Shifts in humpback whale distribution and increased overlap with human activities may exacerbate these threats. Over the past three years, we observed an unprecedented influx of humpback whales into San Francisco Bay, with photo-identification records confirming individuals from the Mexican DPS. Multiple humpback whales entered the bay to feed on northern anchovy (*Engraulis mordax*) during the spring-fall, with a total of 989 sightings by trained observers during April-November of 2016-2018. The three seasons varied in length and intensity, with peak daily numbers in summer reaching 24 whales in the strait west of the Golden Gate Bridge and 15 whales inside the bay east of the bridge. Whales were not resident in the bay throughout their spring-fall feeding seasons. Rather they transited to and from the habitat in a tidally-dependent pattern. We compiled the first photo-identification catalog for San Francisco Bay humpback whales based on comparisons of fluke images. Of 61 cataloged whales, 41 were matched to North Pacific catalogs, including 27 known from their breeding grounds in Mexico. Photo-identification confirmed whales using the bay in successive years. Although arrival of humpback whales in San Francisco Bay may herald recovery of both the Mexican DPS and the bay estuary ecosystem, conservation concerns include potential adverse interactions with vessel traffic in this urban habitat. In addition to disturbance by recreational users making close approaches, the risk of large ship strikes increases as whales enter the narrow, congested Golden Gate Strait. While a relatively new phenomenon, annual feeding by humpback whales may play a significant role in the San Francisco Bay ecosystem.

Surfacing and diving behaviour of snubfin dolphins (Orcaella heinsohni) and implications for visual surveys

Snubfin dolphins (*Orcaella heinsohni*) are an endemic species found in near-shore habitats throughout northern Australia and southern Papua New Guinea. The IUCN recently listed the species as 'Vulnerable' due to small population sizes, high site-fidelity, limited gene flow, low reproductive rates, and strong overlap with coastal human activities. Consequently, accurate abundance estimates are essential for ongoing assessments of conservation status and population trends, as well as creating informed management plans. Distance sampling is an effective method for estimating dolphin abundance, but is plagued by often unquantified errors related to imperfect detectability (perception bias) and intermittent animal availability (availability bias). This limits the contribution of outcomes to wildlife management plans. However, addressing availability bias requires an understanding of dolphin surfacing behaviour and dive cycles.

In this study, video surveys were conducted from a static, at-sea platform to determine surfacing-diving intervals of snubfin dolphins. The study took place in Roebuck Bay, Western Australia, home to the largest known population of snubfin dolphins. Fieldwork was undertaken in September and October 2014 on-board a permanently-moored

vessel (elevation 7.5 m above the water line). Visual observations were conducted using binoculars and a digital camcorder to record dolphin group size, composition and behaviour. Video footage was reviewed to record surfacing bout duration, breathing rates, and dive duration.

During 46 hours of survey effort, 73 groups were observed. Median group size was one dolphin (maximum eight individuals). Groups were predominantly travelling through the study area (71%), although some foraging (24%) and socialising (5%) behaviours were also recorded. Surface-dive cycles were assessed according to group size and behaviour to evaluate the proportion of time snubfin dolphins are visually available at the surface. Our work provides, to our knowledge, the first estimates of availability bias for Australian snubfin dolphins and will aid on-going conservation plans for this species.

Acoustic tracking reveals at-depth coordination in groups of Blainville's beaked whales

Blainville's beaked whales (*Mesoplodon densirostris*) are visually elusive, deep-diving cetaceans that roam the deep ocean beyond the continental shelf in small pods of 2-4 animals. Despite their cryptic surface behaviour, the strong, directional echolocation clicks they use to echolocate prey during their frequent deep foraging dives can be detected routinely with passive acoustic monitoring systems. However, acoustically derived population estimates depend crucially on how animals in groups coordinate movement while acoustically active. To investigate this, we used an array of bottom-mounted, cabled hydrophones in Tongue of the Ocean, Bahamas, to track the 3-dimensional movement of 29 beaked whale encounters with 1-3 diving animals. We found that individuals within a group coordinated their foraging behaviour at depth in several ways. Blainville's beaked whales exploited two separate deep foraging layers, but groups of animals almost always exploited the same prey layer, and there was a tendency to only go to the deeper layer when in triplets vs pairs or singletons. While acoustically invisible during the initial portion of the descent, they typically started the vocal portion of their deep dives close together, separated while at depth, and finally converged again before ascending back to the surface. This behaviour is likely driven by a need to balance two conflicting evolutionary pressures: predation risk while at the surface, where being in a silent group is advantageous, and inter-specific competition for prey while at depth, where being too close together is a disadvantage. We discuss the implications of these findings on passive acoustic density estimation.

Insights into cetacean immunology: Do ecological and biological factors make the difference?

Marsili, Letizia[1]; Di Guardo, Giovanni[2]; Mazzariol, Sandro[3]; Casini, Silvia[4]

The aim of this study was to evaluate the expression of Major Histocompatibility Complex (MHC) class I chain-related protein A (MICA) in fibroblast cell cultures of cetaceans (skin biopsies of free-ranging specimens and skin samples of freshly stranded cetaceans) by an immunofluorescence technique and to outline possible variations in MICA expression linked to different ecological and biological factors, while also investigating MICA expression after in vitro treatments with different contaminants. Free-ranging or stranded specimens of cetaceans were sampled in the Sea of Cortez (Mexico) (*Balaenoptera edeni, Delphinus capensis* and *Orcinus orca*) and in the Mediterranean Sea (*Balaenoptera physalus, Physeter macrocephalus, Tursiops truncatus* and *Stenella coeruleoalba*). Cell cultures were treated with an OC mixture, flame retardants, PAHs, MeHg and BPA. The 3 species from the Sea of Cortez showed higher basal activity of MICA and lower levels of DDTs and PCBs than the Mediterranean species. A Pearson's linear coefficient equal to -0.59 also confirmed this tendency to have high levels of MICA and low total OC levels. Treatment of cultured fibroblasts with different contaminants mostly resulted in the upregulation of MICA protein expression by at least one treatment dose; downregulation was also found in some species or treatments. MICA alteration indicates a state of stress of the organism and a modification of the immune system's

response and can be proposed as a noninvasive immunological marker that can be measured in skin biopsy samples, thus offering a good alternative to blood measurements.

Whale watching platforms as a tool for the monitoring of the health status of wounded cetacean individuals in the Strait of Gibraltar

Whale watching is a globally ever-growing activity which under good practice can offer a more sustainable, eco-friendly alternative to massive tourism. Apart from observing animals in their natural habitat, these opportunistic platforms can act as a potential tool for scientific research and environmental education purposes. In the Strait of Gibraltar, whale watching has been developing in the last couple of decades. This area sustains populations of seven resident or transient cetacean species, while it is one of the most important maritime pathways, being the only connection point between the Atlantic Ocean and the Mediterranean Sea. Consequently, the huge volume of commercial maritime traffic, together with the presence of recreational boats, daily fast ferries and intensive fishing activity, represent sources of high anthropogenic pressure for the cetaceans. During the whale watching trips of Turmares Tarifa, scientific data are collected and photographs are taken by the biologists-guides onboard, with the datasets growing in quality and quantity year by year. The analysis of more than 45000 photos since 2012 has revealed injuries and wounds on various sperm whale (*Physeter macrocephalus*), bottlenose dolphin (*Tursiops truncatus*), killer whale (*Orcinus orca*) and pilot whale (*Globicephala melas*) individuals. Such marks can be either attributed to natural causes (e.g. genetics, pathology, interactions with other animals) or to human activities directly (e.g. collisions) or indirectly (e.g. pathogen transfer). Thanks to the continuous data collection during whale watching trips, the evolution of some cases and the health status of the affected individuals have been monitored throughout a timescale varying from months to years. Moreover, the passengers are directly made aware of this problematic situation which forms a large part of the threats cetaceans face in the area. This study highlights the potential contribution of this eco-touristic activity to the conservation policies of cetacean species in the Strait of Gibraltar.

Joining efforts to protect a species? "Expedición Vaquita 2017" a crowdfunding experience.
Martínez Hernández, Benjamín
Explorando la vida , Mexico, CDMX, Mexico
Corresponding Author:
benmar@explorandolavida.com

Described for the first time in 1958, the vaquita (*Phocena sinus*) has remained virtually anonymous and despite national and international efforts, populations have shown a constant decline from 600 individuals in 1997, to today's estimates of just a few tens, meaning it is currently on the verge of extinction. In 2017 "Explorando la Vida" joined in efforts to protect the vaquita, through the creation of "Expedicion Vaquita 2017" The project's purpose was to improve the conservation of this species by fostering increased public and policy maker's awareness, supporting the running of population studies and cleaning the vaquita habitat from ghost and illegal fishing nets. Throughout the project, which was financed through crowdfunding, we made allies and worked with policymakers, museums, schools, universities, NGO´s, scientist, science disseminators, and others passionate people, who helped in making the vaquita known and promoted the crowdfunding through didactics and ludic fundraising activities. The support of the media and a group of celebrities allowed us to receive donations around the globe. From 17th-22nd August 2017, we cruised the vaquita refuge, especially in the areas that historically had the highest acoustic detection; near "Roca Consag" (31° 07' N, 114° 29' W) aboard the "Narval" the Scientific Vessel from the "Museo de la Ballena y Ciencias del Mar". Main activities were tracking to locate ghost nets, revision, data recovery and reinstallation of hydrophones. Survey efforts involved power binoculars (big eyes), video and photographic documentation and the testing of a new tool; a drone with a thermal camera. A highlight of expedition was the rescue of shipwrecked fishermen three days after their engine failed. The project faced several challenges but sets a precedent showing how people interested in protecting nature can support science through a crowdfunding platform in Mexico.

Heaviside's dolphins (Cephalorhynchus heavisidii) relax acoustic crypsis to increase communication range.

The costs of predation may exert significant pressure on the mode of communication used by an animal, and many species balance the benefits of communication (e.g. mate attraction) against the potential risk of predation. Four groups of toothed whales have independently evolved narrowband high-frequency (NBHF) echolocation signals. These signals help NBHF species avoid predation through acoustic crypsis by echolocating and communicating at frequencies inaudible to predators such as mammal-eating killer whales. Heaviside's dolphins (*Cephalorhynchus heavisidii*) are thought to exclusively produce NBHF echolocation clicks with a centroid frequency around 125 kHz and little to no energy below 100 kHz. To test this, we recorded wild Heaviside's dolphins in a sheltered bay in Namibia. We demonstrate that Heaviside's dolphins produce a second type of click with lower frequency and broader bandwidth in a frequency range that is audible to killer whales. These clicks are used in burst-pulses and occasional click series but not foraging buzzes. We evaluate three different hypotheses and conclude that the most likely benefit of these clicks is to decrease transmission directivity and increase conspecific communication range. The expected increase in active space depends on background noise but ranges from 2.5 (Wenz Sea State 6) to 5 times (Wenz Sea State 1) the active space of NBHF signals. This dual click strategy therefore allows these social dolphins to maintain acoustic crypsis during navigation and foraging, and to selectively relax their crypsis to facilitate communication with conspecifics.

Do controlled exposure experiments with navy sonar signals elicit a startle response in cetaceans?

The startle reflex is a response to sounds that reach a level of 70-90 dB (depending on species) above the hearing threshold within milliseconds of the onset of the signal. This reflex, which results in a sudden muscle contraction (flinch), appears to be present in all mammals. A recent study showed that startle responses can occur in stimuli with rise times of up to 100 ms but response magnitude is lower at long rise-times. In contrast to most other sounds, repeated exposure to startling sounds can lead to a sensitization of subsequent avoidance response in most animals. The characteristics of military sonar sounds have the potential to elicit startle response. Here, we investigate whether long-fin pilot whales (n=5), killer whales (n=5), sperm whales (n=4), humpback whales (n=5) and northern bottlenose whales (n=1) show an acoustic startle response to military sonar. These animals were exposed to 1-2kHz sonar stimuli in the 3S controlled exposure experiments between 2006 and 2013. We measured the animals' muscle contractions using triaxial accelerometers and magnetometers recorded with DTAGs during the 1 second window after the start of the stimulus and compared it to movements within a second before and a second after the end of the stimulus as a control. None of the killer whales and long-fin pilot whales here studied appear to show a clear flinch when exposed to stimuli of received levels between 100 and 177 dB re 1 µPa and rise times of 50 ms. This result suggests that the methodology in this study was unable to detect weak flinches above background muscle activity and/or that the test stimuli were unable to elicit the reflex. On-going analysis of the other species will give an indication on the presence or absence of acoustic startle responses and whether they are followed by sensitization or habituation.

Seasonal patterns of the presence of bottlenose dolphin (Tursiops truncatus) and photo id in the South of Iberian Peninsula

The waters between Algeciras and Gibraltar are well-known for the presence of short-beaked common dolphin (*Delphinus delphis*), but there is little information about others species of dolphins in the area. The Mediterranean subpopulation of bottlenose dolphins (*Tursiops truncatus)* are considered vulnerable species by the IUCN, widely distributed in the Mediterranean Sea and considered resident in the Straits of Gibraltar.

In order to understand if the presence of bottlenose dolphins exhibit seasonal patterns in these waters, a study was carried out from January 2016 until December 2018. Data was gathered on board opportunistic dolphin-watching platforms including photo ID data to be able to identify the individuals. The study compromised of 14,909.4 miles and 2,247 sightings recorded of various species of cetaceans, of these 133 were bottlenose sightings. Encounter rates varied seasonally, revealing a peak in spring. A total of 62 bottlenose dolphin individuals were Photo ID catalogued showing a high proportion of re-sighted individuals.

The groups were located in shallow waters, close to shore, near rivers, inside harbours; as well as in deeper waters of the slope along the submarine canyon located in the middle of the Bay. Preliminary behavioural observations and photographic evidence suggested that bottlenose dolphins use these waters as a feeding ground.

Conservation actions taken to prevent population decline in these species have not been effective to date. The waters between Algeciras and Gibraltar are considered one of the busiest shipping lines in the world, alongside with intense commercial and recreational dolphin watching, as well as commercial and recreational fishing activities.

It is proposed by this study to declare small sized MPA´s to be able to preserve habitat, minimize the risk of by-catch and lower stress from noise or any other disturbance. Enforcement is compulsory together with effective awareness programs and long-term research.

Next generation of animal telemetry, getting more data from marine mammal satellite tags

Understanding the movements of large marine animals at varying spatial scales is a fundamental need for conservation, management, and research. BOEM and NASA's Advanced Exploration Systems Division are working to accelerate small satellite technology development for the next generation of animal tracking systems. A crowdsourcing ideation challenge and a high altitude balloon experiment were conducted to conceptualize the feasibility of a new telemetry network leveraging small satellites for tracking highly mobile marine megafauna.

Large marine animal tracking is challenging because of the physical constraints of operating in the ocean and the very large distances that animals may travel over small periods of time. Understanding their movements depends upon tools like satellite telemetry. Nearly all satellite telemetry research is transmitted via the Argos system, which is constrained by bandwidth and numbers of satellites. Advances in tag design have improved dramatically, but data transmission from space remains limited and costly. Small satellites, or CubeSats, are revolutionizing the space industry as they significantly reduce the economic costs associated with assembly and launch. Approximately 18,000 CubeSats will be orbiting Earth in the coming decade; leveraging this network could dramatically improve studies of marine animal movements.

NASA's Center of Excellence for Collaborative Innovation convened a global ideation challenge in 2018 to conceptualize an improved telemetry network, the first in a possible series addressing Next Generation Animal Tracking. An expert group consisting of BOEM, NASA, and independent scientists working on telemetry studies developed entry requirements. The challenge had 432 entrants from 32 countries with 36 proposals submitted; two winners were selected. Results of the balloon flight demonstration and submissions to the initial challenge will inform potential future

solutions for open system architecture and software integration.

Differentiation and characteristics of the coastal population units of the humpback whale in Mexico and Central America

The humpback whales make migrations in all the oceans of the world. Although, the structure of their populations in the North Pacific is complex, it is known that these whales have high fidelity to their feeding areas and that there is very little exchange of individuals among them. A different situation occurs in its winter aggregations, where its fidelity is lower, and the exchange between congregations is frequent, either in the same or in different seasons. Recently, it has been proposed that the humpback whales from the Mexican Pacific belong to at least two population units, one coastal and one offshore. The goal of this study is to clarify the relation between the coastal population with the one from Central America, which is considered endangered by the NOAA. The study is based in order to identify their movements and migratory origins (photo-identification and stable isotopes signatures) and their genetic differences (haplotypic diversity). The photo ids were obtained from our team in Baja California Sur and the collaboration with 5 research groups from the states of, Sinaloa, Nayarit, Colima, Guerrero, Oaxaca. and in Central America. We photo-identified 2,800 different humpback whales from 2013 to 2019. The skin samples were collected in three different locations in the Mexican Pacific: Los Cabos (BCS), Barra de Potosí (Guerrero)., and Puerto Angel, (Oaxaca)., during the winter seasons of 2018 and 2019 and we obtained 165 skin simples. Preliminary results from the photo-identification indicated a strong relationship between the whales from Guerrero, Oaxaca, and Centramérica in the south, and between the whales from Colima, Nayarit, Sinaloa and Baja California Sur in the north. The analysis of the haplotypes and stable isotopes will be presented in December.

Evaluation of gray whale´s body condition in Laguna San Ignacio, BCS, Mexico. during 2018 and 2019 breeding seasons.

Corresponding Author: yellowwhale@hotmail.com

The Eastern North Pacific (ENP) gray whale (*Eschrichtius robustus*) population feeds during the summer around Bering, Chukchi and Beaufort seas, and migrates to winter breeding and calving grounds along the Pacific coast of Baja California, in Mexico. Measurements of the whales' body condition upon arrival at the breeding ground is an indicator of "health and reproductive condition," and indirectly is an indicator of the health of the environment. We photographed and evaluated the body condition of gray whales in Laguna San Ignacio (LSI) in Baja California Sur in 2018 (n=287) and in 2019 (n= 569). Photographs were sorted into two reproductive-sex categories: Females with calves, and Single whales (male or female without a calf). Condition was scored as "good", "fair", or "poor." using a method developed for the Western North Pacific (WNP) gray whales. In LSI the proportion of single whales with "good condition" in 2018 was 43.5%; "fair" 48.3%, and "poor" 8.2% and in 2019 were 22.1%, 54.3%, and 23.6%, respectively. The percent of "poor" body condition in 2019 is the highest observed in LSI. The proportion of females with calves with "good," "fair", and "poor" condition in 2018 were 43.8%, 53.7%, and 2.5%, respectively, and in 2019 were 50.0%, 50.0%, and 0%, respectively. The decrease of single whales in "good" condition during 2018-2019 was not reflected in the percent of females with calves, but may be the result of a small sample of female-calf pairs photo-identified in 2018 (n=86) and 2019

(n=41), compared to the average 226 pairs photo-identified from 2011 to 2017. We conclude that the body condition of all whales were probably similarly affected; however, comparison and correlated with environmental data from the feeding grounds is needed to understand the factors that contribute to the whales' body and reproductive condition.

Hg and Se in tissues of three species of dolphins stranded in the Mediterranean coastline of Southeastern Spain.

Martínez-López, Emma[1]; Peñalver, José[2]; Lara, Luisa[2]; García-Fernández, Antonio Juan[1]
(1) University of Murcia, Murcia, Spain
(2) Region of Murcia, Murcia, Spain
Corresponding Author: emmaml@um.es

Hg and Se concentrations have been measured in liver, kidney, brain, lung and muscle samples of 5 bottlenose dolphin (*Tursiops truncatus*), 4 common dolphins (*Delphinus delphis*) and 4 Risso´s dolphin (*Grampus griseus*) stranded along the Murcia coast, Southeast Spain, in order to estimate potential risks associated to Hg exposure. Our results were similar to those described for other dolphins in the Mediterranean Sea during the same period of study. Positive correlations between Hg and Se in liver ($r=0.930$, 30 $p<0.001$) and in kidney ($r=0.917$; $p=0.001$) were observed; and the ratio Se/Hg molar was higher than 1 in most cases. These results confirm that Mediterranean Sea is more polluted in than other seas and oceans; however, it seems a decreasing trend in Hg concentration in this ecosystem, which is reflected in cetacean´s tissues. Our results suggest a protective effect of Se against Hg toxicity is occurring in cetaceans. However, we have detected levels of Hg described as responsible liver damage and neurotoxicological effects. So other tools, as biochemical markers, should be included and more studies are needed to evaluate the risk of Hg contaminant exposure in dolphins from Murcia coastline.

Dolphin health monitoring program off the central coast of Veracruz, México.

The National Park "Sistema Arrecifal Veracruzano" (Veracruz Reef System, VRS), located in the middle of the Gulf of Mexico, is a 65,000 ha Federal Natural Protected Area of biological, ecological, economic, and social importance. However, one of the largest urban development projects in the country is currently being held here: the Veracruz Port expansion. Thus, it is imperative to develop in-depth research using bio-indicators such as dolphins, which can reflect the long term impacts of human activities on marine ecosystems. The main goals of this program are: to assess dolphin spatio-temporal distribution, density, and habitat use; to study behavior, with a focus on trophic ecology; and to determine heavy metal concentrations in dolphins' tissues. From systematic boat-based censuses, distinct techniques were applied to collect ecological (linear transects, *ad libitum*and scan sampling observations, GIS, photo-identification) and physiological data (biopsy samples). From June 2016 to February 2019, three species were recorded: *Tursiops truncatus*,*Stenella attenuata* and *Steno bredanensis*, all showing a coastal distribution (up to 40 m isobath), mainly in the northern zone of the VRS polygon. Two photo-identification catalogues (for *T. truncatus*and *S. bredanensis*) with 154 and 110 individuals, respectively, were built, and more than 50% were resident animals. It was detected that dolphins have habitat preferences for their different activities. Thanks to long-term monitoring pictures, distinct processes and diseases were recorded such as lobomycosis (*Lacazia loboi*) occurrence, and a 3-month healing rate from a shark bite. Physiologically, high concentrations of six heavy metals (Pb, Cr, Fe, Ni, Cu, Zn) were estimated and preliminary results from stable isotope analyses indicated the dolphins' trophic level in the marine food chain. This study constitutes the first effort towards a long-term health monitoring program in the VRS, and provides relevant scientific information for environmental stakeholders in order to promote marine ecosystems conservation.

Residency patterns of Risso's dolphins off São Miguel and inter-island matches with Pico Island (Azores).

The Risso's dolphin *(Grampus griseus)* is a frequently sighted species in the Azores. Major studies concerning this species have been conducted in the central group of the archipelago, where social structure, residency and nursery

patterns have been investigated for a long term followed population off Pico Island (n=1250).

Here, we aim to identify and analyse the distribution of Risso's dolphins around São Miguel Island, using photos taken during whale watching trips between 2009 and 2018. A photo-ID program to classify dorsal fin marks was developed. The resulting catalogue currently consists of 569 individuals identified from 1124 photographs.

Individuals were classified as "residents" if re-sighted in the study area (south of São Miguel Island) during at least 4 different years with a minimum of 15 sightings. All the other individuals were classified as transient. Accordingly, we identified 557 transient Risso's dolphins and only 12 resident ones in our study area.

This resident pod has been sighted every year of the study except in 2012 and 2013. Since 2014, three new individuals were added to the group. Nowadays (April 2019), this pod is formed by 9 adult females and 3 calves.

Comparing individuals identified off São Miguel with the catalogue from Pico island, we found inter-island matches of at least four different male individuals that were sighted in 2012 off São Miguel. These males were sighted more than 200 times in Pico since 2004 until 2017 but did not appear in 2012. This indicates that presumable "residents" move through the archipelago.

Further research will focus on comparing the catalogues of both islands and analysing habitat conditions for resident vs. transient individuals.

Evaluating long-term change in the risk of parasitism by anisakid spp. nematodes for endangered and threatened marine mammals.

Intestinal parasites are an understudied but potentially consequential stressor for marine mammal species. These parasites are often found in marine mammals at necropsy. Although they are infrequently identified as a cause of mortality, these parasites could drive cryptic declines in individual fitness – including declines in nutritional status – by acting synergistically with other stressors. Nematodes in the family Anisakidae are intestinal parasites that are ubiquitous throughout the world's oceans and are transmitted to marine mammal hosts through the consumption of fish and cephalopod prey. There is growing evidence that the prevalence of these parasites is increasing around the world across many fish species, and we sought to assess whether marine mammals face a rising risk of intestinal infection due to this increase in anisakid burden of their potential prey items. We used data compiled from a recent meta-analysis of anisakid abundance in fish and invertebrates over the past 50 years. We then reviewed the diets of 33 species of IUCN- or ESA-listed marine mammal species to identify their key prey species. We extracted data on anisakid burden for each of the key prey species and tested whether anisakid abundance in these key prey species had increased over time. Our preliminary findings suggest that anisakid burden in key marine mammal prey species has increased over the past fifty years and could play a role in slowing the recovery of endangered and threatened marine mammals.

The importance of marine mammals at Isla Foca, Peru: Small scale monitoring and its large-scale conservation impact.

Peru has become an epicenter for some of the world's most expansive extractive activities such as fisheries, mining and oil exploitation. With a 30% poverty rate in the country, these activities offer a source of employment and the opportunity to fight poverty. The region of Piura, in northern Peru, has 70% of Peru's extractive activities, and at the same time possesses the largest sources of anthropogenic disruptors. Here we analyze the importance of marine mammals at Isla Foca (S5°12'06.27" W81°12'31.47" – S5°12'51.18" W81°12'16.22"), to be identified as a geo-strategic center for monitoring human impact, critical for the conservation of the marine ecosystem in the north of Peru. By an observational, descriptive, exploratory and longitudinal methodology, we used geo-spatial analysis from the Landsat-5 imagery with high resolution monitoring the distribution and expansion of extractive activities, compared with cetacean sightings and pinniped population at Isla Foca since 2010. Our findings reveal a significant increase of threats surrounding Isla Foca and La Islilla, a small-scale fishing village, also exposed to these threats. Mining and oil distribution plants originally absent are now present. Increased density of fishing boats (from 15 to 157) overlapped the decline of cetacean sightings (N=177 for 6 species) from 36 to 3 per year while sea-lion population

declined from 982 to 114 individuals in the same time period. In the outcome of this analysis, we were able to visually and interpret the geo-oceanographic extent and increase in fisheries, oil platforms and mining. The rapidly expanding extractive activities and their potential hazards can cause irreversible damage, while there is a growing concern for its implications on the marine biogeochemical cycle that can affect marine mammals, humans and the ocean's health. Until today, the proposal of Isla Foca as part of the Mar Pacifico Tropical (Tropical Pacific Sea) Protected Area remains archived.

Fish in - fish out! I pull - you bite!

Food-sharing is a prime example of altruism, a behaviour that reduces the actor's fitness while increases the recipient's. Despite of Darwin's theory of the survival of the fittest, altruistic behaviours are present in both human and non-human populations, including cetacean. According to our knowledge, this study is the first systematic testing, designed to investigate altruistic food-sharing in dolphins, focusing on role separation and mechanism.

The study involved five, male Indo-Pacific bottlenose dolphins (*Tursiops aduncus*), including a father-son pair and three dolphins from the same mother. A novel cognitive enrichment device was designed for potential altruistic food-sharing, made of a PVC tube with two caps and handles. One end of the device was fixed to the poolside the other was free for the dolphins to interact with it. The device contained an internal plastic plate that could hold five capelins and was connected to the free handle with an elastic band. Thus, the fish could only be accessed if one dolphin pulled and kept the device open revealing the internal plate. In addition to the trial outcomes, the dolphins' partner choice in play and swim activities was also recorded.

A total of 188 (31%) fish were removed in altruistic manner with the participation of all five dolphins. Two dolphins preferred the role of 'consumer', three preferred to be 'actors'. Reciprocation was recorded only on a single occasion, while food-sharing between kin (98 occasions) and non-kin (90 occasions) was near equal. Positive correlation was found between partner choice in food-sharing and other social activities. In conclusion, group augmentation is a more likely explanation for food-sharing than reciprocity or kin-selection.

Our study provides an example of how ex-situ experiments could support conservation efforts by modelling and investigating behaviours that are observed in the wild but lack of full understanding.

Migration and foraging areas of baleen whales revealed by radiocarbon isotopic signatures of baleen plates.

We investigated the use of radiocarbon isotope, carbon-14, in the baleen plates for reconstructing the migration history and foraging area of baleen whales in the western North Pacific Ocean. This new approach relies on the prominent latitudinal gradient of dissolved inorganic carbon $\Delta^{14}C$ values in surface seawater, which is characterized by low values (ca. -50 ‰) in the subarctic area (influenced by Oyashio Current) and high values (ca. 30 – 40 ‰) in the subtropical area (influenced by Kuroshio). Because $\Delta^{14}C$ -DIC signatures are transferred to higher trophic level organisms via food chain, the position-dependent change in $\Delta^{14}C$ of a baleen plate, from its root to tip, reflects the shift in the baleen whale's foraging area, serving as a useful recorder of its migration history. We examined five individuals of baleen whales stranded on the coast of Japan, including a calf of blue whale, a juvenile and an adult humpback whales and two minke whales. The tissues were sampled at a 1 cm interval from root to tip. The $\Delta^{14}C$-baleen values of the blue whale and the juvenile humpback whale were low regardless of position, suggesting that these individuals foraged only in the subarctic area. In contrast, the $\Delta^{14}C$-baleen values of the adult humpback whale displayed an unimodal pattern, with low $\Delta^{14}C$ values at the root and tip and high $\Delta^{14}C$ values in the middle. This indicates that the adult humpback whale migrated over a large scale, covering the

subarctic and subtropical areas during the period of its baleen formation. The $\Delta^{14}C$ -baleen values of the minke whale stranded on the coast of Japan Sea and the coast of Pacific were high and low, respectively, indicating the presence of intra-species variability in the foraging area among minke whales around Japan.

The growth and sex maturation parameters of harbor porpoise around Hokkaido, Japan.

Harbour porpoises are susceptible to human activities because their habitats are mainly in the coastal areas. The biological parameters of harbour porpoises are extremely poor in Japan, even though it is essential to understand effect of human activities. Especially sexual maturation and growth are the factors that determine population dynamics. The activities of Stranding Network Hokkaido (SNH) enable to obtain samples of Harbour proposes on Hokkaido coast. In this study, we report sexual maturation and growth parameters of harbour porpoise in Japan. Date, location and length of 140 stranded porpoises were provided from SNH. Moreover, teeth of 58 porpoises were provided and age determination was conducted by using Growth Layer Groups (GLGs) to assess growth parameter. As a result, while the growth rate of males after 4 years old was less than 1cm per year, females grew up after 4 years old. Application of the Gompertz growth model to length at age data indicated an L_∞ of 177.1 cm in females and 135.8 cm in males, and it reflected sextual dimorphism. In sex maturation parameter, sexual maturation was determined based on Kasuya (1978) using 38 males and 19 females. The number of mature animals was only 1 male and 2 females, and it reported harbour porpoise in Japan appear sex maturation at least from 8 years old male and 3 years old female. Even though previous research in Atlantic Ocean or east Pacific Ocean reported considerable number of harbour porpoises under 1 year or pregnant individuals were stranded, it recorded 3 cases in the past 10 years in Japan as far as we know. In this way, it suggested that coast areas of Hokkaido were not used as a breeding area.

Assessment of Pacific white-sided dolphin migration patterns by burst pulse monitoring off the coast of the Syakotan Peninsula, Hokkaido, Japan.

Pacific white-sided dolphins (PWS) migrate within both the Sea of Japan and the western North Pacific along the Japanese archipelago. Shakotan Peninsula, Hokkaido, Japan is known as an important route of PWS migrating along Sea of Japan. Little is known, however, about their migration patterns or their schooling patterns along the peninsula. Here we investigated seasonal and diurnal patterns of PWS occurrence along the peninsula by continuously recording their underwater vocalization. Two autonomous recorders were moored from April through June 2018 to capture their burst pulse (BP) sounds 24-hours. The largest number of BPs was recorded in early May and in the morning, indicating the seasonal and diurnal peak of their activity. In addition, BPs were recorded over several hours continuously, suggesting that dolphins did not merely pass through the area but stay there for feeding and/or resting. Additionally, the PWS produced stereotypic combinations of BPs (90 types in total), which should be used as group-specific signals. Of these, 14 types were repeatedly recorded over multiple days, and further 6 types were recorded even over multiple years. Furthermore, some types of BPS were recorded in pairs on multiple days. These results suggest that the same groups might regularly migrate to the Peninsula with other familiar groups. The present study reveals the migration pattern of PWS in the waters near the Peninsula and also the degree of intimacy in this PWS group affecting its fission-fusion dynamics.

Marine mammal acoustic presence in relation to sea ice concentration off Tasiilaq, East Greenland.

The summer sea ice off the coast of southeast Greenland is increasingly retreating leading to longer and mainly sea ice free summer periods. This grants seasonally migrating cetacean species access to more coastal areas and allows them to stay longer in the feeding area, while habitat for ice-dependent species is decreasing. Only a few marine mammals (MM) surveys have been conducted in east Greenland and especially long time data on MM presence and seasonality is lacking. Hence, this study aims to assess the presence and the spatial and temporal distribution patterns of MMs in relation to the sea ice concentration in the waters off Tasiilaq, East Greenland, to establish a baseline of knowledge in distribution and timing of ice-dependent and migrating species off East Greenland. The Greenland Climate Research Centre collected passive acoustic monitoring data from August 2014 until September 2018. Autonomous acoustic recorders (AURAL-M2) were deployed at two positions: Kulusuk, 65.6°N; 37.4°W and Sermilik, 65.5°N, 38°W. These are currently being analysed visually and aurally for the daily presence of MMs. Preliminary analyses involved screening of every 7th recording in one year of data (September 2016 to September 2017). Fin whales were predominant and acoustically present from August to end of January. Humpback whales and bowhead whales were detected from June until end of January. However, the call differentiation between these two species is difficult and further effort will be required to differentiate between these species acoustic appearance in more detail. Sperm whale acoustic presence was detected from July until end of November. Bearded seal trills could be detected from late February until the end of June. This suggests that the area off Tasiilaq might be an important feeding ground for mysticetes and sperm whales, while bearded seals use the area during breeding season.

Acoustic activity patterns of the Antillean manatee (Trichechus manatus manatus) in Belize.

Conservation of the endangered Antillean manatee (*Trichechus manatus manatus*) requires applying new technologies to monitor and protect them, especially in turbid habitats. In this study, we deployed passive acoustic monitoring (PAM) systems to detect wild manatees and document their diurnal and nocturnal acoustic activity patterns in the shallow, coastal habitats around St. George's Caye, Belize. A SoundTrap HF300 was bottom-mounted and deployed in a few locations to continuously record natural and anthropogenic sounds. Spectrograms were generated and analyzed using Raven acoustical analysis software (version 1.5) to quantify and measure the sounds (e.g., vocalizations, mastication) produced by manatees over time. Although there was some variability in activity patterns across the deployment locations and days, vocal activity tended to increase in the late night and early morning hours. A majority of the sounds produced by the manatees were multi-harmonic, tonal sounds described as squeaks that were suggestive of social interactions. Our results suggest that the resting holes and other shallow habitats in Belize are important areas for social and feeding activities, especially at night. These findings also demonstrate the strength of acoustic monitoring for detecting fine-scale trends in manatee activity, which can inform the management of this species in Belize.

Status of marine mammals in Papua New Guinea waters.

There has been very little study of marine mammals in Papua New Guinea (PNG) waters, with most confirmed records from opportunistic sightings or limited dedicated surveys. As of 2007, 16 marine mammals were confirmed to inhabit PNG waters. At present the larger cetaceans are protected under national Whale Act & CITIES Appendix 1 and 2 at international level, there is no formal protection for small cetaceans at national level, only Dugongs and turtles are protected under the Fauna Protection and Control Act.

The lack of dedicated marine mammal study and appropriate legislation has resulted in limited knowledge of, and subsequent protection for, small cetaceans in PNG waters.

The project aims were to a.) provide a comprehensive review of marine mammal status in

PNG waters, b.) critically evaluate factors that may influence the success of coastal boat based surveys in PNG.

The comprehensive review resulted in 18 marine mammal species being confirmed from PNG waters, including two vulnerable coastal dolphins; the Australian snubfin dolphin (*Orcaella heinsohni*) and Australian humpback dolphin (*Sousa sahulensis*). These two species are not currently found elsewhere in the Pacific Islands. Constraining factors identified to do further marine mammals studies in PNG waters includes; limited local expertise, lack of government awareness, funding, and high logistic costs.

The results of this study have provided the PNG Government with a comprehensive summary of marine mammal diversity and important habitats in PNG waters. The data obtained from this study has been entered into a custom-made database to facilitate PNG's marine mammal's records and will be available for marine protected area planning. The database will soon be launched and it is hoped the study can now contribute information towards development of appropriate legislation to protect small cetaceans.

Evolutionary shifts in body size and signal frequency suggest independent evolutionary histories

That body size and call frequency have an inverse relationship is one of the fundamental assumptions, or biological rules, in animal acoustics. However, recent studies have suggested that such constraints may be reduced in aquatic mammals like cetaceans. A possible explanation is that a rapid evolution of large body sizes in the aquatic habitat changed the relationship between these traits, resulting in a 'decoupling' that rendered signal frequency able to respond more strongly to natural selection. Because aquatic mammals rely on sound for their survival and reproduction, a signal frequency that is "free to evolve" could contribute to speciation in these lineages. To test this hypothesis, we examine evidence for rate shifts in body size and acoustic signal frequency, and speciation across three mammalian lineages within which aquatic life styles have evolved independently: Artiodactyla, Carnivora, and Afrotheria. We find that the evolutionary shifts in body size and signal frequency do not co-occur phylogenetically suggesting independent evolutionary histories. In contrast, we find that in the fully aquatic mammals signal frequency and speciation rates positively correlate, whereas in terrestrial or the semi-aquatic pinnipeds they do not. Our results show that through evolutionary time, the relationship between body size and frequency has been broken down in lineages with fully aquatic species, and that rapid evolution of signal frequency may contribute to diversification of these animals.

Bottlenose dolphin, Tursiops truncatus, seasonal distribution and behavioral response to a freshwater flood in Pensacola Bay, Florida.

Shauna.McBride47@gmail.com

Pensacola, Florida experienced a flood on April 29, 2014, resulting in an unprecedented >2-meter freshwater surface layer (<5 ppt) throughout Pensacola Bay that gradually receded inshore over two months. Bottlenose dolphins (*Tursiops truncatus*) can suffer adverse health effects from prolonged freshwater exposure, but few studies have examined whether dolphins change their distribution in response to abrupt salinity changes. The study objective was to determine whether dolphins changed their distribution after the flood. We used data from a photo-identification, mark-recapture study to test the hypothesis that dolphins would either leave the area or move south towards more saline waters around the mouth of the bay. Four seasons were sampled twice across nine mark-recapture sessions from 2013 through 2016, plus an extra session in early spring prior to the flood, resulting in 78 surveys and 288 groups. Getis-Ord Gi* hot spot and kernel density estimate results showed that dolphins exhibit seasonal distribution patterns similar to other populations in Florida, in which dolphins use inshore areas during summer and move to the mouth of the bay during winter. Dolphins moved closer to the mouth of the bay where salinity was highest after the flood in spring 2014, but this distribution was not substantially different from that of spring 2015. Dolphins continued to exhibit their regular seasonal distribution patterns by moving further inshore during the summer after the flood despite low salinities (average ~8 ppt). Preliminary results suggest there was no significant relationship between distribution and salinity after the flood, but we are expanding our analyses to further explore these relationships. If dolphins are not moving

away from low salinity environments, then they may be at increased risk from abrupt changes in their habitat which can have implications for prey availability, population health, management, and conservation.

Mitogenomic phylogeny and comparative genomics support a third species in the genus Berardius.

Beaked whale species are offshore, deep-diving, and cryptic, and some species have never been observed alive in the wild. Their phylogeny remains unresolved and a new species was proposed as recently as 2016. A dark-colored morph ("black form") of Baird's beaked whale (*Berardius bairdii*) in the North Pacific was suggested to represent a third unnamed *Berardius* species based on fixed differences within the mitochondrial control region. With the proposition of a new beaked whale species, the phylogeny of the genus *Berardius* and its evolutionary position with other beaked whale genera warrants revision. We sequenced complete mitochondrial genomes and whole-genome sequences for the three putative *Berardius* species. Divergence time estimates and phylogenetic relationships between the three species as well as between all five genera of beaked whale lineages were based on mitogenomes, modeled using a fossil-calibrated Bayesian phylogenetic approach. *B. arnuxii* and *B. bairdii* gray-form mitogenomes were most similar (98.1%), while the *B. bairdii* black form was less similar to *B. bairdii* gray-form and *B. arnuxii* (95.4% and 95.5%, respectively). The mitochondrial genomic analysis supported *B. bairdii* as a paraphyletic group, differing from its initial delimitation as monophyletic. For the draft genomes, the scaffold N50s were between 14,560 and 15,499 base pairs, and genome coverages were 31x (*B. arnuxii*), 17x (*B. bairdii* black-form) and 1x (*B. bairdii* gray-form). Effective population size trends in deep time were assessed by pairwise sequentially Markovian coalescent (PSMC). The complete mitogenomes and whole-genome sequences produced in this study provide a valuable resource for further beaked whale comparative genomics.

Cortisol binding globulin response to repeated ACTH administrations in juvenile northern elephant seals (Mirounga angustrirostris)

Corresponding Author: mmccorml88@gmail.com

Total cortisol concentration is frequently used in stress assessments. However, most circulating cortisol is bound with its carrier protein, cortisol binding globulin (CBG), and only a fraction of total cortisol is unbound ("free" in circulation) and able to interact with target receptors. Understanding stress-related fluctuations in CBG will better enable interpretations of increased cortisol concentrations. We previously administered ACTH to juvenile northern elephant seals (n = 7) once daily for four consecutive days and assessed total circulating cortisol levels in a time series of samples collected after ACTH administration on days 1 and 4 (a single sample was taken prior to ACTH administration on days 2 and 3). Here, we measured corresponding concentrations of CBG and calculated CBG influence on circulating cortisol. Statistically significant variation in CBG concentration followed the first ACTH administration on day 1 ($p < 0.05$), but there was no difference between baseline and subsequent samples (Dunnett's test; $p > 0.05$). No differences were found in CBG concentrations on day 4 relative to the day 4 pre-ACTH sample. Bound cortisol concentrations increased on day 1 but did not fluctuate on day 4, likely due to an ACTH-induced increase in total cortisol concentration and subsequent saturation of CBG. Free cortisol concentrations significantly changed on day 1 and day 4 ($p < 0.05$); CBG levels in most samples from each day were higher than pre-ACTH levels from that day. These results suggest that CBG concentration may not significantly alter interpretations of the total cortisol response to ACTH administration in juvenile northern elephant seals.

Investigating the presence of invertebrate prey and parasitic load via hard parts analysis and next-generation sequencing in a northwest Atlantic population of the grey seal (Halichoerus grypus)

McCosker, Christina[1]; Olson, Zachary[2]; Flanders, Kelly[3]; Dufault, Michelle; Mellone, Dominique[4]; Bair, Halli; Ono, Kathryn A[1]

Pinnipeds such as the grey seal (*Halichoerus grypus*) are ecologically important in marine ecosystems as they shape community structures via top down effects. Following near extirpation in the mid-1900s, grey seal populations continue to rise today in the northwest Atlantic. Many controversies surround grey seal diet in terms of competition with local fish populations, but few studies have attempted to analyze the impact of grey seals on invertebrate communities in United States waters. Invertebrate prey remains may be quickly digested, leading to potential bias in diet studies that rely on the passage of in-tact hard prey remains. Hard parts analysis of seal scat samples (N=113) was combined with next-generation sequencing of prey DNA in seal scat from two breeding sites in Massachusetts, USA. A metagenomics approach also allowed for the assessment of grey seal parasitic infection rates and potential correlations between parasite species and grey seal predation on invertebrate and vertebrate prey. Invertebrate prey was detected in 6 samples via hard parts (6.1%) but in 35 samples via next generation sequencing (36%). Similarly, 5 species from Decapoda and Bivalvia were detected via hard parts, whereas 10 orders were identified through sequencing, including Decapoda, Copelata, and Mytilida. At least one type of parasite was present in 86% of seal scat samples, with nematode infections (83%) more prevalent than either trematode (33%) or tapeworm (20%) infections. Neither seal sex, parasite load, nor parasite type affected the number of prey species per sample, prey biomass per sample, or the diversity of prey species within each sample. The results indicate previous studies on grey seal diet may be underestimating the diversity and importance of invertebrate prey in the diet, but further research is needed to address how parasitic load could be affecting grey seal diet.

Long-term variability in spinner dolphin acoustic activity measured at two resting bays off Oahu, Hawaii

McElligott, Megan[1]; Lammers, Marc[2]

(2) Oceanwide Science Institute, Honolulu, Hawaii
Corresponding Author: meganmmcelligott@gmail.com

Spinner dolphins (*Stenella longirostris*) frequent the Waianae coast of western Oahu as part of their daily behavioral routine of foraging at night on offshore, mesopelagic prey and resting during the day in shallower, inshore waters. Dolphin resting habitats are in close proximity to human activities—particularly swim-with dolphin tours—which raises concern for the potential disturbance of their crucial resting behavior. Makua Beach and Kahe Point are two well-studied spinner dolphin resting habitats on the Waianae coast. Recent deployments of bottom-moored acoustic recorders have sampled the soundscape at both locations intermittently from 2016 to 2019. Acoustic data were also collected from both sites in past studies between 2008 and 2009. These historical data provide the opportunity to quantify the difference between soundscapes and dolphin acoustic activity over time at these locations. Data subsets were taken from March-May of 2008, 2017, and 2019 for Makua Beach, and from March-May of 2009 and 2019 for Kahe Point. Daytime recordings from these deployments were manually scanned for dolphin signals, and dolphin acoustic activity was quantified using an index based on the amount and type of calls in each recording. Acoustic activity was then used as a proxy to examine variability in the spinner dolphins' use of the two resting habitats over an approximately 10-year period. Additionally, the mean sound pressure level of each deployment was calculated in 1-octave frequency bands to characterize the ambient noise levels. Determining the variation in dolphin acoustic activity and ambient noise between years and across sites can inform management of spinner dolphins' potential to adapt to changing environments.

Seasonal and spatial occurrence of Brucella ceti in stranded bottlenose dolphins (Tursiops truncatus) from South Carolina, USA waters

McFee, Wayne[1]; Wu, David; Schwacke, Lorelei[2]; Colegrove, Kathleen[3]; Meredith, Andrew[4]; Young, Robert[5]

Corresponding Author: wayne.mcfee@noaa.gov

Brucellosis is a disease caused by the gram-negative facultative intracellular bacterium *Brucella* spp. This zoonotic bacterium in terrestrial species is a global public health risk, and there is also concern over the zoonotic potential of marine forms, such as *Brucella ceti*, which affects cetaceans. Due to the detection of *Brucella ceti* in

samples from bottlenose dolphins (*Tursiops truncatus*) during the 2010-2014 Gulf of Mexico Unusual Mortality Event, a long-term study of the prevalence of *Brucella* in stranded bottlenose dolphins from South Carolina was conducted. From 2012 through 2017, 282 stranded bottlenose dolphins were tested for *Brucella ceti* via real-time PCR, using the QIAamp DNA Mini Kit for amplification and primers directed at the IS711 gene. Nearly 32% of the dolphins tested positive for at least one sample (brain, lung, blowhole swab). Very little information exists in the literature on seasonal occurrence of *Brucella* in marine species, though in terrestrial species higher prevalence is often reported in spring. Similar results were found in this study with the peak occurrence being between March and June, a known period of calving in South Carolina. When observed spatially, Hot Spot Analysis using ArcGIS Desktop, the 12-Digit Watershed Boundary Dataset in Hydrologic Unit Code 8 (HUC) geodatabase for South Carolina, and the Getis-Ord Gi* statistic, features around Charleston, South Carolina had statistically high clusters spatially of *Brucella ceti* in dolphins. These features are in urban areas influenced by both industry and agriculture. Results from this study provide important insights into the seasonality and spatial influences of the marine bacterium *Brucella ceti*.

What's in a name? Motivational information within signature whistles of Indo-Pacific bottlenose dolphins (Tursiops aduncus).

Bottlenose dolphins produce individually distinctive whistles called "signature whistles". These are thought to contain individual identification information within the frequency modulation pattern and function as contact calls between conspecifics. Here, we investigate if signature whistles also contain other information regarding the vocalizing individual, for example their motivational state. "Motivation" in non-human animals refers to the drive to carry out a behavior, and previous research on terrestrial species' has identified vocal parameters which carry this information. Signature whistles from a group of 11 provisioned wild Indo-Pacific bottlenose dolphins (*Tursiops aduncus*) were recorded using a static hydrophone array. Each whistle was localized and assigned to the vocalizing individual. Simultaneous video footage was used to record the behavior of the whistling individual at the time of whistling. From the video footage, three behavioral states were classified using a *K*-means cluster analysis with a principal components analysis; low arousal, high arousal/aggressive and high arousal/sexual. We then determined whether differences in signature whistle parameters (i.e. start/end/min/max frequency, bandwidth, duration, inflection points, frequency trend) were linked with different behavioral states. A total of 18 days of recording produced 772 useable whistles to analyze (i.e. high signal to noise ratio, localizable, in camera view). Results from the preliminary analysis of one adult male's signature whistle (n = 82) indicate that whistle duration increased, and whistle end frequency decreased, as the individual's arousal level increased. Based on terrestrial studies, whistle duration was expected to increase with arousal, however, end frequency was not expected to decrease. These preliminary results suggest that signature whistles do contain other information besides individual identity. However, further analyses on the other group members and more in-depth behavioural analyses are needed to determine whether this is linked to motivational state.

Phylogenomic resolution of the cetacean tree of life using target sequence capture.

The evolution of cetaceans, from their early transition to an aquatic lifestyle to their subsequent diversification, has been the subject of numerous studies. However, while the higher- level relationships among cetacean families have been largely settled, several aspects of the systematics within these groups remain unresolved. Problematic clades include the oceanic dolphins (37 spp.), which have experienced a recent rapid radiation, and the beaked whales (22 spp.), which have not been investigated in detail using nuclear loci. The combined application of high-throughput sequencing with techniques that target specific

genomic sequences provide a powerful means of rapidly generating large volumes of orthologous sequence data for use in phylogenomic studies. To elucidate the phylogenetic relationships within Cetacea, we combined sequence capture with Illumina sequencing to generate data for ~3200 protein-coding genes for 68 cetacean species and their close relatives including the pygmy hippopotamus. By combining data from >38,000 exons with existing sequences from 11 cetaceans and seven outgroup taxa, we produced the first comprehensive comparative genomic dataset for cetaceans, spanning 6,527,596 aligned base pairs and 89 taxa. Phylogenetic trees reconstructed with maximum likelihood and Bayesian inference of concatenated loci, as well as with coalescence analyses of individual gene trees, produced mostly concordant and well-supported trees. Our results completely resolve the relationships among beaked whales as well as the contentious relationships among ocean dolphins, especially the problematic subfamily Delphininae. Our analyses continue to support the paraphyly of genera such as *Balaenoptera*, *Sagmatias*, *Cephalorhynchus*, and *Stenella*. We performed Bayesian estimation of species divergence times using MCMCtree, integrating recently described fossils. Divergence dating analyses indicates that the diversification of Crown Cetacea began as early as the beginning of the Late Eocene and the divergence of Crown Delphinidae as early as the Middle Miocene.

Turning the tide: Addressing increasing adverse human-dolphin interactions through complementary research and outreach approaches.

Bottlenose dolphins (*Tursiops truncatus*) in Sarasota Bay, Florida experienced a dramatic increase in adverse human interactions (HI) following a severe red tide (*Karenia brevis*) harmful algal bloom that decimated prey fish populations in 2005-2006. Injuries from recreational fishing gear and unnatural foraging behaviors focused on anglers' bait and catch spread throughout the long-term resident dolphin community and remained elevated for several years post-bloom, motivating sustained research and outreach efforts to better understand and mitigate HI. In addition to fisheries interactions, dolphins in Sarasota Bay face high levels of recreational boat traffic with frequent disturbance from close approaches and boat-based viewing activities. Here we summarize field and outreach approaches that have been most effective to assess and address the large suite of HI concerns in our region, including new techniques we are testing to monitor interactions and engage stakeholders, which may be applicable at other sites dealing with impacts from widespread recreational fishing and boating activities. Traditional photographic-identification surveys document anthropogenic injuries and provide baseline data to assess long-term trends in prevalence and frequency of unnatural foraging behaviors by resident dolphins. Stranding network reports facilitate opportunities to rescue injured animals and confirm fates of those succumbing to anthropogenic injuries. Dedicated sampling at identified HI hotspots, including focal animal behavioral observations and remote monitoring via deployment of passive acoustic and multi-view video systems enhances these efforts, providing comprehensive interaction data helpful to more efficiently target educational outreach efforts. Community engagement focuses on stakeholder groups whose activities overlap with and impact resident dolphins, encouraging best practices in three areas: 1) safe boating and fishing near dolphins, 2) preventing injuries through marine debris reduction, and 3) effectively reporting injuries and interactions to expedite intervention and facilitate monitoring.

Celebrating our marine mammal community: Researchers, educators and conservationists.

The diversity of members of the marine mammal community is rich, and wide-ranging. The typical Biennial conference hosts an average of 1,700 attendees, with over half of them giving presentations on a broad-range of topics, from anatomy and taxonomy, to policy and education. What is the common thread amongst this diverse community? Is it just the subject matter? And as a community, who are we? Is the overarching interest of the

community solely information gathering? Is there a fundamental concern for conservation and awareness? Looking at the interests and motivations of individual members of the community will help to identify the overall motivation and aspirations of the entire community.

A survey of the marine mammal community investigates these questions to develop a baseline understanding of the community's interests and strengths. Science, education and advocacy are all important components of marine mammal research and conservation. How do individual members identify within these three categories? How much overlap is there? Do you feel confident in all three areas, or would you prefer to partner with others that can help provide data for your advocacy campaigns, or educational curriculum? Collaborations can connect specialists with outcomes that can empower each other to improve methods, materials and impact.

Reduction in Australian fur seal pup numbers limited to the larger breeding sites.

Ecosystem change may be evident in trends of annual pup production by fur seals, which are top-predators with large biomasses. South-eastern Australia is a global hot-spot for ocean warming and Australian fur seals (*Arctocephalus pusillus doriferus*) reside year-round in these waters. Changes to prey species availability due to local ocean warming will likely result in changes to Australian fur seal distribution and pup production. Our aim has been to establish a monitoring system to document trends in pup production, and clarify factors causing change. After near extirpation in the 1800s, and a stifled population recovery caused by on-going lethal interactions with emerging fisheries, the population increased during the 1990s. To document population status, four species-wide censuses were performed in the Austral summers of 2002, 2007, 2013 and 2017. These, plus opportunistic estimates at individual colonies, were used to examine population trends since 1989. In 2007, pup numbers peaked at 22,900. Then, for the first time since recovery began, numbers reduced between 2007 and 2013, at an apparent rate of 4.2% per annum (p.a.). Breeding sites with >2000 pups experienced a 20–50% reduction, but some smaller sites showed increases. The apparent decline might have been due to annual variability; however, further monitoring has confirmed the decline. In 2017, pup numbers had reduced again, at a rate of decline of 1.4% p.a., to 15,600 pups. Factors considered to be contributing to this reduction include fisheries interactions and environmental pollutants affecting survival and reproductive rates. Teasing out changes due to ocean warming and those due to other factors will require on-going monitoring. Current research is focussed on using drones to increase survey frequency and minimise the disturbance caused by on-ground based pup counting methods, partnering with the fishing industry to reduce marine debris entanglement and bycatch and documenting changes in prey species abundances, and identifying health factors affecting vital rates.

Sights, sounds and touch: Wearable brain imaging using functional near-infrared spectroscopy.

We tested the efficacy of functional near-infrared spectroscopy (fNIRS), a wearable non-invasive biomedical imaging technique which measures oxy- and deoxyhemoglobin concentration changes, to detect cortical activation in grey seals (*Halichoerus grypus*) (n=5) and identify regions of the cortex associated with different senses (vision, hearing and touch). When neurons are activated, their increased metabolism reduces O_2, triggering a hemodynamic response that increases the delivery of oxygenated blood. Active regions of the brain, therefore, have higher oxygenated haemoglobin concentrations [HbO] than inactive regions. By comparing the absorption of near-infrared light at two frequencies, one of which is absorbed more by HbO and the other by deoxyhemoglobin, fNIRS

can non-invasively measure changes in blood volume and oxygenation in brain tissue. We used a standard human fNIRS experimental framework to test this method on a marine mammal species. An array of fNIRS sensors was used with 5 grey seals in the presence and absence of sensory stimuli – light for vision, sound for hearing and vibrissal stimulation for touch. The magnitude of the activation signal ranged from 0.4-0.6 $\mu.mol.L^{-1}$, with statistically significant differences ($p<0.05$) between [HbO] during the presence and absence of all stimuli. Specific areas of cerebral activation were associated with each primary sensory pathway. These were similar to those of other carnivores (dogs and cats), as was the associated frontal cortical activation. There was marked contralaterality in regional activation associated with stimulation of the eyes and whiskers. Auditory stimulation displayed differences in activation between the right and left hemispheres of the frontal cortex, potentially indicating lateralisation in the processing of sound in seals. Thus, fNIRS can successfully detect cortical activation in grey seals. fNIRS is non-invasive and wearable, with fewer movement artefacts than EEG, suggesting that it may offer a new tool to quantitatively investigate sensory perception in free-ranging marine mammals.

Using side-scan sonar with GIS applications for marine mammal research

Understanding how animals interact with their environments is crucial to aiding conservation and habitat preservation. Since the benthic zones of marine habitats are not always easily observable from the surface, it is necessary to employ alternate techniques. Side-scan sonar is one such technique that is both time and cost effective. Side-scan sonar allows large areas to be surveyed in a relatively short amount of time, providing information about benthic substrates as well as bathymetric data. These data can then be paired with GIS (Geographic Information Systems) applications to assess habitat use. In this study, the reliability of low cost side-scan sonar to accurately identify soft substrates such as grass and mud was tested. A total area of 11.5 km^2 was surveyed with the sonar in a large, brackish mangrove lagoon system. Individual points were ground-truthed for comparison with the sonar recordings to provide a measure of accuracy. Five substrate types were identified: Dense seagrass, sparse seagrass, mangrove soil, mangrove soil with rock, and silt. A zoned benthic substrate map was created from the sonar recordings. Dense seagrass was most accurately identified. Sparse seagrass had the lowest accuracy. A bathymetric map was also created from the sonar recordings with depths ranging from 0 to 10.3 m. Georeferenced manatee sightings were overlaid on these maps using QGIS (Quantum Geographic Information System) to preliminarily assess habitat use. Most manatee sightings occurred in areas 2–6 m deep and characterized as mangrove soil.

Gross and histopathologic diagnoses from North Atlantic right whale (Eubalaena glacialis) mortalities between 2003 and 2018.

Seventy mortalities of North Atlantic right whales, *Eubalaena glacialis* (NARW) were documented between 2003 and 2018 from Florida, U.S.A. to the Gulf of St. Lawrence, Canada. This included 29 adults, 14 juveniles, 10 calves, and 17 unknown age class. Females represented 65.5% (19/29) of known-sex adults. Fourteen cases had photos only; 56 carcasses received external examinations, 44 of which were also necropsied. Cause of death was determined in 43 cases, 38 (88.4%) of which were due to anthropogenic trauma: 22 (57.9%) from entanglement and 16 (42.1%) from vessel

strike. Gross and histopathologic lesions associated with entanglement were often severe and included: deep lacerations caused by constricting line wraps around the flippers, flukes, and head/mouth; baleen plate mutilation; chronic extensive bone lesions from impinging line, and traumatic scoliosis resulting in compromised mobility in a calf. Chronically entangled whales were often in poor body condition and had increased cyamid burden reflecting compromised health. Vessel strike, blunt force injuries included skull and vertebral fractures, blubber and muscle contusions, and large blood clots. Propeller-induced wounds often caused extensive damage to blubber, muscle, viscera, and bone. Overall prevalence of NARW entanglement mortalities increased from 21% (1970-2002) to 51% during this study period. Thus, despite mitigation efforts, entanglements and vessel strikes continue to inflict profound physical trauma and suffering on individual NARWs. Their cumulative impacts at the population level are unsustainable. Urgent and aggressive intervention is needed to end anthropogenic mortality in this critically endangered species.

An investigation into the fine scale habitat use of fin whales (Balaenoptera physalus) in the Celtic sea.

Marine mammal sightings and effort data have been collected annually in the Celtic Sea by the Irish whale and dolphin group during Irish Marine Institute research cruises since 2004, and by Marinelife during CEFAS research cruises since 2013. Fin whales have been increasingly seen in certain areas but there have been no specific studies to investigate when and why Fin whales are present in the Celtic sea. Recent studies suggest fin whale distributions are changing globally, and that they are utilising productive mid latitiude feeding grounds along migration routes more than before. This project merged different datasets for a broader spatial and temporal resolution, to investigate the key drivers of distribution for the fin whales during the autumnal months when the surveys occur to test the hypothesis that they are feeding there. There were significant challenges to using the combined dataset and methods were first developed to correct inconsistencies in the data, including cutting and combining segment sizes to create evenly sized segments which met the assumptions required for distance sampling techniques. Then a two-stage count model was developed using Multiple Covariate Distance Sampling to calculate a detection probability and correct the fin whale densities. The corrected counts were used with General Additive Models to explore which environmental covariates were significant to the distribution of fin whales. Initial results show that fin whales prefer depths between -100 and -70 metres below chart datum; and either high or low tide heights between -0.5 to -1.5 m below, or 1 to 2m above chart datum, but seemingly avoiding slack tide. Further data is being added to the model to continue to investigate their distribution and in particular test the significance of the Celtic deep as a likely feeding area.

An assessment of UAS technology for studying Atlantic spotted dolphins.

McPherson, Liah[1]; Herzing, Denise[2]

Corresponding Author: liah@live.unc.edu

Studying dolphins in the wild is complicated by the limited effectiveness of vessel-based observation. In particular, visually observing dolphins in a manner which allows researchers to track individuals and their interactions with conspecifics and the environment is challenging. The presence of a research vessel may also cause behavioral disturbance. We address these issues by assessing the feasibility of a small unmanned aerial system (UAS) for behavioral observation, habitat classification, and both respiration and photogrammetric measurements. In 2018, we conducted 6 UAS flights to follow and record Atlantic spotted dolphins (*Stenella frontalis*) in the Northern Bahamas. Dolphins displayed no observable behavioral response to the UAS at altitudes as low as 5 meters. During video review we documented 19 different behaviors within 5 behavioral states: travel, rest, play/socialize, aggression and courtship. Referencing the vessel-based or underwater observation notes taken prior to each flight, 92% of fused (mature adult, n=14), 100% of mottled (young adult, n=2), 50% of speckled (juvenile, n=8) and 60% of two-toned (calf, n=5) individuals were identifiable in videos for which group size was small (<10 dolphins). All dolphins documented underwater prior to a UAS flight were identifiable in respective video. Benthic habitats sand (n=4), sand/grass (n=5), reef/rock (n=1), and deep water (n=1), were visually discernable in all flights. Respiration rates of traveling dolphins were quantifiable at altitudes of up to 60 meters and averaged at 1.8 breaths per minute. Additionally, preliminary photogrammetric

measurements of a stranded, rehabilitated, and released dolphin suggest that body measurements via UAS are feasible. These findings indicate that UAS have the potential to improve fieldwork methodologies, allowing more detailed observations and measurements of dolphins and their environment. We anticipate UAS technology becoming more prevalent in both our continuing research, and that of other marine mammal scientists.

Science education; The redundant phrase that is a call to action for all scientists to "Pay it Forward" by adopting young students and sharing their work. A win-win model for inspiring STEM careers.

McWeeny, Bill[1]; Knowlton, Amy[2]
(1) Adams School/THE CALVIN PROJECT, Castine
(2) Anderson Cabot Center for Ocean Life at the New England Aquarium, Boston
Corresponding Author: bmcweeny@castineschools.org

Student engagement in STEM fields is enhanced by direct contact with established scientists working on current projects. Given the opportunity to rub shoulders with scientists, students are more likely to explore and choose a career in the sciences. It is a simple fact that doing science is the ultimate education process as it integrates many facets of learning. Scientists are constantly educating themselves. They are life long learners by default. Nobody has to learn how to be a scientist, quite the contrary. People have to learn how not to be scientist. Almost every young person is curious and therefore naturally acts like a scientist by asking questions, performing experiments, collecting data and forming conclusions. Have you ever seen a four year old examine a caterpillar? Puberty is a critical time when young people begin to put their curiosity aside and instead start dealing with social, emotional and physical growth. Young people lose their curiosity easily if they are not encouraged, especially at school where much of their life centers. Young people stay curious if they are exposed to authentic science experiences. But these experiences are few and far between. Science teachers benefit greatly when scientists interact with their students. The formula for keeping students engaged in the sciences includes direct contact with scientists and their work. This is a clear call for scientists to share their work with young people. Scientists are natural teachers and through the articulation and translation of their work to young people scientists strengthen their own understandings and students are inspired to become scientists. Scientists can help maintain the curiosity in young people simply by engaging young people in their own work. Examples of scientists mentoring middle school students and inspiring students to go into STEM fields are provided from a teacher's perspective.

Characterising the small vessel fleet using passive acoustics: Implications for Southern Resident killer whale critical habitat management.

McWhinnie, Lauren[1]; Pine, Matthew[2]; Dakin, Tom; O'Hara, Patrick[3]; Juanes, Francis[2]

Anthropogenic noise from vessels, ranging from large cargo ships to small pleasure boats is increasingly being recognized as both a persistent and pervasive pollutant. Furthermore, the spatial and temporal variability of vessel noise represents a significant challenge for implementing marine conservation, management and planning measures. While large vessel traffic (> 300 GT) can easily be tracked using mandatory Automated Identification System (AIS), no similar method exists for monitoring the movements of smaller vessels, which are not required to broadcast over AIS. This poses a challenge for understanding the contribution of small vessels to the marine soundscape, particularly in densely populated coastal regions. This study explores the use of passive acoustics to capture information related to non-AIS vessels in Boundary Pass, a recognised important foraging area for endangered Southern Resident Killer Whales (SRKW) within the Salish Sea. An acoustic vessel detector, a land-based camera and an AIS system were used in conjunction to gather information about the type and behaviour of non-AIS vessels using this important area.

This presentation will outline how information related to non-AIS vessel traffic can potentially be classified using acoustic data and used to predict small vessel presence and properties such as type and speed of boat within a localised area. This work aims to provide managers and decision-makers with insights about how we can capture quantitative and qualitative data related to the non-AIS vessel fleet, and highlight the importance of having this knowledge for making informed decisions. In the Salish Sea, non-AIS or small vessel traffic is currently largely unaccounted for in management assessments and noise models often due to insufficient data. Therefore the specific goal of this work is to help inform future management

and monitoring plans for vessels within SRKW Critical Habitat.

The characterization of the toxicologic effects of particulate hexavalent chromium in female and male fin whale cells.

Meaza, Idoia[1]; Speer, Rachel[2]; Toyoda, Jennifer[2]; Wise, John Pierce[3]

Chromium is a global marine pollutant and high chromium levels have been reported in North Atlantic whales including fin whales. This study focuses on hexavalent chromium [Cr(VI)] and uses zinc chromate as a representative particulate Cr(VI) compound because it is commonly used as an antifouling and anticorrosion agent on marine boats and equipment, making it a likely source of chromium exposure for whales. We characterized the toxicity of particulate Cr(VI) in skin fibroblasts from both sexes of fin whale (*Balaenoptera physalus*). Hexavalent chromium is a known carcinogen and reproductive and developmental toxicant. Although the mechanism underlying its toxicity is uncertain, it is clear DNA damage, manifested as strand breaks and chromosomal changes, plays a central role. Therefore, in this study we analyzed the cytotoxic and genotoxic effects of both acute (24h) and prolonged (120h) particulate Cr(VI) exposures. Particulate Cr(VI) induced a cytotoxic and genotoxic response in a concentration dependent manner in both sexes. Both acute and prolonged exposure induced similar amounts of cytotoxicity, but prolonged exposure induced less genotoxicity than acute exposure. Intracellular chromium was lower after prolonged exposure than acute exposure. These data suggest whale cells may have mechanisms to reduce Cr accumulation inside the cell that may trigger cell death pathways. Cells from both sexes responded similarly. Overall, compared to previously published data in human cells, both fin whale sexes showed a resistance to Cr(VI), as prolonged particulate Cr(VI) exposures in human cells increased the amount of toxicity. This suggests marine mammals may have developed cellular mechanisms to counterbalance chromium induced toxicity. In the future, assessing cellular mechanisms activated after the Cr(VI) exposure, such as, Cr transport, DNA repair and cell death pathways, could provide insights into why fin whale cells are resistant to genotoxic agents. This work was supported by NIEHS grant ES016893 (J.P.W.).

Collateral mortalities of marine mammals in small-scale fisheries: Too big to ignore.

Meireles de Castro, Rita[1]; Broadhurst, Matt[2]; Domit, Camila[3]
(1) IMBRSea

Small-scale fisheries (SSF) often are perceived as individually sustainable, but comprise 95% of global fishers and cumulatively represent marine ecosystem threats, which encompass collateral mortalities. Marine mammals are particularly vulnerable to SSF and have been the focus of conservation strategies. However, in many cases, such strategies have fallen short of objectives and effectiveness. This study aimed to elucidate the associated issues by compiling global mitigation measures among SSF and identifying: (i) successful measures and their influencing factors; (ii) information deficits; and (iii) a coherent approach to success. Among 113 peer-reviewed articles (1994–2019) there was exponential temporal output, and while gillnets were the most studied (72%), efforts have recently expanded to other gears. Approximately 68% of publications proposed mitigation measures, but only 42% assessed relative effectiveness. The latter studies recently decreased, implying less time is spent discussing improvements. Community engagement is essential for conservation, but was the least used approach (39%). Nonetheless, it has increased greatly, as the past decade represented 84% of these publications. This increase appears correlated with studies describing management approaches at the expense of typical bycatch assessments. European and North American fisheries were the most studied, whereas those in Africa were the least. Mitigation approaches were categorized as: (i) spatio-temporal fishing closures (30 studies); and modifications (ii) within existing gear configurations (3); (iii) beyond existing gear configurations (18); or (iv) to operational and/or post-capture handling (7). These categories were assessed in 'strength, weaknesses, opportunities, threats' (SWOT) analysis. While common strengths and weaknesses varied, opportunities and threats were similar. From success studies (68%), mitigation measures should optimally benefit multiple species ('strengths'), avoid regular maintenance ('weaknesses'), improve governmental aid and community engagement ('opportunity'), and consider non-compliance ('threats'). Options are available to protect mammals from SSF, but these require impetus for

adoption, which is best done via community engagement.

Risk of collision between Tursiops truncatus (Montagü, 1854) and merchant ships in the National Park "Sistema Arrecifal Veracruzano", México.

The Veracruz Reef System National Park [UdMO1] (PNSAV by its acronyms in Spanish) is an area of economic, social, cultural and ecological importance which houses more than 3,000 species such as coral reefs, seagrasses and vertebrates including marine mammals. Currently, the local port is expanding their facilities, so was needed a monitoring program to assess the potential impacts in the local wildlife and the marine ecosystem. In order to analyze spatial and temporal density and the risk of collision between merchant ships and bottlenose dolphins, 63 boat-based navigations were developed from 2016 to 2017 troughout the study zone divided into four zones, recording geographical positions of both dolphins and ships and an index of collission was estimated. A total of 274 individuals of *T. truncatus* were registered mostly in front of the port of Veracruz, while 380 merchant ships had a greater density in zone three in front of the Jamapa river. In terms of temporal density, bottlenose dolphins and ship presented a higher density in the Cold Fronts season, being distributed closer to the coast. Likewise, the general Collision Index was 0.78, indicating that there is a high risk of collision. In the same way, a higher Collision Index was found in the northern season and in the area in front of the port of Veracruz. This study is one of the first to analyze the risk of collision between bottlenose dolphin and ships in the PNSAV, and constitutes a valuable input for both the port administration and environmental skateholders to conserve this species as a bio-indicator of marine ecosystem health.

Keywords: density, distribution, Collision Index, marine mammals, merchant ships.

Identification of biomarkers that reflect the physiological status is fundamental for assessing population health, as well as to provide more accurate estimates of life history parameters. Recovered from commercial whaling, both blue (*Balaenoptera musculus*) and gray (*Eschrictius robustus*) whale populations feed on lower trophic levels and migrate between the Eastern Tropical and the Eastern North Pacific Ocean. With increasing disturbances (e.g., changing environment and human activities), understanding the physiological stress response and coping mechanisms is of growing importance. Here we validated assays for steroid hormones in blubber samples from live and stranded blue (n=73) and gray (n=15) whales, and then evaluated existing relationships among hormone concentrations, health status, and reproduction.

Reproductive status was determined for females (pregnant vs. non-pregnant) using progesterone concentrations and for males (immature vs mature) using testosterone concentrations, coupled with sighting history data. Validation of stress-related corticosteroids indicated that detection and concentrations of corticosterone, cortisol and aldosterone varied among species and between sexes. In blue whales, cortisol was validated in both sexes, while corticosterone was detectable only in females, and aldosterone only in males. Preliminary results show higher corticosterone concentrations compared to cortisol, in stranded animals, but not in live whales. No difference in concentrations of either of these hormones was found between pregnant and non-pregnant females. In gray whales, assays of both sexes validated for all three corticosteroid. Corticosterone and cortisol concentrations showed no difference between

males and females, in this species. Blubber depth analysis showed cortisol to be more concentrated in the outer layers (closer to skin), while corticosterone concentrations did not change across the depth of the blubber sample. Hormonal biomarkers linked with resighting histories of large whales provides valuable insight into long lived animals whose populations are in need of supplemental life history information.

Examining shark bite scars on bottlenose dolphins (Tursiops truncatus) off Bimini, The Bahamas

Corresponding Author: melillok@hotmail.com

Bottlenose dolphins *(Tursiops truncatus*) off of the coast of Bimini, The Bahamas have scarring and/or injuries that can be attributed to non-fatal shark attacks. However, the rate of shark predation on small cetaceans in general is limited as it is often dependent on the identification of crescent-shaped injuries or scars as indicators of shark attacks. Photo-ID and behavioral research in Bimini is ongoing and can be used to assess the prevalence of shark-induced injuries on bottlenose dolphins to evaluate their predation risk. In this study, photographs of individual dolphins were analyzed to describe the presence, shape (e.g., crescent or linear), and location of scars. Initial analysis suggests at least 10 (7.7%) of the 130 dolphins in the current catalog have scars or injuries likely attributed to sharks, with another 22 dolphins (16.9%) with undetermined scars. Most of these scars were located on the dorsal side of the peduncle area, rather than the ventral side which would more likely result in fatality. Based on the regions these scars are located, we estimate the angle of attacks resulting in non-lethal bites and compare these injuries to reports of attacks on dolphins in other geographic locations as well as sympatric Atlantic spotted dolphins. This information contributes to longitudinal studies of the dolphins in this region and provides insight into the predator-prey relationship between shark species and dolphins off Bimini.

The truth in scat: Effects of season, location, and year on diet composition of grey seals (Halichoerus grypus) in New England.

The expanding Northwest Atlantic population of grey seals, *Halichoerus grypus,* has generated a number of presumed conflicts with commercial fisheries in New England. This has led to an ethical debate with many now questioning the ecological roles of grey seals in the New England ecosystem. We used hard parts analysis of grey seal scat to determine if grey seals are contributing to the depletion of commercially important fish species, most notably Atlantic cod (*Gadus morhua*), to assess determinants of diet variation, and to ascertain their overall diet composition. Two hundred fifty seven scat samples were analyzed from two locations, Muskeget and Monomoy Islands, MA over multiple seasons from 2004-2018. Analysis included sieving samples to identify prey remains; otoliths found were identified and measured to calculate prey species and biomass, as the length of an otolith can be used to calculate the length and wet weight of a prey item. Three variables were examined in relation to biomass and prey richness (the number of prey species present in each sample): season (spring/summer), location, and period (old = 2004-2009, recent=2010-2018). It was determined that season (p=0.018), location (p=1.44x10^{-6}), and period (p=0.001) all had significant effects on total prey biomass, but only season (p=0.004) and period (p=0.009) had significant effects on prey richness. The three main species contributing to prey biomass across all variables and samples were American sand lance (*Ammodytes americanus)*, summer flounder (*Paralichthys dentatus*), and winter flounder (*Pseudopleuronectes americanus*), with Atlantic cod only making up 0.3% of the total biomass. These data support the hypothesis that grey seals in New England are not contributing to a decrease in the cod population, an important commercial target species, and indicate that other factors need to be examined to explain the decline in major fish populations.

The acoustic repertoire of wild Araguaian river dolphins, Inia araguaiaensis

Melo-Santos, Gabriel[1]; Marmontel, Miriam[2]; Oliveira, Marcelo[3]; Janik, Vincent[4]

The recently described Araguaian river dolphin, *Inia araguaiaensis*, is present only in the Tocantins-Araguaia River Basin in Brazil. The first vocal repertoire description of this species only analyzed sounds produced by one group of known, human-habituated individuals in the Lower Tocantins River. However, a wider survey of this species is needed to evaluate the species' repertoire. Here we report new sounds produced by Araguaian botos. We conducted boat surveys between the mouth of the Tocantins River (1°33'33.05"S 48°50'36.28"W) and the city of Marabá (5°19'35.41"S 48°50'36.28"W). We recorded 482 calls using a high frequency Sound Trap. During each encounter, we noted group size and composition, behavioural state, habitat type, presence of boats and fishing gear. To categorize signals produced by wild Araguaian botos, we extracted parameters of the fundamental frequency as well as measurements of noisiness, Wiener entropy and harmonicity using the bioacoustics software Luscinia. We used a dynamic time-warping analysis to compare sounds and subjected the resulting dissimilarity matrices to statistical analyses (NMDS and UPGMA clusters). In addition to previously described repertoire features, we identified several novel call types in our recordings. These were predominantly tonal sounds: whistles, stereotyped downsweeps, sequences of short (<100ms) tonals, and unusually high-frequency whistles with maximum frequency up to 74 kHz and harmonics up to 150 kHz. Preliminary observations suggest that these sounds are associated with large groups (8-20 individuals) engaged in social behaviour, when surface displays such as individual and synchronized leaps and exhibition of flippers and flukes are frequent. Our results show that investigating a larger set of contexts in wild river dolphins gives a more comprehensive overview of their acoustic repertoire, allowing us to passively monitor their behaviour and distribution in the future.

Photo-identification and movements of bottlenose dolphins in the waters around Sicily (Italy).

The abundance estimates and movements of Mediterranean bottlenose dolphins living along the Italian coast have not yet been determined, although different photo-identification efforts have been reported. Here we present information on bottlenose dolphin photographic recaptures across six different areas along the coast of Sicily based on data collected between 1997 and 2018 by different research organizations. Specifically, we compared images for 42 dolphins identified in the Aeolian Archipelago (northern-eastern Sicily; Catalogue A), 25 dolphins identified in the Strait of Messina (eastern Sicily; Catalogue B), 103 dolphins identified along the Mazara coast (western Sicily; Catalogue C), 47 dolphins identified along the Agrigento coast (south-western Sicily; Catalogue D), 27 dolphins identified in the waters nearby Catania (eastern Sicily; Catalogue E) and 83 dolphins identified around the Island of Lampedusa (southern Sicily; Catalogue F). We found only 12 matches among catalogues, an average (± SD) of 0.8 ± 2.5 matches for pair ranging from 2-10 matches for pair. Particularly, we found 10 matches between C and D catalogues, which are neighboring areas, suggesting that some dolphins may move across the coastline both in the western and south-western of Sicily. We also found 2 matches between the A and B catalogues, suggesting some seasonal movements, most likely for feeding purposes, from areas in the Aeolian Archipelago and those in the nearest coast of Sicily and/or the Strait of Messina. These results support previous findings showing that Mediterranean bottlenose dolphins tend to aggregate primarily with individuals coming from the same sub-area and only few animals roam widely connecting with different subgroups living in distant areas. The few matches found in this study suggest that geographically isolated bottlenose dolphins might remain within relatively small areas, where they exhibit specialized behavior and feeding habits and face a high risk of local extirpation.

Skies with limits: Optimising Unmanned Aerial Vehicles (UAVs) as a marine mammal survey tool for remote and challenging environments – a Welsh case study.

Conservation, management and policy surrounding marine mammals are dependent on monitoring population levels, behaviour, disturbance and their habitats. Lightweight Unmanned Aerial Vehicles (UAVs), or drones, have become an important and reliable survey tool for successful data capture and are replacing traditional survey applications. Until recently, marine mammal monitoring surveys have focussed on time and resource intensive manned aircraft, land or boat-based observation surveys. In the last decade, UAV technology, applications and accessibility has improved dramatically, revolutionising traditional surveying techniques, not only within the marine mammal field, but enhancing cross-disciplinary research and into the wider science and regulatory community.

In order to better inform the scientific community, regulatory bodies and policies for conservation and management, it is important to examine the challenges and applications associated with using UAVs within the marine mammal field. In this study we examine common challenges and opportunities associated with using different UAV types i.e. fixed-wing Vs multi-copter UAVs, in monitoring and surveying pinniped and cetacean populations and habitats in remote and challenging coastal areas of Wales. Particular challenges discussed are associated with: (i) UAV deployment, (ii) location, (iii) UAV type, (iv) weather, (v) regulatory limitations, and, (vi) flight operations. Here, we share our knowledge to the scientific community and regulators surrounding potential barriers and considerations to improve survey design to ensure efficient data capture and develop mitigation measures for future UAV marine mammal studies in coastal regions.

It also considers future UAV application opportunities and advances within the marine mammal research field such as: remote sample collection, photogrammetry and camera types, and highlights our UAV marine mammal associated research within Wales.

First scientific field research and citizen science for bottlenose dolphin conservation in the Calabrian (Italy) Ionian Sea.

Many studies demonstrated that protection through the institution of a marine protected area (MPA) can be effective for marine mammals resulting in the improvement of their survival. Cetaceans are impacted by different anthropogenic pressures and particularly bottlenose dolphins (*Tursiops truncatus*), the subject of this study, suffer from multiple pressures due to their preference in coastal waters. As this vulnerable species is protected under the European Habitat Directive and various other conventions (Bern, Barcellona, Bonn) and agreements (ACCOBAMS), it requires MPAs (such as SCIs - Sites of Community Importance and SACs -Special Areas of Conservation) for their protection. Bottlenose dolphin research and citizen science carried out in the stretch of the Ionian Sea, between Brancaleone and Botricello, is necessary as there is still a gap in knowledge in this region on the presence and distribution of cetacean species. This first year-long study has been developed through the regional operational program 2014-2020, 6.5.a.1- sub-action 2 "Conserving, restoring and protecting habitats and species of the Natura 2000", funded by EU FESR – FSE for the Calabria Region. The project involves a multi-action approach including scientific field research in order to study the distribution and the habitat used by the dolphins; a citizen science approach in order to increase knowledge and awareness regarding the marine environment and dolphins conservation; removal of the marine litter in the SCI *Fondali di Staletti*, in order to reduce the negative impact these could have on the health of the bottlenose dolphins (entrapment in abandoned fishing ghost nets, plastic ingestion, etc.). Preliminary results on the presence and distribution of the bottlenose dolphins is presented. This project contributes towards effective conservation management efforts for the bottlenose dolphin, in a geographic area that is under-investigated despite presence of this species as demonstrated by past stranding events and citizen sightings.

Exposure of marine mammals to noise pollution in the Northeast Atlantic.

Evidence of adverse impacts to marine mammals from underwater noise pollution has grown rapidly in recent years, including indirect mortality, permanent and temporary hearing impairment, behavioural responses, physiological stress, and acoustic masking of communication signals. To understand the risk of impact, many governments and intergovernmental organisations have begun monitoring and assessing levels of noise pollution in their waters. In some cases, high-level commitments have been made to ensure that noise pollution is at levels which do not harm marine ecosystems.

In the Northeast Atlantic, countries coordinate marine environmental policy through the OSPAR Convention, and since 2015 an impulsive noise registry has been recording relevant noise-generating human activities (explosions, seismic surveys, pile driving, sonar and acoustic deterrent devices) in OSPAR waters. Joint monitoring programmes have also been established to measure and map levels of shipping noise in the North Sea and Northeast Atlantic.

In this study, we build on this monitoring effort to combine maps of the pressure from underwater noise pollution with the distributions of marine mammal species in the region. We present risk maps which highlight the areas of greatest risk for exposure to impulsive and continuous (i.e. shipping) noise for a range of marine mammal species, and areas of relatively low risk. We then demonstrate how quantitative noise exposure indicators can be derived from these maps, enabling the management of cumulative levels of noise pollution according to the predicted risk to marine mammal populations.

Kogia conundrum: Variability in the acoustic signals of dwarf and pygmy sperm whales in deep water.

Dwarf and pygmy sperm whales (Kogiids) are found throughout the world's tropical and temperate oceans, but because of their small size and cryptic nature much of what is known about the two species is based on strandings. Recent recordings in the presence of both pygmy and dwarf sperm whales indicate it is possible to reliably acoustically identify the clade; however, variability in signal characters across recordings suggested additional work was needed. We used Kogia recordings collected in various locations, depths and with different instrumentation to examine the source of the signal variability. Data from four deepwater sources, including a cabled instrument observatory (MARS) at 900 m in Monterey Bay, CA, a click-detecting deepwater instrument (C-POD F) and a High-frequency Acoustic Recording Package (HARP) on a mooring at 750 m off Hawai'i, and drifting buoys (DASBRs) with a 2-element hydrophone array at 150 m in the Hawaiian Islands and Mariana Archipelago. Narrow-band, high frequency (NBHF) clicks were detected on all instruments, and we are confident in identifying them as Kogiid signals because there are no other deep-diving, NBHF species at these locations. Collectively, these data have consistent centroid/peak frequencies of 115-125 kHz, lower than that known from recordings of dwarf sperm whales near the surface. Encounters contain a mix of clicks with narrow and wider bandwidth, with a portion of clicks detected at all sites containing energy below 100 kHz, another characteristic not seen on surface recordings. Recordings from the DASBR vertical array provide evidence of a dive profile with a 45 minute dive cycle, including clicks detected both above and below the array. Variation in click characters detected at deep vs. shallow instruments does not appear to be related to the recording hardware or recording location, with propagation or behavioral factors the most likely cause of spectral variability.

Maternal foraging trip durations: Establishing a monitoring index of prey availability for the northern fur seal.

Since 1998, the Pribilof Islands population of northern fur seals (Callorhinus ursinus) has been in decline with variation observed between islands [St. George (STG) & St. Paul Islands (SNP), Alaska]. Maternal females from groupings of breeding rookeries (rookery complexes) forage in

geographically distinct habitats, primarily on walleye pollock. Females alternate between visits ashore to nurse pups and feeding trips at sea, the duration of which [maternal foraging trip duration (MFTD)], is an indicator of foraging condition (e.g. prey availability). This study aimed to identify variation in MFTD at the rookery level (averaged across females) across the lactation period and determine if that variation could explain observed population trends between islands. Between 2010 – 2018, 264 females at six rookeries were tagged with VHF radio transmitters to monitor individual MFTD. Data was used to examine whether longer MFTDs were associated with negative trends in population and if unfavorable foraging conditions – reduced pollock biomass and increased ocean temperature – were associated with increased MFTD aggregated by rookery complex using resource selection functions (RSF). Average MFTD was shorter for STG than SNP females; population indices show a declining SNP but relatively stable STG populations. Amongst the STG rookeries, animals from the SG-North complex made slightly longer seasonally-averaged foraging trips than those from SG-South. Because MFTD varied by complex, MFTD may be most appropriately used to understand conditions of the local marine environment at the rookery-complex level. At the SP-East complex, RSFs explained variation in MFTD in the early portion of the season (74%) but not later in the summer/fall. Early season MFTD was shorter in years where pollock biomass was greater, and surprisingly when surface temperature was warmer. Because MFTD varied with trends in population, it may serve as a population-level monitoring index of prey availability related to the foraging environment.

Interactions between short-finned pilot whales (Globicephala macrorhynchus) and the Atlantic Pelagic Longline Fishery in the Cape Hatteras Special Research Area (CHSRA) off Cape Hatteras, USA.

Mesa, Roosevelt[1]; Fader, Joseph[2]; Read, Andy[3]; Webster, Daniel[4]

Short-finned pilot whales (*Globicephala macrorhynchus*) are susceptible to bycatch in the Atlantic Pelagic Longline (PLL) fishery along the east coast of the United States. The National Marine Fisheries Service (NMFS) estimates that, on average, interactions between pilot whales and the PLL fishery resulted in 192 serious injuries or mortalities annually between 2010 and 2014. This level of mortality is above the Potential Biological Removal level for this stock of pilot whales, which is 159. In 2009, the Atlantic Longline Take Reduction Team recommended establishment of the Cape Hatteras Special Research Area (CHSRA) in response to a high rate of interactions between pilot whales and the PLL fishery in this area of the shelf break off Cape Hatteras. Our goal was to assess the overlap between pilot whales and PLL fishing effort in the CHSRA using the tracks of 57 pilot whales tagged off Cape Hatteras and the distribution of PLL fishing effort from logbook records provided by the Southeast Fisheries Science Center (SEFSC). We analyzed spatial and temporal overlap between the fishery and pilot whales in the CHSRA between May of 2014 and December of 2016. During the spring, summer and fall, pilot whales and the PLL fishery both occur frequently in the CHSRA. Kernel density analyses showed that approximately 70% of the CHSRA can be considered an area of high overlap between pilot whales and the PLL fishery. Our study highlights the importance of the CHSRA as an area likely to continue to present high rates of interactions between pilot whales and the pelagic longline fishery.

Socio-economic incentives for vaquita conservation: Unrealized opportunities and daunting challenges.

Nearing extinction, the world's smallest porpoise numbers less than 22 individuals. Mexico's vaquita (Phocoena sinus) faces one primary threat – entanglement in gillnets. Although gillnet fisheries are currently banned by the Mexican government in the range of the vaquita, illegal fishing with gillnets threatens the survival of the species. Illegal fishing is motivated by high prices paid in China for the swim bladders of the endangered fish, totoaba (Totoaba macdonaldi), and by a lack of legal permits for alternative gear for other fisheries. We describe efforts and challenges encountered in establishing viable alternative fishing gears and

economic livelihoods for the local communities when neither fisheries management nor enforcement are effective in combating illegal activities. Approaches that support fishers willing to use alternative gears can be a complementary and effective incentive-based conservation tool if efforts are made to establish market connections with buyers and chefs interested in "vaquita-friendly" products. We describe a supply-chain approach and market data analyses, which reveal potential increases in net earnings are possible when consumers share costs of conservation. We use a machine-learning method, Random Forest, to analyze seafood price data from the primary market of southern California for shrimp from the Upper Gulf. A three-year, stratified random sample was collected from 72 locations (28%) of retail markets in San Diego County (n = 6938 shrimp product observations). Analyses revealed the most important price determinant was access to high value markets coupled with the large-size class shrimp found only in vaquita's range. Additionally, eco-labeled products can increase marketplace prices by 12.7-43.7%, thereby offering evidence of the potential benefits of an incentivizing approach. Reliance on enforcement alone cannot abate the lucrative illegal trade for totoaba swim bladders; a new system of compliance with communities is needed. However, any approach to saving the vaquita requires eliminating gillnets throughout their

Combined stable isotopes and tracking analyses reveal an environmental-driven change in the females southern elephant seals foraging strategies

The Kerguelen southern elephant seal (SES) population underwent a drastic decline in the 1970-1980s, thought to be caused mainly by modifications in the Antarctic ecosystem structure. In the context of global change, the Southern Ocean (SO) is expected to undergo major oceanographic changes (e.g. frontal shifts, sea-ice seasonality, thickness and extent variability). Considering that female SES have two major foraging strategies (interfrontal zone *versus* Antarctic), it raises the question of whether this population will experience new environmental constraints, and if that will lead to changes in foraging strategies over time. To answer this question, ~100 SES pups were blood-sampled and weighed each year at the same site over 13 years (2006-2018). Stable isotopes analysis (SIA) of carbon and nitrogen was conducted on blood samples from the pups to determine foraging strategies of their mothers. This information was related to the pup's weaning weight - a proxy of reproductive success. $\delta^{15}N$ reflects the trophic level at which individuals feed, whereas $\delta^{13}C$ reflects their foraging latitude, which is specific to the SO. SIA revealed no significant change in $\delta^{15}N$, but a decrease in $\delta^{13}C$ over time. This means either that more SES females are using the Antarctic strategy, or that their prey are moving northwards. 96 tracks (2006-2017; 3-16 ind. per year) of post-moult females were analyzed to better quantify potential changes in latitudinal distribution. There is no clear trend over time. However, when splitting the dataset into two periods (2006-2011 and 2012-2017), the Antarctic strategy becomes more prevalent. These results show for the first time a change in the relative proportions of foraging strategies displayed by females SES over time, and may highlight a restructuring of the SO trophic web.

Individual foraging variation drives social organization in bottlenose dolphins.

Identifying foraging variation within a population and assessing its relationship with social structure is essential to increase knowledge about the evolution of social systems. Here, we investigated individual foraging variation in bottlenose dolphins and its potential influence on their social organization. We used generalized association indices and applied social network analysis to data collected over 4 consecutive years of research in a coastal area subject to significant use and pressure

by humans. Our findings revealed variation in foraging behavior among individual bottlenose dolphins, which in turn shapes their social organization. We demonstrated that bottlenose dolphins preferred to affiliate with other individuals with similar foraging strategies (i.e. homophily). Our results also indicated that individuals that regularly foraged within human-altered areas exhibited denser and longer-lasting associations. These bottlenose dolphins profit from a reliable and easily located food source which may increase their energy intake. We suggest that these individuals could benefit from increased cooperation and reduced intragroup competition, which is likely to facilitate social learning processes related to the development and maintenance of efficient foraging strategies in this human-altered environment. We further propose that these foraging strategies may be perpetuated by both horizontal and vertical transmission of information between individuals. Additionally, the observed homophily could promote, through time, a segregation of the population into behaviorally distinct groups. These findings provide valuable insight into the evolution of bottlenose dolphin social systems and their response to human-induced changes in the marine environment.

Using citizen science to assess migration patterns of humpback whales in Australia.

Meynecke, Jan-Olaf; McCulloch, Sarah
Griffith University, Australia
Corresponding Author:
o.meynecke@griffith.edu.au

Globally, baleen whales have been recognised to undergo changes in migration, behaviour and health and these shifts have been attributed to climate change in some cases. These changes raise concerns over the future of whale recovery even for populations that have reached near pre-whaling numbers. Detecting such changes requires long-term data and detailed observations over large spatial scales. However, migratory species like humpbacks whales (*Megaptera novaeangliae*) are difficult to monitor due to their vast home ranges. Acquiring extensive datasets on these animals can be expensive and time consuming. We have compiled a large data set comprising of a minimum of species, number of animals and sighting location with some data including calf sightings and behaviour categories for Australian coastal waters. The data set contained over 100 000 entries covering up to 25 years of observation. The majority of this data originated from citizen science projects. We have assessed the data for suitability of detailed analyses. A spatial and temporal representation of the sightings suggests that breeding grounds, migratory corridors and resting areas are covered. Migratory patterns and number of calves sighted were compared between regions showing similar trends between the east and west coast of Australia. However, collection methods and effort varied greatly between data sets and required standardisation. A number of standards and rules were identified that would improve the value of citizen science data and make it more comparable for future research projects. Overall, we conclude that large-scale data sets derived from citizen science projects can assist in predicting future movement and populations of humpback whales.

Evaluation of the immune response in the threatened Australian sea lion using novel technologies: qPCR and ddPCR

The Australian sea lion, *Neophoca cinerea*, is listed as endangered (IUCN Red List, 2008) and ongoing population declines have been identified due to a number of factors including the species' breeding life history and anthropogenic disturbances. More recently, disease in pups was identified as a threat contributing to population declines. In two South Australian colonies, Seal Bay and Dangerous Reef, hookworm infection (*Uncinaria sanguinis*) affects 100% of neonatal pups causing high morbidity and mortality. Novel approaches in pinniped immunology will help to pave the way for understanding mechanisms that affect survival after infection and improving management decisions when new disease arise. In order to address key knowledge gaps for the species in relation to immunocompetence, quantitative PCR (qPCR) primers were designed and optimised for the detection of relative gene expression of pro-inflammatory (Il-6, TNFα) and regulatory cytokines (IL-10, IFNg, IL4) in *N. cinerea*. As field limitations precluded the use of lymphocyte stimulation assays, samples were collected into RNAlater for subsequent analysis of natural cytokine expression. Despite high qPCR efficiency, samples from *N. cinerea* pups frequently produced qPCR Ct values approaching or below quantifiable limits, suggesting the need for the development of more sensitive methods for detection.

Here we describe the development and utility of the novel molecular biology technique, droplet digital PCR (ddPCR), as a highly precise, more sensitive

and reliable method for measuring cytokines of *N. cinerea* that by the current gold standard methodology, qPCR, are too low or impossible to detect. The application of novel methodologies such as ddPCR, which requires lower sample volumes and provides absolute quantification of immune markers, provides greater insights into managing populations resilience in the face of endemic and emerging diseases and population decline. These methodologies can be applied to both individual and population health investigations in *N. cinerea* and other threatened pinniped species.

Harbour porpoises in the southern North Sea – seasonal migration from East to West?

In the German Bight, harbour porpoise (Phocoena phocoena) occurrence is perennial, however, the distribution is fluctuating, indicating a seasonal migration pattern. Related to wind farm construction in the German Bight (including adjacent Dutch waters) passive acoustic monitoring devices (porpoise detectors, C-PODs) were deployed and digital aerial surveys conducted. We analysed information from 130 C-POD locations in the German Bight on 79,384 recording days from 2010 to 2016 and compared the findings to porpoise distribution patterns derived from 172 aerial surveys from 2014 to 2016. To identify habitat-driven regional differences in the German Bight, we clustered C-POD positions into four subareas. Clustering of C-POD locations was based on temporally static variables (e.g. water depth, distance to shipping lane). It resulted in 4 subareas: the eastern German Bight, the southwestern German Bight (including adjacent Dutch waters), the northeastern German Bight, and the central German Bight. Porpoises were distributed most evenly during winter, when porpoise activity was similar throughout the subareas. During all other seasons, porpoises were less common in the central German Bight, compared to the other subareas. Especially in summer, the northeastern subarea was characterised by high porpoise activity. The annual pattern in this subarea was clearly distinctive, showing a maximum of porpoise activity in summer and a minimum in the winter months. In contrast, the central German Bight showed a maximum in porpoise activity in winter and a minimum in summer. Throughout the German Bight a shift from high porpoise activity in summer in the eastern German Bight to high porpoise activity in winter in the southwestern German Bight including adjacent Dutch waters was visible both in C-POD and flight data. Our findings are an indication for seasonal porpoise migration from the eastern German Bight in summer to the western German Bight in winter.

Bite me: Using cookie-cutter shark bite scars to estimate age of Blainville's beaked whales in Hawaiian waters.

Beaked whales (family Ziphiidae) make up almost a quarter of all cetaceans. However, with the exception of a few species taken in whaling operations, little is known of their life history, ecology or population structure, due primarily to their offshore distribution and long dives. Blainville's beaked whales (*Mesoplodon densirostris*) have been studied extensively around the main Hawaiian Islands and a long-term photo-identification catalog has revealed a small resident population off Hawai'i Island. Adult individuals in this population have large numbers of scars from cookie-cutter shark (*Isistius spp.*) bites, and such scars remain visible for up to at least 21 years, aiding in identifying individuals. To determine whether scar acquisition rates could successfully predict age, we compared age estimates derived exclusively from scarring to those from a photo identification catalog using a sample of 18 whales seen over long time spans (median=8.5, max=19.6 years). A standardized area three times the length and the height of the dorsal fin centered beneath the fin was assessed for sightings of individuals with good or excellent quality photos where the full area of interest was visible. We both quantified the total number of scars and the area of the scars measured within the polygon. Of the two methods, individual scar acquisition rates produced more realistic age estimates than changes in scarring areas, due to overlap among bites over time. Acquisition rates will be used to estimate age when individuals were first encountered to derive estimates of longevity and sexual maturity (i.e., age first seen with a calf for females or tooth eruption for males). Possible age-related and individual variability in scar acquisition rates need to be explored to better

assess the utility of this method, however it shows promise as a way to better understand life history and population dynamics of this species.

Initial results of Antillean manatee (Trichechus manatus) milk microbiome

Microbiome in milk is an essential component calf growth of a healthy gut microniome. Previous studies on milk microbiome on different mammals (humans, cows, otters) have found a high variety of bacteria, including *Staphylococcus epidermidis, Bifidobacterium longum, Clostridium sp,* and *Clostridium coccoides.* The aim of this study was to describe the microbiome on Antillean manatee milk in order to develop techniques to improve nutrition of manatee calves rescue and under human care, particularly in the Caribbean and South America. Milk DNA was obtained from 4 lactating females, three in México and one in Colombia. Milk was treated with saline solution to allow separation of fat, followed by DNA extraction with a commercial kit. DNA was then used for library preparation and whole shotgun genome sequencing was done on an Illumina platform. 22.343.699 reads were generated and read quality was assessed using Fastqc followed by analyses in Qiime 2 and Mothur pipelines on Galaxy to identify OTUs. Among 19.349.392 unique reads aligned with 16s available databases, 111 OTUs were identified. All OTUs belonged to Bacteria, with similar groups found in each of the four samples. Phylums Proteobacteria (90%) and Firmicutes (10%) were detected. Among Proteobacteria, Enterobacteriales were the most common class found (32%), followed by Pseudomonadales (31%) and Aeromonadales (25%). Class Bacili was the most common among Firmicutes. Alpha diversity indexes were similar to values reported for human and cow milk (Shannon Index SI= 4.67 ± 0.13; Simpson Index = 0.0016 ± 0.0011; Chao = 484.15 ± 255). These milk samples are also being researched, used with traditional microbiologic techniques in order to identify which of these bacteria could be grown to produce nutritional and probiotic supplements for manatees under human care.

Community outreach as a tool for Antillean manatee conservation in Puerto Rico

Antillean manatees are endangered in Puerto Rico initially from extensive hunting, but today due to watercrafts collisions, habitat degradation and encroachment. While research and government management efforts have existed since the late 1970s, and intensified during the past 30 years, conservation efforts must include a community component to be effective. With this in mind, we have developed an extensive community outreach campaign to address public knowledge and the role they can play into contributing directly to manatee conservation. These public efforts include the distribution of printed materials, a public service announcement campaign, and an active presence in the web and social networks, in addition to participating in local environmental activities and receiving visitors at our Manatee Conservation Center. The guided tours, given by volunteers and interns, allow visitors to see firsthand the active conservation efforts on behalf of the species and helps inspire them to become active in their respective day-to-day to preserve and care for manatees, the ocean and the environment. Parallel to this, the Center was instrumental in 2013 in the enactment of a Puerto Rico law that declares the manatee as Puerto Rico's national mammal and established the 7th of September as the "Day for the Conservation of the Caribbean Manatee." During the past years, over 1,000 teachers were trained and 148,650 students celebrated this day with different environmental

activities in their own school and communities. All together, these varied community outreach and education efforts have increased over the years; the sum of all during the past 5 years is some 17,513,459 people impacted. Academic research and government management guide recovery efforts for endangered species, such as the manatee, but its true recovery from endangerment can only be secured if the community is involved and their detrimental habits are turned towards positive conservation behaviors though education.

Temporal patterns of humpback whale non-song calls on their Newfoundland foraging grounds

Mikhailitchenko, Anna; Davoren, Gail
University of Manitoba, Winnipeg, Manitoba, Canada
Corresponding Author: mikhaila@myumanitoba.ca

While animal signals convey information intra- and interspecifically, their adaptive importance is often unknown. Humpback whales (*Megaptera novaeangliae*) of all sexes and age classes produce non-song calls on their foraging grounds; however, little is known about these calls and their function. As a first step to investigate their function, the temporal patterns (daily, weekly, annually) in non-song call activity of humpback whales were examined on their Newfoundland foraging grounds – an understudied area – from July-August, 2015-2017. During each year, continuous 24-h recordings of non-song calls were collected using a hydrophone moored within a key spawning area of their main fish prey species (capelin, *Mallotus villosus*). Whale abundance and capelin biomass were quantified weekly via ship-based surveys. Acoustic recordings were aurally/visually surveyed in Raven Pro 1.5 to identify the date and time of non-song calls, and calls were subsequently classified into broad classes (i.e., high frequency, low frequency, pulsed, compound call). Call activity for all call classes was consistently higher during light relative to dark periods across all days in all years, suggesting that communication and/or foraging occur less during dark periods. Additionally, call activity varied daily within and across years, associated with varying capelin biomass. While the precise function of non-song calls remains unclear, preliminary research highlights their importance and common occurrence during daylight behaviours, potentially for foraging. Thus, comparing humpback whale call activity to density of their main prey species in this high-latitude foraging grounds allowed varying prey availability to be connected with patterns in non-song call activity, thereby providing further insight into the context of these non-song calls.

Clear response of seals to acoustic deterrence sounds using on-animal sound and movement recording tags

Few studies are available on behavioural responses of wild seals to underwater noise. Among the few, are Acoustic Harassment Devices (AHD) or 'seal-scarers' that are used for deterrence around fish farms, but also for mitigation of hearing damage prior to anthropogenic activities producing intense underwater sound. These studies have typically only been able to monitor the distance between animals and AHD or their presence/absence. To learn about the behavioural responses of individual seals, we deployed long-duration sound and movement recording tags (DTAG-4) on harbour seals (*Phoca vitulina*) in Limfjorden, a semi-enclosed fjord in Denmark. AHDs are not commonly used in Danish fisheries and the seals were thus presumably naive to the sound. Four animals were tagged with DTAGs and VHF transmitters. After a minimum of 48 hours after tagging, they were then re-located at sea and exposed to the AHD for one hour. Repeated exposures of the same animal (maximum three) were separated by 1-7 days. All seals experienced an initial sound pressure level of $L_{eq125ms}$ in excess of 140 dB re 1 µ Pa, and all showed clear responses, indicating that the response threshold was below this level. Responses were evident as changes in dive behaviour and acceleration. Three out of four animals exhibited increased stroke rate throughout the one-hour exposure period while received levels dropped, indicating that the seals swam away. One animal with a detailed GPS track moved away from the sound source to a distance of 4 km within the exposure period, considerably further than reported in other AHD exposure studies. Habituation between exposures was not observed. Exposure levels recorded on the DTAGs deviated up to 20 dB from predicted levels based on on-site measurements and propagation modelling, illustrating the importance of on-animal sound recordings during exposure studies in shallow water habitats with complex sound propagation.

The underwater soundscape of fear: Behavioural responses of cetaceans to naval sonar and playback of predatory killer whale sounds.

The risk-disturbance hypothesis proposes that anthropogenic sounds may be perceived by animals as a threat similar to predator presence, driving individuals to trade fitness-enhancing behaviours such as foraging for perceived safety. We tested this hypothesis by quantifying how cessation-of-feeding responses to playbacks of mammal-feeding killer whale (kw) sounds (at natural source levels of 150-160 dB re1µPam) of four cetacean species in Norwegian waters (long-finned pilot, N=11; humpback, N=11, sperm, N=17 and bottlenose N=4 whales) corresponded to responses during separate experimental exposures to 1-4 kHz naval sonar (max source levels of 214 dB re1µPam). Using species-specific movement and/or echolocation click production parameters recorded on suction-cup attached Dtags, we quantitatively distinguished dive types (intense-active foraging vs non-foraging and exploratory behaviour) using hidden Markov models. Across species intense foraging time was lower during both predator playbacks ($p<0.001$) and sonar exposures ($p<0.001$), compared to pre-exposure baseline periods, while no effect of broadband noise ($p>0.9$) or vessel-only (no-sonar) control exposures ($p>0.2$) was found (Generalized estimating equations Wald test). The mean proportional reduction to kw playback and sonar correlated strongly across species ($r^2=0.93$, n=4), though there was notable variation across individuals. Bottlenose whales responded most strongly with a 100% reduction in foraging during both stimuli types, followed by humpback (97% for kw playback, 80% for sonar) and long-finned pilot whales (~75% both stimuli). The least responsive species was sperm whales, which reduced intense foraging time by ~50% during both stimuli types. This strong correspondence in reductions of intense foraging provides clear support for the risk-disturbance hypothesis. The low-frequency specialist humpback whale had an intermediate level of response to sonar compared to the higher-frequency odontocetes. We conclude that the risk of disturbance from anthropogenic sounds may be better predicted by a species' underlying vulnerability to predation than its hearing sensitivity relative to the sonar band.

Instantaneous stamp tattoo: A refined marking method in Phocid seals.

Milne, Ryan[1]; Moss, Simon[2]

(2) Sea Mammal Research Unit, St. Andrews, United Kingdom
Corresponding Author: rm610@st-andrews.ac.uk

Wildlife research often involves marking animals to facilitate the collection of data specific to individuals over time. Minimising the short- and long-term effects of marking on the animal's behaviour and health is not only imperative for animal welfare, but ensures that the data collected can be perceived as natural, with little or no effect from the identification mark/tag.

Here we describe the first documented use of an instantaneous stamp tattoo as a marking method in phocid seals and assess its efficacy and impact.

Short term captive grey (*Halichoerus grypus*), n=11, and harbour seals (*Phoca vitulina*), n=3, held at the Sea Mammal Research Unit Pool Facility, were marked with an instantaneous tattoo, under anaesthesia, during handling for associated procedures. Uniquely identifying marks were applied to the hind flipper webbing using modified ear tattoo pliers, 7mm alphanumeric stamps and tattoo ink. The application of the tattoo was carried out in seconds and the procedure had a negligible impact on the animal. The equipment used is portable and the application process required minimal training.

Images of the tattoos were taken during subsequent handling events and tattoo marks scored for impact and efficacy. The longest duration between mark application and imaging was 132 days. All tattoo marks became less defined over time but remained obvious and readable. There was no health complications or damage to the tissue as a result of the instantaneous tattoo.

The initial evidence from this study shows that this marking technique is effective for phocid seals, has no impact on the animals' anatomy, physiology and their ability to perform natural behaviours. Although this study was relatively short in duration and longer testing is required to

confirm the durability of marks, it demonstrates a refinement of marking method and should be considered as an alternative to current methods.

Monitoring the abundance of common bottlenose dolphins in Vis archipelago (Central Adriatic Sea, Croatia)

Data on the occurrence of the common bottlenose dolphin (*Tursiops truncatus*) within a study area centred around Vis Island (Adriatic Sea, Croatia) has been collected during summer seasons from 2007 to 2018. We used this long-term photo-identification dataset to obtain annual abundance estimates and test for a trend in abundance. Boat-based surveys resulted in a total of 13,673 km of research effort in favourable weather conditions. There was a total of 660 encounters with bottlenose dolphins in this period, from which 1060 sufficiently distinctive individuals were identified. Annual abundance estimates were calculated using the mark-recapture closed population model and the Mth estimator of Chao. These were then corrected for the proportion of non-distinctive individuals. The resulting corrected estimates ranged from a minimum of 353 (95% CI: 287-483) to a maximum of 600 individuals (95% CI: 462-866). The annual variations in abundance are possibly attributable to non-uniform research effort or habitat use patterns of the studied community, rather than actual changes. This is corroborated by the regression analysis results which did not indicate a statistically significant trend in annual abundance. The bottlenose dolphin community in the study area appears to have been stable within the reported period. This data contributes to informed management of the SCI for bottlenose dolphins (HR3000469) which is part of the chosen study area.

Stranding monitoring program in Brazilian coast: Analysis of reports.

Marine mammals stranding occurs worldwide due to natural and human-related factors. In Brazil there are many different activities that can negatively impact marine mammals. Fishing is important to many people, yet impacts from fisheries on marine mammals are still difficult to measure. Oil and Gas Industry is another relevant sector that can affect negatively the animals. Pre-salt oil region exploration brought a major concern as it is a huge area where the number of boats has been increasing, besides seismic studies, underwater noise, oil spill, number of ports and others. Some researches are analyzing the impact of this activity on marine mammals in a long term, however no one knows the real impact. As part of Oil and Gas Licensing, governmental environment agency requires the development of environmental programs, including stranding monitoring program (PMP). The main objective of PMP is to collect data to evaluate the interference of hydrocarbons extraction on marine tetrapods. Different institutions are contracted by Oil Companies to execute PMP. Most of them are member of the Stranding Network coordinated by ICMBio/CMA which created a working group to analyze marine mammals reported by PMP in five geographical areas covering 3.388km between Ceará and Santa Catarina State. From 2010-2017 a total of 2.594 individuals stranded. Besides remarkable spatial-temporal variation in mortality and the overall high number of stranded animals, the most immediate issue is the stranding of 1.325 Guiana Dolphin (*Sotalia guianensis*) and 1.234 Franciscana (*Pontoporia blainvillei*) individuals, classified as EN and CR in the National List of Endangered Species, respectively. Together, both species represented 70,14% of the total recorded mortality. The stranding majorities occurred in the months August, September and December in the Northeast coast, and between June to October in the South. The analysis provided important overview of marine mammal information for management and conservation actions.

Abundance estimate of beaked whales (Family Ziphiidae) in the Canary Islands from a distance line transect acoustic survey.

Miranda, Daniel[1]; Aguilar de Soto, Natacha[2]

Corresponding Author: dmirandaglez@gmail.com

The Canary Islands archipelago (Spain) is one of few places in the world where beaked whales (Ziphiidae) are known to occur year-round. These deep-water cetaceans are especially vulnerable to acoustic pollution and affected by other human impacts also, such as ship-strikes or debris ingestion, which cause strandings at the archipelago. However, there are no data on the local abundance of Ziphiid species to evaluate their conservation status. This study reports the first abundance estimate of the family Ziphiidae in the Canary Islands, derived from a line-transect acoustic *Distance* survey performed using a stereo towed hydrophone array in autumn-winter 2009-2010; this resulted in 99 transects totalling 3030 km length. Acoustic detections of beaked whale clicks were extracted and processed in *PamGuard* software to obtain perpendicular distances of the whales to the transect line, horizontal distances correction assuming animal depths from DTAG data was applied to reduce bias. *Distance Sampling* methods were applied to estimate absolute abundance within the sampled area of 52933 km^2 including the national territorial waters. A previously estimated $g(0)= 0.3$ was applied to correct for the availability bias. AIC criteria selected a hazard-rate model without adjustment terms as the best model for the detection function, with an effective detection distance of 500 meters. The detection function was estimated using 104 event detections. The best density estimate is 0.013 beaked whales/km^2 (95% CI 0.005 – 0.026), and the best abundance estimate is 688 (95% CI 311 – 1386) individuals for the survey area. This study provides a starting point for future work to monitor the status and population dynamics of beaked whales in the Canary Islands, essential for the conservation management of the species.

Tracking northern fur seal migrations using 14C in whiskers and satellite tags.

Northern fur seals (*Callorhinus ursinus*; NFS) breed on the islands mainly in the Okhotsk Sea (Tyuleny and Kuril islands), and the Bering Sea (Commander and Pribilof islands) during June–August. Overwintering NFS makes southward migration, and in the past decade, they have been reported to interact with coastal fisheries along the Hokkaido coast of the Sea of Japan. Previous studies using flipper tags suggest that NFS overwintering in the Sea of Japan was from islands in the Okhotsk Sea and the Bering Sea, however, there is little information after the population in the Pribilof islands has depleted. In this study, we aimed to reveal migration patterns of NFS from the Sea of Japan by using radiocarbon (14C) and satellite tags. In Japanese waters, cold Oyashio Current with low Δ14C flows southward along the Kuril islands, through Pacific coast of northern Japan. And warm Kuroshio Current with high Δ14C run northward along the Pacific coast of Japan. The Tsushima Current, split from the Kuroshio Current, flows from into the Sea of Japan. Therefore, analyzing whiskers of NFS can produce sequential records of habitat use. We attached satellite tags on 5 NFSs caught off the coast of Hokkaido, and sampled whiskers in 2017. Each whisker was sectioned from root to tip, and used for 14C analysis. Two tags transmitted long enough to reach breeding islands, Commander islands. Δ14C values in whiskers showed several oscillations with the lowest values (-40 ~ -50‰), which may indicate values in the Bering Sea, and with the highest values (10 ~ 20‰), which may reflect the values in the Sea of Japan. Therefore, it is suggested that NFS traveld back and forth between the Bering Sea and the Sea of Japan. The combination of bio-logging and chemical tracers enabled us to track individual long-term migration.

Science, law and marine mammals - analysis of a complex relationship and review of the legal framework in place to protect marine mammals in the UK.

Mitcheson, Helen
, Prenton, United Kingdom
Corresponding Author:
helen.mitcheson@googlemail.com

The relationship between science and law is complicated for a number of reasons, including:

- Scientific knowledge is uncertain, open to revision in light of new evidence and tends to advance more quickly than law;
- Science deals with uncertainty in ways that do not match legal systems; and
- Law is frequently limited to a particular jurisdiction, whereas scientific subjects are often transboundary in nature.

Marine mammal research is advancing rapidly, with technological developments (e.g. animal-borne sensors and processing of big data) enabling scientists to learn more about their subjects than previously. Many marine mammal populations, however, remain data deficient with a lack of knowledge of their biology (e.g. distribution, abundance and life history) and conservation status. In addition, there will also be statistical uncertainty.

The UK has more than twenty species of marine mammals living in its waters and a number of legal frameworks protecting them. Extensive scientific research has been undertaken in the UK for many decades. Despite the wealth of knowledge this has provided there is no UK legislation dedicated to the protection of marine mammals. Instead, there is a legal patchwork, with some legislation decades old and initially established to protect terrestrial species and habitats.

This presentation will analyse the difficulties in reconciling science and law and the role of scientific research in the creation and implementation of a legal framework for marine mammals. It will further review the effectiveness of UK legislation and the challenges of ensuring strict protection under the Conservation of Offshore Marine Habitats and Species Regulations 2017 and the Conservation of Habitats and Species Regulations 2017. In particular it will consider the difficulties in enforcing offences such as deliberate disturbance and intentional or reckless damage or destruction of habitats, together with the implications of such enforcement, or potential lack of, going forward.

Euthanasia of an adult humpback whale (Megaptera novaeangliae) in South Brazil.

Live whale strandings are always challenging and when rescue is not possible, euthanasia is a choice to be considered. IWC recognizes mechanical and chemical methods for large whale euthanasia and here we describe a successful procedure in an adult humpback whale that stranded in Solidão Beach/RS (-30.57497;-50,38458). On 27th February the authors were informed about a live stranded humpback whale. It was 12.7m long, estimated 20tons of weight, had corneal, palpebral and pain reflexes, could follow people with eyes and was vocalizing. As it had half of the body buried in the sand, was considered in poor body condition and beach conditions did not allow any kind of safe rescue, the staff decided for euthanasia. Animal was monitored by the staff and drugs for euthanasia were acquired. In an adaptation of published protocols to the available drugs, on 2nd March we decided for the following protocol: 1-local block with lidocain, small incision on dorsal bubbler for best access to the epaxial muscle. 2-IM injection of midazolam (0,05 mg/Kg), acepromazine (0,25mg/Kg), cetamin (2,47 mg/Kg). 3-IM injection of xylazine (2,5mg/Kg). 4-after reflex loss, local block with lidocaine and intracardiac injection of KCl (200mg/Kg). After 20 min of the first IM injection, the animal started to show nystagmus and had lowered palpebral reflex. Xylazine administration was performed after 40 min of the start of the procedure and leaded to palpebral reflex loss. We did a local block, the manufactured stainless steel needle was inserted just behind right pectoral fin insertion and KCL was administrated in the heart. The animal stopped breathing just after the start of KCL administration. After 40min after the last breath, the animal was considered dead. Although there are published papers about chemical euthanasia in large whales, every case is unique and has new important information to be shared.

Establishment of fibroblast cell lines and induction of pluripotent stem cells derived from four-finned dolphin Tursiops truncatus

【Objective】 In 2006, one common bottlenose dolphin Tursiops truncatus having a pair of pelvic fins was found and kept alive. It was expected to

elucidate the molecular mechanism of loss/regeneration of pelvic fins of cetacean and unveil the mystery how they lost their hind limbs during their evolution through the research of the four-finned dolphin. Unfortunately, this dolphin died without generating offspring. Here, we focused our studies on establishments of (1) cell lines derived from the four-finned dolphin fibroblasts to conserve its genome resources, and (2) induced pluripotent stem (iPS) cells to utilize them for various studies.

【Methods】 (1) Four-finned dolphin fibroblasts were cultured and infected with recombinant lentivirus encoding immortalizing factor SV40T or hTERT. These lentivirus also have a blasticidin S-resistance gene. In infection experiments, either individually or mixed virus solutions were used. Two days after transfection, blasticidin S was added to select infected cells. (2) Four-finned dolphin cell lines were co-transfected by electroporation with human derived reprogramming factors Oct3/4, Sox2, L-Myc, Klf4, Lin28. A week after electroporation, these cells were re-seeded on feeder cells and cultured for 3 weeks. Also, we are trying to construct vectors encoding dolphin derived reprogramming factors.

【Results】 (1) Blasticidin S-resistance cells were obtained under conditions with SV40T alone, or mixture of SV40T and hTERT. These cells have replicated past the Hayflick limit. Then, we collected single cell clones and made growth curves. All transfected clones showed remarkable increases in growth rate compared to the non-transfected cells. Also, SV40T expression was detected from these clones by Western blotting. (2) A month after electroporation, iPS cell-like colonies appeared. In addition, these colonies showed positive reactions by ALP staining suggesting that these colonies may be in a de-differentiated state.

Historical distribution of whales in the Eastern North Pacific based on data from the US Whale Discovery Marking Program, 1962-1969.

Between 1962 and 1969, the US whale Discovery marking program conducted 14 exploratory research cruises, mostly in winter months. The surveys ranged from northern California to the southern tip of Baja California, east to mainland Mexico and west to the Revillagigedo Archipelago. Winter surveys in these areas were and remain uncommon. Data from these cruises provide rare insights on historical winter distribution of whales.

During these cruises, 991 groups of whales were sighted, including one group of right whales, 514 groups of gray whales (approximately 6 whales marked, no recoveries), 70 groups of humpback whales (44 marked, no recoveries), 73 groups of minke whales, 74 groups of Bryde's whales (19 marked, no recoveries),31 groups of sei whales (12 marked, 2 recoveries), 79 groups of fin whales (56 marked, 11 recoveries),73 groups of blue whales (84 marked, no recoveries), 54 groups of sperm whales (176 marked, 7 recoveries), and 17 groups of killer whales. There were also five sightings of a species similar in size to Bryde's and sei whales, seen in a mixing area for these species, which the experienced observers (DWR, KCB) found difficult to identify. Based on field descriptions, they may have been Omura's whales.

Gray and fin whales were seen throughout the entire area surveyed. Humpback whales were seen in different areas off Baja California seasonally. Minke whales were not seen in the lower third of Baja California but were seen in southern areas offshore. Sperm whales were mostly seen north of Baja California. Blue whales were seen in large numbers off Baja California in winter. Sei whales were seen north of the southern third of Baja California and Bryde's whales were seen in the middle and southern areas of Baja California, although never sighted north of 26° N. Killer whales were seen sporadically along the entire coast.whale

Comparisons and relationships of genetic characteristics of Japanese harbour seals in eastern Hokkaido between breeding and non-breeding seasons.

In Japan, harbour seals inhabit the Pacific side of Hokkaido, and major breeding grounds are located in four administrative districts: Erimo, Akkeshi, Hamanaka and Nemuro. Breeding site in Erimo is

150km away from the closest site in Akkeshi, while each breeding ground in Akkeshi, Hamanaka and Nemuro are separated by 20km. Japanese harbour seals are known to disperse in non-breeding season but come back to the same breeding site in subsequent years. The past population genetic studies using mtDNA and microsatellite markers suggested they are separated into two populations; Erimo and eastern Hokkaido. The eastern Hokkaido is strongly affected by the gene flow from the north east, where currently much larger breeding ground is located (>1000). In this study, we compared the genetic characteristics of eastern Hokkaido harbour seals divided into four groups; Akkeshi-breeding, Hamanaka-breeding and Nemuro-breeding and non-breeding, to see how the immigration from the north east affect the breeding groups in eastern Hokkaido. Genetic differentiation was observed only between Hamanaka-breeding and non-breeding for microsatellite Fst ($p<0.05$). MtDNA marker on the other hand suggested population differentiation between Hamanaka-breeding and Akkeshi-breeding for Fst ($p<0.05$), and Hamanaka-breeding and non-breeding for both Fst ($p<0.05$) andΦst ($p<0.01$). PCA analysis indicated only the second axis was significant ($p<0.01$) which accounted for 41.39%. Hamanaka and Akkeshi-breeding were genetically the farthest away while Nemuro-breeding and non-breeding showed genetic similarities. Our result based on both mtDNA and microsatellite markers supported seals breed in Hamanaka has the largest genetic differentiation compared to the other groups, suggesting the seals here are least affected by the immigration from the north east, making them subgroup in eastern Hokkaido. Furthermore, this study suggested importance in sampling seasons for understanding the relationships of subgroups of harbour seals within population.

Efficacy of using acoustic alarms on gillnets to reduce harbour porpoise bycatch in Norwegian fisheries

Moan, André[1]; Bjørge, Arne[2]

Corresponding Author: andre.moan@hi.no

Incidental takes in gillnets is the most serious global threat to harbour porpoise (*Phocoena phocoena*) populations. In Norway, the incidental mortality due to bycatches is about 3000 porpoises per year. Ten small fishing vessels operating in the Norwegian coastal zone targeting cod (*Gadus morhua*), saithe (*Pollachius virens*) and monkfish (*Lophius piscatorius*) were used in multiple season-long field trials to determine the potential of acoustic alarms (pingers) mounted on gillnets to reduce incidental takes (bycatch) of harbour porpoises. We collected catch and bycatch data for a total of 50 000 net-weeks. A total of 17 porpoises were taken, distributed with 11, 1, and 5 porpoises in the cod, saithe and monkfish fisheries, respectively. Our analyses show that the efficacy of the pingers was 70% in the cod fishery, 100% in the monkfish fishery and 100% in the saithe fishery. We conclude that pingers can potentially bring harbour porpoise bycatch in Norwegian fisheries well into sustainable levels. However, the fishers reported that they had to take extra care in handling nets with pingers to avoid damaging or entangling the pingers. The conservation benefits of pinger use for the harbour porpoise must be balanced against economical and practical considerations due to an extra time and work cost of handling gillnets with pingers attached. The pingers also contribute to anthropogenic underwater noise that displaces porpoises away from preferred habitats. We propose that a partial, rather than a full-scale, pinger deployment strategy should be used in a area/time targeted fashion to reduce expected bycatch to some predetermined, sustainable level.

Relative abundance of humpback whales in Maui Nui--preliminary results of 2019-20 aerial surveys.

Mobley, Joseph R.[1]; Deakos, Mark; Pack, Adam[2]
(1) University of Hawaii at Manoa, Honolulu
(2) University of Hawaii at Hilo, Hilo, Hawaii
Corresponding Author: jmobley@hawaii.edu

Evidence from 2016-2018 suggested that the Hawaiian humpback whale distinct population segment may be in decline. Earlier aerial surveys (1993-2003) of the main Hawaiian Islands showed the wintering population to be increasing at a rate of 7% per year, with highest densities in the Maui Nui (Maui, Molokai, Kahoolawe and Lanai) and Penguin Bank regions. The goal of 2019-20 aerial surveys is to replicate that earlier effort to detect changes in relative abundance and/or distribution in the latter high density areas. The first year's results (2019) are reported here.

Surveys were performed from a twin-engine Partenavia P68 aircraft flying at an altitude of 244 m (800 ft) and a speed of 100 knots. Tracklines consisted of north-south systematic lines spaced 14 nmi apart, extending 7 nmi past the 1000-fathom depth with random lines connecting endpoints. GPS, altitude, distance from the trackline, group size and presence of a calf were collected for each sighting. Survey

crew consisted of a data recorder and two observers, one on each side of the aircraft.

Surveys were conducted on dates to correspond to peak whale densities (Feb. 8, 18 and March 1) based on prior surveys. A total of 174 whales were sighted across 1,709 km effort for an overall encounter rate (ER) of 0.102 whales/km. ERs from earlier surveys ranged from 0.062 in 1993 to 0.101 in 2003. Despite earlier evidence of a rapidly increasing population, the 2019 ER was equivalent to that in 2003. The percent of groups containing a calf was higher in 2019 (9.2%) than that seen earlier (from 5.2% in 1995 to 8.6% in 2003). Thus, the 2019 surveys presented conflicting evidence regarding the current status of the wintering population in the Maui Nui region necessitating additional state-wide surveys.

In vitro evaluation of cytotoxic and genotoxic effects of Di(2-ethylhexyl)-phthalate (DEHP) on bottlenose dolphin (Tursiops truncatus) skin cell line

Cetaceans are long living species, that occupy different trophic levels in the food chain. Most cetaceans are wide ranging, showing seasonal movements and changes in habitat use, which can be very variable even at individual level. Due to their position at the top of the food chain, the low rate of their metabolism and the presence of a layer of blubber, which accumulates lipophilic pollutants, cetaceans bioaccumulate high quantities of marine contaminants. For these reasons, cetaceans are considered good indicators of the status of marine waters. In more recent years, several studies have associated the death of many of these organisms to the ingestion of marine litter, mainly constituted by plastic debris, which can become a major source of pollutants. Di(2-ethylhexyl)-phthalate (DEHP) is the most abundantly used plastic additive and it has been reported to affect multiple biochemical processes both in humans and wildlife. Nevertheless, there is limited information on the toxicological effects of DEHP on marine organisms, in general, and on cetaceans, in particular. In this study, we evaluated the cytotoxic and genotoxic effects of DEHP on Bottlenose dolphin skin cell line, employing specific *in vitro* tests to assess cell viability and DNA damage. Cytotoxicity tests showed a slight dose-response decrease of cell viability after 24 h of exposure to DEHP. Genotoxicity tests, such as Comet and Cytokinesis-Block MicroNucleus (CBMN), detected only a slight increase of DNA strand breaks but a clear indication of a significant micronucleus induction after treatments. The overall results demonstrate that *in vitro* exposure to DEHP has cytotoxic and genotoxic effects on Bottlenose dolphin skin cell line. Moreover, these results are discussed in comparison to DEHP effects detected on the standardized Chinese Hamster Ovary cell line (CHO).

The Navy Acoustic Effects Model (NAEMO): Adapting to Changing Requirements.

The Navy Acoustic Effects Model (NAEMO) was developed in 2008 to assess the potential level of behavioral disturbance and physiological impacts (e.g., temporary and permanent threshold shifts) for individual marine mammals and sea turtles likely to be in the vicinity of Navy training and testing activities. Recent updates to NAEMO include a web-based data collection system and the continual incorporation of the best available scientific data (e.g., marine species density and distribution data, updated acoustic impact criteria and thresholds). NAEMO has been adapted to consider different output requirements based on the level of analysis required, such as analyzing groups of species (i.e., stocks or guilds) instead of only assessing potential impacts at the individual species level. As NAEMO enters its fourth generation of software, the Navy is evaluating how to adapt the inputs and apply analytics to account for future regulatory requests or requirements. Potential enhancements may include analyzing how density layers are used in the model, examining the number of simulations required for densely or sparsely populated species, increasing the complexity of the event being

modeled, increasing resolution in environmental data, accounting for the effects of moving animals, incorporating potential mitigation and avoidance, and developing additional statistics to inform results. These prospective changes will be explored considering the best available science and evaluated to determine their potential to better understand the acoustic impact of Navy activities on marine species.

Genomic estimates of effective population size for blue whales.

Estimation of effective population size (Ne) and abundance (census size, Nc) remains challenging to derive for wildlife species, particularly for those with wide ranging distributions, high mobility and cryptic behaviours. Ne and Nc are key parameters for the conservation and management of wildlife because they can determine the degree to which populations are at risk. While Nc impacts demographic and ecological processes, Ne affects genetic drift, loss of genetic diversity and levels of inbreeding. Genetic methods have recently gained popularity for estimating Ne due to the development of various statistical approaches, and the availability of user-friendly software. Blue whales (*Balaenoptera musculus*) were reduced to very low numbers during the whaling era, with some subspecies and populations impacted more heavily than others. Here we estimate contemporary Ne for populations of three blue whale subspecies (*B. m. musculus*, *B. m. intermedia*, and *B. m. brevicauda*) using a single-sample estimator based on the Linkage Disequilibrium (LD) method, and a panel of >15,000 unlinked single nucleotide polymorphism (SNP) loci. Samples (n= 277) originated from Antarctica, Eastern South Indian, Western South Pacific, Eastern North Pacific, Eastern Tropical Pacific, and Eastern South Pacific. Population genomic analysis in general indicated higher differentiation and low contemporary migration rates between subspecies, and lower differentiation and moderate migration rates between populations within subspecies. Ne estimates ranged from 43 to 455 (mean= 240, SD= 140), depending on the population, and Ne/Nc (for populations with Nc estimates available) ranged from 2 to 41% (mean= 0.20, SD= 0.17). Simulations indicated that factors impacting robustness of estimates include migration rates, strength of bottlenecks, sample sizes and scheme, and choice of parameters for estimation. This study identifies issues to be considered when planning genomic estimates of Ne for cetacean populations, and assists in interpreting estimates within a conservation management context.

Updating a photo-id catalog of bottlenose dolphin off Catania.

Updating a photo-id catalog of bottlenose dolphin off Catania.

Monaco C.[1, 2], Susini C. [1], Pellegrino G. [1, 3]

clamonaco@unict.it

1 Marecamp association. Lungomare Scardamiano 1, 95021 Aci Castello, Catania, Italy.

2 Department of Agriculture, Food and Environment of the University of Catania. Via Santa Sofia 98-100, 95125 Catania, Italy.

3 Accademia del Leviatano. Viale Astronomia 19, 00144 Roma.

To fill the gap of data on presence, distribution and social interactions of cetaceans off the coast of Catania, after a decade of interruption of the photo-identification works in the Gulf of Catania (Ionian Sea, Italy), the Marecamp association decided to update an existing old catalog of dorsal fin of bottlenose dolphins living in the area (Monaco et al., 2010). The visual method of Würsig & Würsig and the computer-assisted programs DARWIN (Stanley, 1995) and SOCPROG were used (Whitehead, 2009).

The old catalog contained 39 individuals identified from 1997 to 2008 while the new one permitted to update many reference photos of 3 previous classified specimens and also to add new items, reaching 49 bottlenose dolphins photo-identified until 2018. We collected 320 new photos during 2 hours of sighting overall, for a total effort of 90 hours of monitoring.

According to fission-fusion grouping patterns typical of medium size bottlenose dolphins' herds, we saw some confirmed individuals of the catalog maintain relationships between them, while other individuals, confirmed matches and not, established new social associations, moving North-South and back across the Gulf.

Using mark-recapture principles for population study and observing the high slope of the discovery curve, we found that the investigated population has not been still completely identified. Moreover, ongoing studies with some Sicilian organizations are conducting in order to verify any old and/or new relationships with specimens from adjacent areas to the Gulf and to better comprehend population dynamics.

Using U.S. law to protect endangered marine mammals from entanglement and promote ropeless fishing gear.

kmonsell@biologicaldiversity.org

The U.S. Endangered Species Act (ESA) has been described as the most comprehensive legislation for the preservation of endangered species ever enacted by any nation. The ESA is expressly designed to prevent extinction and promote recovery of imperiled species.

We will provide a brief overview of how the ESA works. We will highlight a case study of entanglements of large whales in fishing gear off the U.S. West Coast and how the powerful ESA was brought to bear on the whale entanglement problem.

We will describe how reported entanglements of large whales began increasing in 2014, breaking historical records each of the past four years. Preliminary data from the U.S. National Marine Fisheries Service indicate that at least 45 whale entanglements were reported in 2018. The data show that there were 71 reported large whale entanglements in 2017, up from 62 in 2015 and 30 in 2014. Before that, whale entanglement reports averaged fewer than 10 per year. We will briefly describe suspected causes of the increase in entanglements, including climate change, shifting fishing effort, and increasing whale populations.

We will also describe how, in 2019, use of the ESA, resulted in a time area closure to protect whales during their migration, plans to adopt a science-based risk assessment management program, and incentives to develop and adopt ropeless fishing gear.

Effects of limited dispersal by sea otters (Enhydra lutris) on population dynamics; Relevance to the threatened Southwest Alaska distinct population segment.

Small, isolated populations with limited dispersal capabilities are demographically independent at relatively small spatial scales, and at risk of demographic and genetic constraints to sustainability. Our data from across Alaska indicate that densities and trajectories of sea otters differ among regions separated by <100km. The Southwest Alaska stock of sea otters presents an interesting case, having experienced two discrete population reductions, and understanding population health and sustainability is important, given the Threatened status of the stock. Sea otters were hunted to near extinction in the 18th and 19th centuries, with just 2 remnant colonies surviving in the western Aleutian Islands. Population recovery over the 20th century was slow due to their limited dispersal capabilities and high site-fidelity, but by 1985 sea otters had recolonized most of their former habitat in the western Aleutians. Beginning in the late 1980's, the Southwest Alaska stock suffered another major population reduction (~90%) due to killer whale (*Orcinus orca*) predation. In contrast to pre-decline distributions, the remaining sea otters are concentrated in a few colonies that occur in sheltered habitats. This distribution likely protects them from predation, however the patchy distribution combined with high fidelity likely acts to reduce demographic

connectivity among colonies. We use data from surveys and tagging studies to parameterize a spatial model of population connectivity before and after the recent population decline. We hypothesize that predation-driven selection for reduced movements and high fidelity to sheltered habitats will lead to reduced gene flow and further losses of genetic diversity due to small population sizes. Ultimately, the limited dispersal capabilities of sea otters in combination with predation by killer whales may have implications for the long-term viability of sea otters in the western Aleutian Islands. Management strategies that increase gene flow and maintain remnant genetic diversity should be considered.

Temporal trends in mortality patterns of the endangered franciscana dolphin (Pontoporia blainvillei) in southern Brazil

Monteiro, Danielle[1]; Prado, Jonatas[2]; Botta, Silvina[3]; Estima, Sérgio[4]; Secchi, Eduardo

Corresponding Author:
danismonteiro@yahoo.com.br

The franciscana (*Pontoporia blainvillei*) is endemic to the western South Atlantic Ocean and the most threatened cetacean species in South America mainly due to the bycatch in gillnet fisheries. In the coast of Rio Grande do Sul, Southern Brazil, the overlap between franciscana distribution and gillnet fleets results in a high bycatch rate resulting in thousands of stranded franciscanas along the beach. In 2012, the Brazilian Government published a norm to regulate gillnet fisheries by reducing the fishing effort and establishing no-fishing zones. Consequently, a decrease in bycatch and stranding rates of franciscanas should be expected in most recent years. Generalized Additive Models (GAM) with a time series of five years before (2008-2012) and five years after (2014-2018) the publication of the norm were used to evaluate the temporal stranding patterns. Bycatch data collected by onboard observers in commercial fishing vessels were used to estimate the mortality during the white croaker (*Micropogonias furnieri*) and striped weakfish (*Cynoscion guatucupa*) fishing seasons, from 2013-2015 and 2018-2019 using Hierarchical Bayesian models. The stranding rate showed a slight and non-significant decline after 2012 ($p=0.19$). The strandings were highly seasonal with peaks from November to February which coincided with a higher gillnet fishing effort for the white croaker. The estimated number (Mean; [Credible Interval]) of franciscanas killed in the croaker season ranged from 93[6; 2014] in 2015 to 574 [83; 1157] in 2018. For the weakfish season, the estimated number ranged from 259 [16; 591] in 2015 to 508 [85; 988] in 2018. Current levels of fishing-related mortality of franciscanas are similar to previously reported estimations (i.e. before the norm), thus are still very high and may not be sustainable. Long-term monitoring of incidental captures through on-board observers and beach surveys are essential to evaluate trends in this mortality and to guide management actions.

Marine mammals matter: Combining applied research with education to inspire community conservation action.

Education is key to empowering community and individual capacity to undertake effective conservation and sustainability management within marine environments. With an increasing amount of research dedicated to the impact of plastic and marine debris in marine mammals, such as entanglements and ingestion, it is important to raise awareness to promote positive change. As marine mammalogists we have a unique ability and responsibility to educate the community, foster environmental connection through compassion of whales, dolphins and seals, and empower and inspire action towards a better tomorrow. From communities living in close proximity to coastal environments to those that are geographically distant, understanding key ecological processes, anthropogenic threats and influences, and management and mitigation are important factors in the application of community conservation initiatives. The Marine Mammal Foundation is a not-for-profit research, education, and conservation organisation. With our wide range of education programs, community outreach programs, and citizen science activities, we are uniquely placed to combine applied research with action for conservation and understanding of south-east Australian marine environments. We highlight innovative outreach and education programs that together have reached over 18,832 community members (2017-2019). From curriculum-based school incursions bringing real research into the classroom; litter mitigation programs *Marine Litter Project*, *Bin Not Bay* and *Litter Free Lakes*; community citizen science program *Lakes*

Champions, to our youth empowerment program *Marine Champions*, these crucial initiatives aim to connect, empower and create change. The outcomes include raising awareness of local marine mammals; highlighting impacts of anthropogenic threats such as recreational boating and litter and marine debris; strategies to mitigate threats; encourage youth participation in applied science; and empower individual and community conservation and sustainability action. Volunteer contribution, collaboration between industry, community groups, and other stakeholder organisations, and ongoing funding support has proved vital in the successful implementation of not-for-profit education and outreach programs.

Sonic seas: Hearing abilities of an endangered Cook Inlet beluga, in situ noise measurements and implications for masking.

Cook Inlet belugas (CIBs) are a critically endangered and declining marine mammal population. Anthropogenic noise is considered a primary threat to these animals and sound is critical to key behaviors including communication, foraging, and navigation. Yet there have been no data on hearing in CIB, making it challenging to quantify noise-related impacts. In the fall of 2017, a beluga calf from the endangered CIB population stranded and as part of its health assessment we measured its hearing in October and December using evoked potentials. The beluga calf heard all frequencies tested (4-120 kHz) and showed sensitive hearing (<70 dB) for a wide range of frequencies (16-80 kHz), reflective of a healthy odontocete auditory system and similar to many healthy belugas from the Bristol Bay population (the only other published data set of healthy, wild marine mammal hearing). October and December measurements were similar, showing continued auditory health of the animal throughout the stranding rehabilitation. Hearing data were compared to noise measurements made in Cook Inlet from two primary sources of concern at ecologically relevant locations: pile driving (ca. 4km distance from source) in Cook Inlet and container-ship noise several km from the stranding site. Despite being measured relatively far from the source, noise spectra (in 1/3 octave bands) were substantially higher than the hearing thresholds, suggesting masking is often likely even at 'mid-frequencies' (4-11 kHz) in the communication range and at ecologically relevant distances. Overall, these data provide the first empirical hearing data for a CIB allowing for estimations of sound-sensitivity in this population. Sensitive hearing and ambient soundscape data show noise is a clear concern for this population, and provides important baseline knowledge to better address environmental concerns related to the lack of recovery for the endangered CIB population, and general increase of underwater noise in the Arctic.

The 2018 California Current Ecosystem Survey: A multi-disciplinary assessment of predators and prey off southern Canada, the USA and northern Mexico.

NOAA Southwest Fisheries Science Center (SWFSC) conducted the California Current Ecosystem Survey (CCES) from June – December 2018. Made possible by the Pacific Marine Assessment Program for Protected Species (PacMAPPS) – a partnership between NOAA, the US Navy, and the Bureau of Ocean Energy Management – this ambitious and first-of-its-kind multi-disciplinary survey encompassed waters from Vancouver Island, Canada, to southern Baja California, Mexico, out to 200 nautical miles offshore. This was the 8th large-scale marine mammal and ecosystem survey of the California Current conducted by SWFSC since 1991; however, it was the largest of these in its latitudinal

scope, and in addition to the standard large-vessel visual line- and strip-transect abundance and distribution surveys for cetaceans and seabirds, it also included data collection by drifting acoustic spar buoy recorders (DASBRs) for deep diving cetaceans; continuous acoustic backscatter for prey species; and – in collaboration with Cascadia Research Collective – an unprecedented biopsy sampling and photographic identification effort for humpback and other baleen whales. The cetacean sighting rate was twice that of any previous survey, almost certainly because survey effort was more heavily concentrated over the continental shelf than for past surveys. The NOAA large vessel working together with the Cascadia small-boat facilitated us collecting hundreds of biopsies and thousands of identification photographs. CCES data will be used to update and improve marine mammal stock assessments for the California Current, and additionally, to update cetacean density maps, address trophic ecology questions (predator-prey distributions), improve fishery stock and integrated ecosystem assessments (prey consumption estimates), provide greatly improved population size estimates for beaked and sperm whales, and provide stock-delineation and population biology inferences for humpback whales to inform management associated with high numbers of entanglements in pot and trap fishing gear.

Thermal infrared detection of peri-callosity heat loss, core temperature and subsurface movement in surfacing and skim feeding north Atlantic right whales.

Study of right and bowhead whale thermoregulation has been limited primarily to descriptions of substantial but variable blubber thickness, and of the corpus cavernosum maxillaris (oral rete), a blood-filled erectile sponge, that has been suggested to provide heat loss and avoid cerebral hyperthermia. Here we describe unmanned aerial system infrared thermography of surfacing, and surface and subsurface skim feeding North Atlantic right whales (*Eubalaena glacialis*). Epithelial surfaces adjacent to keratinized rostral callosities are warmer than the callosity keratin and post-cranial epithelium, especially for individuals whose rostra remain above the water surface during skim feeding. The thicker callosity tissue and overlying cyamids may act to insulate heat radiation from callosities. Anatomical examination of the dermis and hypodermis in these areas in samples from a ship struck specimen showed no obvious large blood vessels, or other retial structures. Thus, we suggest that these warm areas may show dorsal radiation of heat from the oral rete. Dorsal views of open blowholes also show very significant heat, suggesting that suitably calibrated vertical images will allow for measurement of core temperature, as described previously for the bottlenose dolphin (*Tursiops truncatus*). Thermal infrared imagery of subsurface swimming right whales can also allow for tracking, by observing upwelling of colder, deeper water during fluke upstrokes. Additionally, one animal showed a large patch of post cranial heat radiating dorsally in the thoracic area, suggestive of underlying pathology. We suggest that this technique could be developed to enable quantitation of core temperature, and rostral heat radiation in different behavioral, acoustic stress, and environmental conditions, providing an acute term assay of thermal response to diverse stressors. Entangled and emaciated animals, and those with healing scars could also be examined using this technique to better understand the effect of these stressors on both local lesions and core temperature. NOAA Permit 17355-01.

The effect of marine traffic on bottlenose dolphin (Tursiops truncatus) behavior in The Ría de Arousa in Galicia, Spain.

Understanding the dynamics between bottlenose dolphin (*Tursiops truncatus*) behavior and anthropogenic behavior is essential for the creation and implementation of effective conservation strategies for the species. Due to a general trend towards coastal urbanization, bottlenose dolphins encounter frequent disturbances due to human activities, facing increased threats to fitness and survival. This study examined the effects of marine vessel traffic on a resident population of bottlenose dolphins in the Ría de Arousa of Galicia, Spain. Marine vessel traffic, specifically commercial mussel farm boats, fishing boats, and tourist

catamarans, is the most common anthropogenic threat faced by the Ría's dolphins. Using land-based observations, data were collected on group behavior and marine vessels interacting with a group. These data were used to compare differences in behavioral transitions, behavioral budgets, and bout durations in the presence and absence of marine vessel interactions. The Ría's resident bottlenose dolphin population was more likely to continue traveling and less likely to remain resting in the presence of marine vessel traffic. The behavioral budget analyses indicated they also spent a higher proportion of time traveling and a lower proportion resting. The average length of behavioral bouts was significantly different in impact situations, during which dolphins experienced longer traveling and socializing bouts and shorter resting bouts. These short-term consequences may result in long-term decreases in reproductive success and survival at the individual and population levels. Thus, steps should be taken to improve local legislation and increase public awareness with the goal of conserving this resident population of bottlenose dolphins.

Identifying important habitat for endangered northern bottlenose whales along the Scotian Shelf in eastern Canada.

The Scotian Shelf population of northern bottlenose whales (*Hyperoodon ampullatus*) comprises fewer than 150 individuals, occupying the shelf edge and submarine canyons off eastern Canada. The population is listed as Endangered under Canada's *Species at Risk Act*, and three noncontiguous areas encompassing the Gully, Shortland, and Haldimand canyons located offshore of Nova Scotia are currently designated as critical habitat. The inter-canyon slope areas separating these critical habitats are rarely surveyed, and there are few reliable sightings of northern bottlenose whales outside the canyons in this region. Here, we combined alternate sources of data to infer the habitat use and movements of northern bottlenose whales within and between designated critical habitat areas. Passive acoustic monitoring conducted with bottom-mounted recorders over a two-year period revealed the presence and foraging activity of northern bottlenose whales in inter-canyon slope areas throughout the year, with a seasonal peak in acoustic detections during the spring. Towed hydrophone array surveys also confirmed species presence in these areas. Photo-identification data collected during encounters with northern bottlenose whales inside the three canyons were used to model residency and movement patterns within and between canyons, based on the lagged identification rate of individuals with unique and reliable markings. Individuals regularly moved between canyons over periods of days to months and also spent time outside of the canyons. Together, these results indicate that inter-canyon areas along the continental slope comprise important foraging habitat for northern bottlenose whales and function as corridors for frequent movement between the core habitat areas within the canyons. This study demonstrates how year-round passive acoustic monitoring combined with photo-identification-based movement modelling can be used to examine habitat use in areas with limited visual survey effort.

Photographic identification of long-finned pilot whales (Globicephala melas) in the Pelagos Sanctuary

Photo-identification is a method of using photographs of natural markings, such as scars and pigmentation patterns, to identify individuals. The study area where photographs of long-finned pilot whales (*Globicephala melas*) were collected is the North-West Mediterranean Sea from 1999 to 2017. The sampling effort was being mostly carried out in the Pelagos Sanctuary (marine protected area for cetaceans since 1999) with a total of 18 surveys and more than 30 hours of observation at sea. The photo identification process carried out for this project was based on natural markers described in the following publications: Sergeant and Fisher (1957), Sergeant (1962a), Kastelein et al. (1990), Gowans and Whitehead (2001). To describe the distribution and abundance of the marks along the flank and the dorsal fin, each mark type found in the photographs was analysed. During the 12 years of sampling (from 2006 to 2017), 18 sightings of long finned pilot whales occurred, and 8211 photos of Globicephala melas were collected and 161 individual of long finned pilot whales were identified with photos of different quality rating. Among these 161 individuals, only one is a calf, all the others are adults or sub-adults. Parameters related to the left side and the right side, was calculated analysing individuals with Quality

Rating ≥1 (the best): 83 individuals for left sides, 115 individuals for right sides. Analysis revealed the presence of 1337 marks. In general, from the data obtained is possible to assert that the right side is more injured than the left side, indeed the right side present 791 total marks compared to the 546 of left side. On the basis of this injuries was possible establish the frequency of recapture from which showed that the 20% were photographically captured (recaptures) more than once.

Remote sensing of polar bears using aerial multispectral imagery

Instrument-based aerial surveys have proved to be an efficient approach to estimating broadly distributed populations of ice-associated seals by increasing survey range, decreasing disturbance of animals, and reducing error relative to surveys with human observers. Automating data collection and image processing increases efficiency of the survey and post processing of collected imagery. Despite the success of detecting seals on ice, reliability of detecting polar bears has remained uncertain. During 2016 surveys of the Chukchi Sea, long wavelength infra-red (LWIR) imagers were used to detect seals and polar bears on sea ice. Automated thermal detection of bears that were either identified by onboard observers and then flown over to collect imagery, or known to be in the survey strip based on post-flight examination of high-resolution color images, revealed a lower detection rate for polar bears than seals (0.70 and 0.96, respectively). Additionally, just 3 polar bears, much lower than the approximately 10 that were expected, were detected in the effective survey area (5830 km2) yielding a markedly lower abundance estimate than that produced from analysis of capture-recapture records. To investigate the possibility that processes such as heterogeneity or activity could have biased polar bear detection estimates, we used an APH-28 hexacopter drone to collect multispectral imagery of captive bears exhibiting behaviors thought to impact detection by visual observers. Using machine learning modeling techniques and aerial multispectral imagery of wild and captive polar bears, we present an evaluation of polar bear detection in infrared, color, and ultraviolet imagery along with 2016 Chukchi Sea survey results.

Prediction of the cochlear frequency map for the harbor porpoise

In mammals, the base of the cochlear spiral within the inner ear encodes high frequency sounds, while low frequencies are transduced in the apex. However, the distribution of frequencies along the spiral, also called cochlear frequency map, is species-specific and non-linear. Cochlear frequency maps are not known for cetaceans. The value of these maps is that they can provide information on the causal sources, if lesions are detected in cases of noise-induced hearing loss. Morphometric variation occurs in cells of the organ of Corti (the hearing organ) along the cochlear spiral. These variations in cell shape and spacing can be related to the frequencies encoded at different locations, as shown in the guinea pig. We used geometric morphometric measurements from scanning electron micrographs of the organ of Corti along 10 locations of the cochlear spiral in harbor porpoises, mustached bats, rats, mice and gerbils. We used machine learning algorithms with the morphometric data of echolocating bats and rodents (species with known frequency maps) to identify a predictive model relating morphometry with coding frequency. Then, we used this model to predict the cochlear frequency map for the harbor porpoise. Subsequently, we validated the frequency hearing range of this prediction using the ear of a harbor porpoise whose audiogram was measured. We found that harbor porpoises have a large area of the cochlea that encodes for the same frequencies, which corresponds to the maximum hearing sensitivity for the species. The ability to combine morphological and auditory data is crucial to validate cochlear frequency maps based on morphological features. In addition, we could apply this approach of cochlear mapping for other species and predict hearing range and frequencies of maximum sensitivity in cetaceans whose audiograms are unknown by analyzing the morphometry of the cells of the organ of Corti.

Management strategy evaluation for a feedback regulatory system to limit marine mammal

bycatch: The bottlenose dolphin case-study.

Bycatch in commercial fisheries is considered a global threat to marine mammals. However, regulatory initiatives to monitor and limit bycatch from commercial fisheries are still limited. The Potential Biological Removal (PBR) and fisheries classification system offers a regulatory framework implemented in the United States' Economic Exclusive Zone to limit bycatch of marine mammals in commercial fisheries. PBR is calculated for each population against which bycatch is compared to classify each commercial fishery as having 'frequent', 'occasional' or 'remote' bycatch. In principle, only fisheries classified as 'frequent' and 'occasional' trigger bycatch management measures. This system is to be applied to fisheries operating outside the US that export fishing products to the US. However, a formal evaluation of the combined management components (PBR and fisheries classification) has not been conducted. In this study, we use a simulation approach (management strategy evaluation; MSE) to determine the performance of the bycatch management system, in particular the proportion of correct and incorrect fishery categorization under scenarios of bycatch (moderate/high), distinctiveness of fishery categories (clearcut/fuzzy) and precision of bycatch and abundance estimates for a population of 10,000 bottlenose dolphins. Correct classification was generally high, in particular for categories that should lead to management measures, i.e. 'frequent' and 'occasional'. Misclassifying 'frequent' as 'remote' and vice-versa rarely occurred, while misclassifying a fishery that is 'remote' as 'occasional' can become common when bycatch is high, an expected outcome for a precautionary system. Unintuitively, the 'remote' to 'occasional' misclassification was exacerbated for clearcut fishery categories, and the effect of precision of bycatch and abundance estimates varied across scenarios. MSE offers a valuable tool to test the robustness of management frameworks aimed to mitigate marine mammal bycatch in commercial fisheries and can be applied to populations with a range of demographics and conservation status.

Data from the dead: New methods extract genetic data from poor-quality samples to breathe life into detecting population structure of harbor porpoise in the Pacific.

Harbor porpoise in the North Pacific are found in coastal waters from southern California to Japan, but population structure is poorly known outside of a few local areas. The small size and elusive behavior of porpoises make them difficult to biopsy and force reliance on stranded and bycaught carcasses for samples. Samples collected over 40 years from stranded or bycaught animals often yielded poor quality DNA. We used multiplex amplicon sequencing and genotyping clusters of SNPs as microhaplotypes to examine the population genetic structure of harbor porpoise along the coast from California to southern British Columbia. We inferred patterns of population structure using genotypes of 292 microhaplotype markers (271 samples) as well as mitochondrial control region sequences (413 samples). We confirmed an overall pattern of strong isolation-by-distance, suggesting that intergenerational individual dispersal is restricted along the US west coast. We also found evidence of regions where genetic differences are larger than expected based on geographic distance alone, implying current or historical barriers to gene flow. In particular, the southernmost population in California is genetically distinct (F_{ST}=0.02 (microhaplotypes); 0.31 (mtDNA)), with both reduced genetic variability and high frequency of an otherwise rare mtDNA haplotype. At the other end of our study range, we found significant genetic differentiation of samples from the Strait of Georgia, previously identified as a potential biogeographic boundary or contact zone between harbor porpoise populations.

Additional signals of low dispersal and population subdivision along the US West Coast suggest variation among populations requiring species management on a regional scale. Microhaplotype genotyping provided high power to detect genetic structure in harbor porpoises despite reliance on poor-quality samples.

Length of the free-ranging wild Indo-Pacific bottlenose dolphins Tursiops aduncus around Mikura Island determined using an underwater 3D camera.

The body length of an animal is used to understand its ecology. A decrease in the growth rate of neonates and calves is an alarm for unhealthy conditions of an animal population. In cetaceans, stranded and/or entangled animals are a source of such information. However, in the small oceanic Mikura Island, Japan, there are only a few strandings and entanglements because of lack of beaches and commercial fisheries. Herein, we report the length of the free-ranging wild Indo-Pacific bottlenose dolphins *Tursiops aduncus* around Mikura Island using a simple commercial 3D camera with underwater housing and measurement software (Applied Vision Systems Corp.) to estimate their body length. This system has errors within 5% for the body length. Only the body length of identified dolphins was used in the analysis as almost all dolphins around Mikura Island have been identified using natural marks on the body. There was no difference in body length between four entangled adult (> 13 years old) dolphins and 19 measured adult dolphins (Wilcoxon/Kruskal-Wallis test, $\chi^2 = 0.32$, $p = 0.57$), indicating that the length estimations are actual values. There was no sexual difference in the body length of adults (Wilcoxon/Kruskal-Wallis test, $\chi^2 = 0.83$, $p = 0.36$). Gompertz 3 parameter curve equation (JMP11, SAS Institute, Inc.) was as follows: $L = a * exp(-exp(-b * (age - c)))$; L = length, a = asymptotic line, b = growth rate, and c = inflection point. An analysis of 40 individuals aged 0-30 years (maximum age for study in Mikura Island) of both sexes revealed that $a = 244.9 \pm 3.49$, $b = 0.50 \pm 0.09$, and $c = -0.69 \pm 0.24$. This simple and inexpensive underwater system is important for monitoring dolphin population health.

Echolocation clicks of rough-toothed dolphins (Steno bredanensis) at the South Brazil Bight, South Western Atlantic

The rough-toothed dolphin (*Steno bredanensis*) occurs throughout tropical and warm-temperate waters worldwide. However, there are few descriptions of the echolocation clicks of the species, and most studies are concentrated in the Pacific Ocean. In Brazil, previous works on their acoustic signals were recorded generally near the coast and reported mostly the whistle descriptive parameters. This work aims to contribute with the acoustic description of the species and to provide more data on their click parameters in the South Atlantic Ocean. Acoustic data was collected during the visual and acoustical vessel-based survey at the 2019 Summer expedition implemented by the Santos Basin Cetacean Monitoring Project (PMC-BS/PETROBRAS). A towed hydrophone array and an acoustic processing system (hydrophones RESON4013, NIDAQ 500kHz and PAMGUARD) were used to monitor the biological signals in real time. The signals were analyzed automatically using the Band Limited Energy Detector of the software Raven Pro 1.5 and manually using a custom LabVIEW based program. A group of approximate 15 dolphins (visual confirmation of group size and species) was recorded on April 3rd, 2019 at a distance of 145 mn from shore (25.1698°S, 41.2942°W) and 2,789 m of depth. An animal was observed with a fish in the mouth, suggesting that the group was foraging. We analyzed 1,018 echolocation clicks of this detection. The preliminary results of 39 minutes of recording presented higher peak (median = 37.10 kHz; range = 14.64 – 72.26 kHz) and center (median = 39.06 kHz; range = 21.48 – 83 kHz,) frequencies than previous described for the Pacific. However, the values were close to another study at the South Western Atlantic. This work is an important step for additional research on the

species in the Atlantic Ocean, contributing to the discussion and understanding of different populations distributed in different ocean basins.

Successful DNA extraction, bisulfite conversion and amplification of baleen whale lamina growth layers in earplugs for use in epigenetic analysis

Epigenetics is the study of changes in gene expression which does not involve alterations to the underlying DNA sequence; a change in phenotype without a change in genotype. To date, studies of epigenetics have shown that alterations in DNA expression are a regular and natural occurrence influenced by age, environment, and disease states called epigenetic drift. Recent advances in epigenetics have shown drift patterns can provide insight into many biological processes such as aging as well as how environmental pressures influence species. However, to date, there has never been a suitable matrix for extracting a methylation profile over the entire lifespan of a long-lived species. We extracted DNA from annually deposited lamina of baleen whale earplugs, historically used as an aging proxy, using a novel method we developed from modern forensic techniques. From our method, we extracted DNA from < 30 mg of earwax material. DNA underwent bisulfite conversion and amplification for Whole Genome Bisulfite Sequencing for use in downstream analysis. Few epithelial cells are trapped in the waxy tissue, making the DNA difficult to separate from this matrix. Furthermore, Next Generation Sequencing is difficult to perform on extracted DNA due to low starting material from museum samples, the extraction process, and subsequent conversion of the DNA with bisulfite. However, we were able to extract DNA concentrations of < 100 ng for full bisulfite conversion and amplification which we validated with a Quibit Fluorometric Quantificationä measurement. This method will allow for future analysis of epigenetic drift in accordance with aging to assess how baleen whales deal with environmental stress.

Insights into long term harbour porpoise (Phocoena phocoena) strandings monitoring on the west coast UK

The UK has a statutory obligation under the EU Habitats Directive to report on the conservation status of harbour porpoise (*Phocoena phocoena*) and to quantify threats and pressures at both an individual and population level. Investigation of stranded marine mammals provides unique insights into population demographics, distribution, health and emerging threats - metrics difficult to obtain by other means. We summarise analysis of 25 years of strandings data of harbour porpoise from the entire west coast of the UK and highlight the implications for management.

Analyses used sex and age parameters to explore population structure and identify potential areas of importance for reproduction. Necropsy data on cause of death were examined for spatial and temporal variation in direct-anthropogenic versus other causes of mortality. Nutritional condition of harbour porpoise was characterised as a proxy for assessing spatio-temporal trends in population fitness.

GAMM modelling showed regional differences in seasonality of strandings independent of age specific mortality. More than a quarter of the strandings on the UK west coast occurred in Cardigan Bay, Wales, and this area showed a significantly higher proportion of stranded neonates, possibly indicating an important breeding area. The most common direct anthropogenic cause of death was fisheries bycatch, with notable clusters on the south west coast and during the months of January-March, consistent with known bycatch hotspots for the inshore fishing fleet. Finally, nutritional condition showed no spatiotemporal trends, indicating no significant change in apparent fitness over time.

This analysis has provided a baseline against which future monitoring will be measured and demonstrates the value of this globally important,

long-term programme of strandings monitoring. It has given us key insights into population structure, mortality and anthropogenic pressures of harbour porpoise in the UK, and delivers a strong evidence base for future marine conservation policy.

Dangerous hood? Build trust and prosper: Associations of female bottlenose dolphins (Tursiops truncatus) and their calves in the Southwestern Gulf of Mexico.

The coastal waters off Alvarado are highly productive and dolphin-fisheries antagonistic interactions are frequent although uncommon in resident individuals due to spatial segregation. Social affiliations in female coastal bottlenose dolphins are often unstable, and commonly involve multiple partners across the years. Conversely, mother-calf pairs last several years, until offspring reach maturity and independence. We studied the dynamics of such associations using 98 photo-id surveys and half weight coefficients of association (HWCA) amongst 103 sexed resident individuals over an eight-year period. We also analyzed the isotopic signatures of $\delta^{13}C$ and $\delta^{15}N$ in dentine formations from growth layer groups (GLG) on five stranded individuals within the study area. From 319 sightings, 45% were all-female, whereas 39% were mixed sex. Overall, 72% of the sightings had fewer than 10 members, and 94% of female groups had less than 7 individuals. HWCA amongst the 73 resident adult females were low (x=0.3, sd=0.06), but stable within the first three months, and decreased exponentially towards the third year. However, eleven females formed long lasting associations (HWCA>0.5) with <3 particular females over time. Also, HWCA values from 20 mother-calf pairs (12 of them with 1-3 offspring) showed high and stable companionships (x=0.5, sd=0.17), that decreased linearly since birth towards the fifth year (r^2=0.99). Furthermore, isotopic signatures in both elements also decreased from the prenatal layer towards the GLG of years 1-2, and increased between the GLG of years 3-5, suggesting feeding independence after the second year of age. Small groups have been related to lower detectability by fishers in this dolphin community. Also, long-lasting associations between known females may help to ease the nursing costs under stressful conditions of harassment by humans and male dolphins. The short nursing period may be a response to the stress produced by the high vessel traffic (x=20 h^{-1}) in the area.

Fine-scale habitat use variation in a common bottlenose dolphin (Tursiops truncatus) population.

Understanding the physical processes and environmental variables influencing cetacean movements on a small scale is necessary to discern the ways in which these top predators utilize their habitat. In this study we analyze the variables related to the presence of common bottlenose dolphins (*Tursiops truncatus*) in two adjacent but environmentally distinct areas within the Ria De Arousa (Galicia, Spain) using land-based data collection techniques. The first location is a wide, open area of varying water depths and bottom substrates, and the second a more protected, shallow channel leading to an estuarine area characterized by a muddy bottom. Environmental factors driving dolphin presence within each area were modelled using General Additive Models (GAMs). Environmental and dolphin sighting data were collected from January to November 2018 with a total of 359 hours in the field, 191 dolphin sightings and an average of 0.53 sightings/hour. Dolphin presence was significantly different between the two areas (average sighting frequency 1.12 and 0.20 sightings/hour) and dolphins appeared to prefer deeper water and varied bottom substrates. A temporal variation (monthly and circadian), as well as tide level variation in dolphin presence was observed overall and within the wider of the two areas. Within the shallow channel, however, none of the environmental variables measured appeared to significantly influence dolphin presence. This study shows that, even at a small scale, marine top predators are very selective in the way they utilize different areas of their habitat based on different

environmental variables through time. While most cetacean studies are often conducted on very large scales, the scale at which this study was completed allows for a more relevant understanding of a local population of marine top predators, information which is crucial to ensure a tailored and efficient protection and conservation plan.

Importance of the pond inlet-eclipse sound-milne inlet area as nursery and calf-rearing habitat for narwhals (Monodon monoceros)

The Pond Inlet - Eclipse Sound – Milne Inlet area (Pond Inlet Complex) is traditionally used during summer by one of six narwhal stocks that inhabit the Canadian High Arctic. Although some interchange of animals between summering areas has been documented, most narwhals are thought to return to the same summering area each year. The reasons that narwhals return to the same summering areas is unknown, but possible reasons include to calve, rear young, avoid predators such as killer whales, and feed.

We analyzed digital imagery obtained during aerial surveys conducted in the Pond Inlet Complex during 1 August-22 October 2014 and 1 August-17 September 2015. Imagery was obtained by two DSLR cameras oriented obliquely to either side of the aerial survey trackline. Imagery was reviewed for time periods coinciding with narwhal sightings during the survey and narwhal images were classified as calves, yearlings, other subadults, and adults based on size and colouration. Totals of 4002 and 1993 narwhals were classified in 2014 and 2015, respectively. Numbers of narwhals in each of nine geographic strata were estimated for each survey in each year using observer sightings. Proportions of animals of each size class from analysis of the imagery were extrapolated to each stratum to estimate numbers of calves in each stratum and overall in the Pond Inlet Complex. During aerial surveys of the main summering period from 1 August to 2 September 2014 and 1-31 August 2015, 9.4% and 6.7%, respectively, of narwhals present were estimated to have been calves. During both years, large influxes of narwhals entered the study area during August with different age classes entering in 2014 than 2015. Such large interchanges between summering areas have not previously been documented and likely influenced the proportion of calves among narwhals present.

Time series analyses of genetic changes in Mediterranean striped dolphin (Stenella coeruleoalba), in response to well known Morbillivirus epizootics over a 21 year period

Morbillivirus infection is a common pathogenic challenge in cetaceans, which has caused well described epizootics in several species across the world. The Mediterranean striped dolphin is a notable example, with two well described epizootics in the past 30 years. Although several studies have been made on the Morbillivirus strain, comparatively few have analysed the genetic composition of the host. Here we provide the first nearly complete time series assessment of genetic changes in striped dolphin from 1988 to 2008 (covering the two best described Morbillivirus epizootics), for both 15 microsatellite loci and functional immune system genes (SLAMF1, Nectin4, TLR4,DQB2). Our temporal analyses show significant cyclical fluctuations in genetic composition, which correlate in time with the occurrence of morbillivirus epizootics. Evidence of selection can be found in both microsatellite markers and both SLAMF1 and DQB2. For SLAMF1 in particular, the frequency of a non-synonymous SNP known to confer resistance to the virus in other species is seen to increase during peak epizootics. The genetic changes of immune system genes are consistent with different host-pathogen models depending on their function, suggesting survival likely results from a combination of the host genetic variation and the occurrence of opportunistic infections. These results suggest that Morbillivirus survival likely involves a genetic component, and that the Mediterranean striped dolphin population is likely undergoing adaptive changes to the repeated epizootics. Our genetic analyses allows us to establish a more accurate cycle time for Morbillivirus occurrence, which can help predict future occurrences more precisely. In addition, the comparison of genetic data with monitoring data

from the Ligurian Sea, shows that the repeated epizootics have likely cause lasting changes in the population age structure. Overall, our study shows the benefits of time series analyses of host genetic composition, in understanding the effects of pathogenic challenge in wild cetaceans.

Foraging habitat influences pup size in southern elephant seals

Maternal foraging success is an important determinant of offspring size and survival in many pinniped species. Environmental factors such as sea-ice extent and climate are known to influence this in southern elephant seals, but broad-scale habitat preferences of mothers (i.e. Antarctic vs sub-Antarctic foraging areas) have also been influential in some populations. We used stable isotope values in the whiskers of newly weaned southern elephant seal pups in Peninsula Valdes (Argentina) collected over two years (2011 (n=60) and 2012(n=68)) to quantify the influence of habitat on the size of pups produced by mothers. We identified four patterns of maternal habitat use: (i) predominant use of the Patagonia Shelf (7% of individuals), (ii) focused oceanic foraging (55%), (iii) exploratory oceanic foraging (16%) and (iv) intermediate oceanic foraging (23%). Pups of mothers that foraged on the Patagonian shelf were longer (mean=143.6±7.5(s.d.) cm) than the oceanic groups, and pups of mothers with focused oceanic foraging were longer (137.6±9.6 cm) than the other two oceanic groups (132.5±11.1 and 135.5±9.5 cm respectively). The patterns of habitat use also varied among the two years, with more mothers using the Patagonian Shelf in 2012 than 2012 (10% vs 3%). In 2012 more mothers exhibited the exploratory oceanic foraging strategy (53%) than in 2011 (46%), resulting in the pups being overall significantly smaller in 2012. We contrasted phytoplankton abundance (from satellite ocean colour) from within the core winter foraging areas identified in previous satellite tracking studies and demonstrated that there was lower phytoplankton in the Patagonian shelf (PS) between the study years, but the values were similar in the oceanic foraging areas. Thus, although the PS is highly productive and consistent physical environment foraging conditions on the shelf may have been poorer in 2012 than in 2011 as reflected by pup size and SI composition.

Identification of behavioural states of grey seal pups in the southern North Sea

Grey seals (*Halichoerus grypus)* have become an important part of the ecosystem in the southern North Sea over the last 50 years. The largest colony in German waters is located on Helgoland, a small island 48 km from the German coastline in the south-eastern North Sea. Information on behaviour of juvenile grey seals after weaning is scarce. However, this period is a crucial phase of their life cycle, when pups need to develop successful foraging strategies to cover the high-energy demands of survival and growth. Knowledge on behaviour and changes within, with the pups' age, is essential to understand processes influencing the population and its adaptability. We therefore recorded the movements of 11 juvenile grey seals born at Helgoland between 2015 and 2017.

For identification of behavioural states, we applied the Expectation-Maximization binary Clustering (EMbC), a robust non-supervised multi-variate clustering algorithm. It allocates the different behavioural states based on speed and turning angle and assigns each location to one of four clusters. Fast directional movement was interpreted as "fast travelling" behaviour, the two states with high turning angles were merged into one and interpreted as "foraging" and slow directional movement was interpreted as "slow travelling/resting" behaviour. A mean of 43 % of the individuals' locations were classified as slow travelling/resting, 52 % as foraging and 5 % as fast travelling. As pups undergo behavioural development through time, information collected from adult behaviour such as values for speed and turning angle, cannot easily be transferred to identify behavioural states of pups. The EMbC analysis does not base on prior information and thus provides an objective approach to classify the pups' behavioural states, contributing to our knowledge of grey seal pup behaviour.

Facial nerve homologies in cetartiodactya

In the human face, the facial nerve (N. VII) is divided in five rami, each for a defined horizontal level. In the terrestrial cetartyiodactyls, such as the bovine, the motor branches of the face are divided in two Rami buccales, a dorsal branch and a ventral branch. Here, in general, the ventral buccal branch innervates muscles associated the lower jaw while the dorsal branch extends to the nasal region. In the toothed whales dissected macroscopically for this study (porpoise *Phocoena phocoena* and dolphins such as *Grampus griseus* and *Stenella attenuata*) we found only a strong dorsal branch reaching the facial muscles of the nasal complex but no ventral branch. Thus we hypothesize that the well-developed dorsal branch in toothed whales is homologous to the Ramus buccalis dorsalis of terrestrial Cetartyodactyls while the Ramus buccalis ventralis is missing.

Source parameters estimates of free-ranging Irrawaddy dolphins (Orcaella brevirostris) echolocation clicks while foraging in Brunei Bay, Malaysia.

Free-ranging Irrawaddy dolphin clicks were recorded using a towed two-channel hydrophones system in shallow habitat of Brunei Bay. Recordings were made during foraging. Mean apparent source level peak-peak (ASL_{pp}) of clicks was 201.23 dB (SD=7.31) re 1 µPa at 1 m. Mean ASL_{rms} was 190.58 dB (SD= 7.53). Mean peak frequency and centroid frequency were 116.51 kHz (SD=15.19) and 116.17 kHz (SD=14.47) respectively. The clicks were with mean duration of 21.14 µs (SD=7.16), -3dB bandwidths of 51.83 kHz (SD=17.66), -10dB bandwidth of 100.97 kHz (SD=20.29), and RMS bandwidths of 26.79 kHz (SD=4.87). The clicks of Irrawaddy dolphins have a mean inter-click-interval of 46.39 ms (SD=32.05). High repetition rate and low source level of clicks produced by the Irrawaddy dolphins in Bay of Brunei possible adaption towards shallow foraging ground and short range detection.

Are killer whales attracted to Norwegian herring fishing vessels?

Marine mammals often interact directly with fishing operations because they may target the same species. Interactions with fisheries may benefit foraging opportunities, but also increase the risk of entanglement, collision and resource competition. In recent years, vast winter aggregations of herring have attracted large numbers of killer whales, humpback whales and herring fishing vessels to local fjord systems in northern Norway. Consequently, whales and fishing vessels often co-occur in restricted areas, especially in situations where whales appear to be directly attracted to herring fishing operations to exploit fish that are aggregated by the fishery or discarded fish. This attraction is most apparent in killer whales. To study the interactions between killer whales and fisheries, we equipped 14 killer whales with Argos satellite tags, between November 2017 and early February 2018. We explored A) the extent of the spatial and temporal overlap between fisheries and killer whales, B) the direction of the interaction, i.e. are killer whales attracted to the fishing operations, or vice versa, and C) the influence of fishing activity on the movement direction of killer whales. We found substantial overlap between killer whale habitat use and fishing activities, in particular within the fjords. The interaction between whales and fisheries appears to be directed towards the fisheries, as killer whales often responded to the start of a fishing event by approaching the location of the fishery. In some cases, such a response was detectable in whales more than 30 km from active fishing operations, suggesting that killer whales respond to acoustic cues. Killer whales also aggregate more densely together in the vicinity of fishing vessels than in the absence of fisheries. Finally, we found that killer whales often selected directions where fishing activity were active, which

indicates that killer whales actively seek out active fishing vessels.

Atlantic spotted dolphin (Stenella frontalis) and bottlenose dolphin (Tursiops truncatus) nearshore habitat utilization, Bimini, the Bahamas.

Muller, Skylar[1]; Melillo-Sweeting, Kelly[2]; Dudzinski, Kathleen[2]; Amy, Hirons[3]

Bimini, The Bahamas include two islands surrounded by a diverse assemblage of ecosystems and a large array of organisms, including two delphinid species, Atlantic spotted dolphins (*Stenella frontalis*) and common bottlenose dolphins (*Tursiops truncatus*, inshore ecotype). Distribution and sighting data of both delphinid species have been collected since 2003 (Dolphin Communication Project). Baseline group composition by species and nearshore habitat utilization exist (Melillo-Sweeting et al. 2015), but an investigation by age class or sex does not. Since this initial study, several potentially influential events have occurred, including Atlantic spotted dolphin immigration, hurricanes, continued and varied tourism and boating, pier construction (dredging, pile driving) and new-use phase of the commercial pier. This study examines Atlantic spotted and bottlenose dolphins' use of coastal areas immediately offshore of Bimini, with attention to potential age class and sex variation for years 2003-2018. Studies on resident dolphin populations from around the world have shown significant differences in distribution by sex (Michaud, 2005; Ruckstuhl & Neuhaus, 2005; Rossman et al., 2015; Sprogis et al., 2018), with change in seasons (Ridgway & Harrison, 1998; Wells & Scott, 1998), by predation and prey availability (Heithaus, 2001; Heithaus & Dill, 2002), and by habitat preference, as well as differences with age (Toth et al., 2011). Preliminary analyses from 2014-2016 show a significant difference in location by species ($p<0.001$) and by year ($p=0.014$). Significant differences between species and years also exist in male ($p=0.046$) and female ($p<0.001$) abundances. A comprehensive analysis of age class and sex differences for both delphinid species will help identify group composition and behavior at this location, as well as how these factors might impact possible responses to changes in the habitat.

Signal degradation as a potential cue for judging sonar distance: Discrimination of acoustic stimuli with high-frequency attenuation and reverberation in bottlenose dolphins.

Some reports have noted a dependence of behavioral reactions on the distances between cetaceans and naval sonars. Specifically, sources perceived by a listener as being nearby can elicit a more immediate or stronger response. Unfortunately, little is known about the specific acoustic features that marine mammals might use to determine the range to a sound source. This study examined the potential for bottlenose dolphins to attend to range-dependent acoustic features when classifying frequency-modulated tones with harmonic structures similar to those of some naval sonars. Various degrees of high-frequency attenuation (HFA) and reverberation (REV) — both of which occur as sounds are transmitted over long distances under water — were simulated in the stimuli. Dolphins were trained to produce phonic responses upon hearing tones simulating a "long-range" source (30 km), and to withhold responses for tones simulating "close-range" sources (up to 1 km). Probe stimuli with simulated ranges that were intermediate to these standard tones were included once the long-vs.-close discrimination behavior was reliably performed. Responses to these probes were used to infer the manner in which the dolphins classified intermediate-range stimuli based on HFA and REV. The dolphins responded to nearly all probes with HFA and REV corresponding to 10 and 20 km. Responses to probes with 1 or 2 km of signal degradation were less common. Additional testing in which HFA and REV were decoupled from the simulated source range and manipulated independently suggested that the dolphins primarily used HFA as opposed to REV in making response decisions for probes. These results suggest that the HFA and REV aspects of signal degradation that occur as sonars spread over long distances under water can potentially be used by cetaceans when deciding appropriate behavioral reactions. Deep diving cetaceans must maintain a high, relatively constant body temperature as they thermally "migrate" between warm surface and cold deep waters multiple times per day. Although they possess anatomical and physiological adaptations to conserve heat, there exist few direct measures of the thermal biology of these mammals. Using infrared (IR) thermography, we investigated the thermal biology of sperm whales (*Physeter macrocephalus*) encountered during research cruises off the western North Atlantic outer continental shelf in winter and spring 2019 (NOAA Permits 14809-03 and 16473). Sperm whales foraging in this region experience a range of ambient temperatures as they travel between warm, Gulf Stream surface waters (mean 22.8 ºC in this study) to cooler, abyssal waters below. IR images (FLIR P50) were collected when weather and sea state permitted and analyzed using FLIR ThermaCam Researcher 2001. Dorsal fin, dorsolateral body, head and fluke surface temperatures were measured and compared to independently collected water temperatures for each sighting. Preliminary analyses of thermal images demonstrate that the dorsal fin and flukes were on average 0.2–1ºC warmer than surface water temperatures, while the head and dorsolateral body surfaces were 1.00–1.5ºC cooler. A single individual, tracked over a 10 min period at the surface, displayed warming of the dorsal fin and dosolateral body from temperatures 0.5 – 1.0ºC cooler, to temperatures 0.5 – 1.0ºC warmer, than water temperature. These preliminary data demonstrate that the sperm whale body surface is thermally dynamic and heterogeneous. Ultimately, our goal is to collect thermal images of D-tagged individuals to investigate how surface temperatures change with dive behavior. These thermal profiles provide baseline data for future studies that may (a) test the efficacy of IR as a mitigation tool for, and (b) directly measure the response of deep divers to, anthropogenic stressors such as seismic surveys.

3D Reconstruction of marine mammals from 360° photographs.

3D renderings of marine mammal body forms benefit research in fluid dynamics and also provide engaging interactive tools for outreach activities. Current models rely largely on idealized dimensions and artistic renderings. Our aim was to develop a low-cost method of generating 3D models of individual animals in both a stranding setting and captive research environment. We explored a photogrammetric method that utilizes a 360º series of photos around the animal to stitch together a 3D reconstruction of the body. Photo collection requires only a single camera and low-cost anchoring targets to be available on site. Advanced processing tools are required only in the analysis phase, allowing researchers and stranding teams to bank photo data for later processing. The procedure was tested during two North Atlantic right whale (*Eubalaena glacialis*) and one humpback whale (*Megaptera novaeangliae)* strandings. 3D models were successfully created for the carcasses, including details of injuries and entanglement. Practical application of this method in the field demonstrated potential for collecting morphology data on largely inaccessible animals, one of which is a critically endangered species. This field testing allowed specific challenges to be identified, such as effect of background image complexity and motion, unique reflectivity issues with whale skin, and image scaling demands and limitations. Those challenges were addressed in follow-up research with small resident marine mammals in an aquarium setting. We also explored the use of these models as outreach tools. Portions of the body forms were 3D printed to provide hands-on teaching materials. To provide a digital interactive experience, we imported the models into a virtual reality environment (Unity software with an Oculus Rift headset), allowing users to view and manipulate the digitized specimens in a 3D setting.

Predicting spinner dolphin (Stenella longirostris) habitats in Lovina (Bali, Indonesia): Implications for the management of

dolphin watching tourism.

Boatmen in the Lovina Marine Protected Area(Bali, Indonesia) have been taking tourists to see spinner dolphins offshore from their villages since 1987. Generating more than USD 4 millions of attributable expenditures (2008 and 2013 data), this industry has attracted many participants (e.g. 182 independent tour boats in 2010). Surveys of western tourists, the most important customers, indicated high levels of dissatisfaction with boat crowding and inconsiderate boat driving behaviours. Suggested reforms include improved codes of practice and reduction in the number of boats. We explored the potential for alternative reforms by investigating the spatial distribution patterns of spinner dolphins in Lovina across different seasons (wet and dry). We analysed spinner dolphin sightings using data from 30 scan samplings days (2008, 2009) and 12 point survey days (2009, 2010) over 100 km^2 using Maximum Entropy modelling to identify dolphin habitat suitability based on 56 independent sightings and 6 environmental variables. Irrespective of the sampling methods, the spinner dolphins were consistently sighted close to the 100m isobath (4 models with AUCs $\geq$0.783), as in Hawaii. The 100 m isobath is 3-4 km offshore and the wet season models suggest that it is associated with areas of higher primary productivity.Our analysis indicates that the location of dolphin sightings in Lovina is predictable and that the suitable habitats extend beyond the usual tourism interaction areas and outside the MPA boundaries. This result suggests that the boundaries of the MPA should be extended to include additional dolphin habitat and that the spatial management of tour activities should be considered as an additional conservation tool to reduce boat crowding.

Cetacean conservation through citizen science in Kenya

Prior to the formation of the Kenya Marine Mammal Network (KMMN) there was scant information about cetaceans in Kenya waters, species and distribution, resident populations and migration routes for conservation planning purposes. Furthermore, little was known about the effect of increasing anthropogenic threats on cetaceans as a result of human population growth along the Kenyan coast and resulting coastal developments.

In order to provide a cost-effective means of carrying out broad scale, long-term monitoring of cetaceans along the Kenya coast a coalition of researchers, conservation groups and government agencies established the KMMN in 2011 as a citizen science data gathering platform. The report area covers the whole 536km of the Kenya coastline and both inshore and offshore waters. From 2011-2018 data was received through designated boat surveys, opportunistic reports from marine users, and Marine Mammal Observers (MMO) from seismic survey vessels. Data collection was assisted by advancements in communication technologies and mobile phone applications including social media and WhatsApp.

The KMMN has recorded 24 species and received a total number of 1,250 of sightings from 112 reporters during the study period. Reports also included 3 entanglements and 21 dead strandings, with 2 necropsies performed.

Information received has been disseminated to the tourism sector to help increase awareness and has contributed to a growing dolphin and whale watching industry, providing economic benefits to impoverished coastal communities.

This study highlights the value of citizen science programs and it demonstrates the effectiveness in carrying out long term monitoring of cetacean species, providing a cost-effective effort in gathering data on cetaceans and monitoring threats and welfare. In the future, KMMN will enable the setup of a rapid response stranding network and ongoing data collection will assist management authorities in developing a national cetacean conservation strategy and marine spatial planning.

Predicting cumulative impacts of disturbances on marine populations.

Marine ecosystems are exposed to a wide range of disturbances that cause animals to change behavior and forage less efficiently, as well as disturbances that directly influence animal survival. Here we present a process-based modeling framework for assessing the cumulative population consequences of such disturbances. It enables population effects to emerge from the reduced energetic status and fitness that individual animals experience when having to flee from disturbances, combined with direct mortality associated with some types of disturbances. Due to the generality of these processes, the framework is applicable to a wide range of species, but here we demonstrate its use by assessing the impact of wind farm construction noise and ship noise on the North Sea harbor porpoise population.

The study shows how the exact timing and spatial distribution of disturbances can affect the dynamics of marine populations and how their cumulative impacts can be assessed with process-based models that directly incorporate animal movement, energetics and fitness. They introduce a new level of realism in marine spatial planning, which will be crucial for ensuring the long-term survival of sensitive marine populations. Process-basedmodels that build directly on the mechanisms that determine animal fitness are expected to have high predictive power in novel environments, and we discuss how they can be used to assess the combined impacts of different kinds of anthropogenic disturbances, includingnoise from offshore work, climate changeand mortality related to by-catch in commercial fisheries.

Behavioural responses of harbour seals to vessel noise in the North Sea

Due to intense global ship traffic, vessel noise is one of the most dominant noise sources in the oceans. Vessel noise is known to impact marine species, such as cetaceans - from masking of communication to behavioural changes, e.g. disrupting foraging activities. However, effects of vessel noise on free-ranging pinnipeds are much less studied. Hence, the aim of the present study was to test for behavioural responses of wild harbour seals (*Phoca vitulina*) to vessel noise in the highly trafficked North Sea. In this context, 10 harbour seals were instrumented with long-term sound and movement tags (DTAG-4), in the Wadden Sea. These tags consist of a triaxial accelerometer and magnetometer, pressure sensor, snapshot GPS and hydrophone (48 kHz sampling rate) and are able to record continuously for four weeks. DTAG sound recordings were screened for passing vessels. As vessel noise is partially masked by low-frequency flow noise from acceleration of the seal, we chose an octave band (1 kHz), whose energy is largely unaffected by the animals' activity and could hence be used to identify vessel passes. To avoid sound transients from splashing, bubbles, etc. at the surface, only sound recorded below 1 m water depth was analysed. Tests of behavioral reactions focused on immediate changes in dive and activity parameters (e.g. descent/ascent rate, dive depth, dive frequency, heading, jerk) prior to, and after, ship encounters, centered on the time of maximum received third octave band levels. Data analysis indicate immediate responses to high-level vessel noise, e.g. avoiding the surface and diving to the seafloor. In addition to immediate responses to vessels, behavioural patterns also changed, e.g. from foraging to travelling, compared to random subsets of the data. These findings are relevant for the development of noise limits for achieving "good environmental status" defined by EU's Marine Strategy Framework Directive.

Ecological implication of marine mammal foraging in deep depth in relation to global

Northern elephant seals dive continuously into the mesopelagic zone in the Northeast Pacific, shallow at night (400-600m, shallow mesopelagic zone) and deep during the day (500-1000m, deep mesopelagic zone). We investigated foraging behavior using jaw motion recorders (kami kami recorders) and video recorders to measure the efficiency of feeding at these extreme depths. Our studies indicated more than 40% of their feeding events occurred in the deep mesopelagic zone, which overlaps with the oxygen minimum zone (OMZ). We predicted that prey, mostly fish, in this low-oxygen environment were metabolically limited and, therefore, easier to capture. We examined this prediction using video recorders and found (1) many fish were drifting motionless in the water column until the seals were very close, (2) seals did not use a quick attack motion for the large benthic fish but instead chased them slowly until the fish were exhausted into a motionless condition due to low oxygen content, (3) this slow attack feeding mode (silent attack) may enhance foraging efficiency when feeding on large prey, which would be more difficult in an oxygen-rich environment. Furthermore, we predict that seals, which attempt to optimize foraging efficiency, may consume a large amount of prey and energy from this zone – perhaps more than the day-time feeding in the shallow mesopelagic. The advantages of foraging in the OMZ may also occur in the deep-diving whales.

Recent global warming affects the deep ocean environment around the world, including the Northeast Pacific, by shoaling the OMZ. This could be beneficial to deep-diving species by further increasing foraging efficiency at a population scale.

Investigation of the social preferences of bottlenose dolphins using a dolphin acoustic touch panel

The ability to discriminate between group members is important for social animals. Much is known about social cognition by vocalizations through auditory playback experiments. However, visual information may also be important for individual cognition. Bottlenose dolphins (*Tursiops truncatus*) are known to produce individually distinctive signature whistles that broadcast the identity of the caller. Conversely, in dolphins, external forms such as body color and body shape differ depending on the species and individual; thus, the possibility of visual species and individual cognition may be considered. In this study, we examined the social preferences of bottlenose dolphins using a Dolphin Acoustic Touch Panel (DATP; AquaSound Inc.). This device can visualize dolphin echolocation clicks as well as function as an acoustically operated touch screen. We presented dolphins with two different stimuli on the screen and recorded the number of time they selected each stimulus. As stimuli, whole body photographs of conspecifics and other species of dolphins were used. When a dolphin selected (touched by clicks) a stimulus (still image) on the screen, a video of the individual associated with the stimulus was played back. Dolphins preferred to view the video images of themselves, familiar individuals (conspecifics or other species), or conspecifics. Dolphins also showed a specific response to the video images of familiar individuals. These results indicate that bottlenose dolphins can discriminate individuals in video images and show social preferences.

Sexual dimorphism observed in the laryngeal sac of common minke whale: Functioning for "song" generation?

The laryngeal sac is a ventral diverticulum of the respiratory tract of baleen whale, but its function is not defined. We hypothesized that, if this organ play an important role of sound generation, intersexual morphological differences would be observed on it, because several species of male baleen whales, including common minke whale emit a typical sound so called as "song" to appeal to the other individuals in the breeding season. Therefore, we aimed to reveal intersexual difference on the laryngeal sac in the North Pacific common minke whale (*Balaenoptera acutorostrata*). Sixty-one animals (male: *n*=40, female: *n*=21) were sampled through JARPNII and NEWREP-NP. We measured the length of eleven sights and the weight of laryngeal sac. Sexual dimorphism was analyzed by comparing the relative growth equation of each measurement sight to the body length. The relative growth pattern of seven measurement sights showed significant sexual differences. The differences were mainly detected in the depth of the sac and the thickness of the surrounding muscular layer around the sac. Although sexually mature males had different development rate of the muscle of laryngeal sac, this rate showed a positive correlation with the weights of testis. Furthermore, as to sexually mature animals, the male laryngeal sac weighed about 1.5 times heavier than females. The intersexual gap on the weight became conclusive among the animals which were more than 6 m in their body length. This indicates that the male laryngeal sac would rapidly develop for preparation of sexual maturity. Present study clarified that the volume of the laryngeal sac shows clear sexual dimorphism and proposed that the development rate of this organ would be associated with its sexual status. Finally, we concluded that the laryngeal sac of baleen whale plays an important role not only in sound generation but also in "song" generation.

Identifying suitable habitats for harbour porpoise (Phocoena phocoena) conservation in Galician waters, NW Spain.

Special Areas of Conservation (SACs) are an increasingly used conservation tool to protect the oceans and its biodiversity. The harbour porpoise (*Phocoena phocoena*) is elegit to such protection by Annex II of the EU's Habitats Directive; particularly the Iberian harbour porpoise, a genetically distinct population, is in need of such conservation measures. This study aims to define the Iberian harbour porpoise ecological niche and identify suitable areas for its conservation in Galician waters (NW Spain). Boat-based surveys, recording ecogeographical data and harbour porpoise presence, were carried out throughout August and September 2017 along the north-westers coast of Spain. Data was analysed in the software Biomapper through Ecological Niche Factor Analysis, a presence-only model that predicts habitat suitability across the entire study area, based on the environmental conditions encountered during harbour porpoise sightings. The dataset used in this study, generated a good quality model which defined harbour porpoise ecological niche as narrow, based on a clear specialisation pattern of shallow areas with high salinity and high tidal coefficients. The habitat suitability map highlighted this narrow niche breadth by identifying three regions, only covering 0.15% of the study area, as highly suitable, because harbour porpoises' ecological preferences differed greatly from average conditions across the study area. In future conservation and management plans for the Iberian harbour porpoise, these three areas within and near the Ría of Arousa should be further assessed for their suitability as SACs; in particular evaluating anthropogenic impacts within them.

Protect or forget? Multidisciplinary approach reveals occurrence of small cetaceans in highly anthropogenic-impacted waters: Dubai and Abu Dhabi, United Arab Emirates (UAE).

Natoli, Ada[1]; Moura, Andre[2]; Sillero, Neftali[3]

In the Arabian/Persian Gulf limited dedicated cetaceans surveys have been conducted and most of them are outdated. Two aerial surveys (1986 and 1999) conducted in Abu Dhabi waters revealed a 71% decrease in small dolphin sightings (*Tursiops aduncus*, *Sousa plumbea* and *Neophocaena phocaenoides*). In the past thirty years, the UAE coastal waters have experienced drastic changes with a five-fold increase in human population, extensive land reclamation, overfishing and increased water pollution.

We utilised a multidisciplinary approach (survey questionnaire, opportunistic sightings, boat-based and land-based surveys) to: a) confirm the species present in the coastal waters, b) identify their distribution range and frequency, c) determine

preferential habitat characteristics, d) provide baseline information for estimating population trends.

Sixty-one questionnaires were administered among boat users, 84% reported seeing dolphins – the majority, in the 2 months prior to the interview. In Dubai coastal waters, 55 boat-based transect surveys were conducted in 2014, covering 3799 km, recording 20 sightings and confirming all three abovementioned species as most frequent. Photo-identification analysis identified 23 humpback dolphin and 89 bottlenose dolphins with a re-sighting rate of 39% and 22% respectively. In Abu Dhabi 109 land-based surveys (tot 406 hours) were conducted and recorded 69 sighting of only humpback dolphins. A total of 1296 occasional sightings reported by the public, validated the same frequent species, with another 4 recorded only occasionally. Ecological niche modeling (using Maxent) for the three most common species confirmed a clear preference for coastal habitats and identified distinct preferred habitat for each species.

We concluded that these three species regularly occur in UAE coastal waters and their habitat greatly overlaps with areas highly affected by anthropogenic activities. Distinct habitat preferences for each species further suggest the need for regular monitoring and species-specific mitigation plans, if current trends of reduced cetacean occurrence are to be reversed.

What the public knows & thinks about whales & dolphins - an international survey.

In 2015, an online survey was conducted to investigate public attitudes and perceptions toward key cetacean (whale, dolphin, and porpoise) conservation and 'hot topic' issues such as legislative protection, whaling and cetaceans in captivity (n=858). Perceptions of participants on the conservation priority of cetacean species did not match with the factual IUCN status, where most participants assumed that the larger and more charismatic whales (blue whale, 24.01%; humpback whale, 22.14%; and killer whale, 23.43%) were more endangered or more important to conserve than the small cetacean species such as the Vaquita or Hector's dolphin. 39.74% of participants indicated the bottlenose dolphin was the most important to conserve. The majority of participants considered dolphins and whales to be "under protected" or only "slightly protected" (29.95%; 41.96%, respectively) and expressed that marine mammal conservation laws and policies were "very important" or "important" (47.43%; and 37.88%, respectively). In addition, 86.83% of participants expressed opposition to the hunting of dolphins and whales (57.93% "strongly opposed" and 28.90% "opposed"); however, only 47.44% of participants were aware that several countries are still involved in whaling. Respondents were significantly more likely to be opposed to displaying dolphins and whales in marine theme parks and aquariums (opposed to captive display: 54.43%; support captive display: 45.57%). Only 5% of US respondents from the USA strongly supported keeping dolphins and whales in marine theme parks and aquariums. Participants that support cetaceans in captivity were significantly more likely to believe cetacean conservation is not important. Six times as many respondents, or 86%, preferred to view cetaceans in the wild via whale-watching (61% preferring boat-based, 25% land-based) versus in captivity. A lack of awareness of the conservation status of whales and dolphins suggests that greater outreach to the public about the conservation status of whale and dolphin species is needed.

Measuring nares expansion reveals variability in breath area and duration

Studying baleen whale respiration has historically been limited to surface observations of breath counts, but the degree to which all breaths are equal in length or nares size remains unknown. We used a novel method, integrated area, to quantify the duration and area of nares expansion during inhalation periods to understand the variation

between initial**,** recovery (all breaths in between initial and terminal), and terminal breaths. Video-recording and orientation-sensing tags were deployed posterior to the nares on 18 blue, fin, humpback, grey and minke whales. We measured the integrated nasal area for 800 surface series. In some cases, the videos were paired with UAS photogrammetry to estimate the changing area of the open nares over the duration of inhalations. We compared the integrated nares area against inter breath interval, previous dive depth, and categorical behaviors including foraging and non-foraging. Initial results indicate that the integrated area of nares expansion on terminal dives is 1.67 times greater than initial and recovery breaths. While the nares size during initial and recovery breaths were about equal in area, the recovery breaths differed from each other and continuously increased in nares expansion as the surfacing sequence progressed. We found that nares expansion is more consistent during a surface period after deeper and longer dives, leading to future questions about how mysticetes preplan for dives and behaviors. This new technique of using video data to measure nares expansion could be improved with higher resolution cameras to estimate the flow rates of air during inhalation. Advances in bio-logging technology will increasingly enable researchers to measure physiological parameters that are important for gaining an in-depth understanding of mysticete energetics, foraging performance, response to environmental change and human disturbance.

African manatee (Trichechus senegalensis) threat assessments in Senegal.

In Senegal, the African manatee exists both along the coasts as well as inland in rivers, lakes and seasonal floodplains. Manatees were previously heavily hunted in Senegal and were believed to be almost extinct, but recent surveys have shown it to be present in all aquatic and marine systems. In 2018-2019, we conducted 167 interview surveys to identify and quantify threats with fishermen and other local people on Senegal's central coast from Mbour to Toubacouta, in 22 villages around Lake Guiers, and along the Senegal, Faleme and Gambia Rivers within Senegal. Questions addressed frequency of manatee sightings, presence of threats and poachers, knowledge of manatees killed, injured or caught, and other sighting information. Threats identified by this study included (in order of significance) accidental capture in fishing nets, mortality in dam structures, entrapment behind dams, illegal poaching, and habitat loss due to human development. Results indicated that fisheries bycatch is frequent in both marine and inland waterways throughout the country, but difficult to quantify due to fishermen's fear of arrest. Two dams along the Senegal River have killed a minimum of 10 manatees since 2009, through capture in gates and entrapment during the dry season. We found only three locations where manatees are still poached in Senegal. Rainy season floodplain habitat loss along the Senegal River was quantified for the first time using Google Earth. We also documented locations of motorized boats, as they are likely an emerging threat for manatees. Results are being provided to the Senegal Water and Forestry and Fisheries Ministries as evidence for them to enforce laws to stop poaching and bycatch mortality. We are also working with the dam authorities to reduce mortality in the Senegal River. Lastly, we are raising awareness through education programs and encouraging reporting through a new hotline.

Blubber fatty acid signature analysis of harbor seals in Alaska over 14 years

While a predator's blubber fatty acid (FA) profile does not exactly match their prey, it has been shown to reflect the FA profile of consumed prey in many marine taxa. As natural and anthropogenic changes in ocean conditions cause prey populations to migrate further offshore, pinnipeds will likely respond by adjusting their diet. In this study, we examined long-term spatial and temporal trends in the blubber FA composition of Alaskan harbor seals (*Phoca vitulina*) to determine (1) if FA profiles vary spatially and temporally, and (2) could potentially be used as an index to monitor long-term changes in their environment. Blubber samples were collected across 14years (n=760) from Kodiak (KOD, n=158), Prince William Sound (PWS, n=254) and Southeast (SEA, n=348), Alaska. A subset of 16 FAs (comprising 90% of the total) was used in analysis. Relationships among

blubber FA signatures, regions, and seasons were analyzed using random forest. The model classified regions with 93.68% accuracy, identifying C20:1n-11 as the major predictor of region. Within PWS, the model classified season with 81.10% accuracy, with summer having the least misclassifications (3.11%) compared to spring (63.63%) and winter (75%). Within KOD, the model classified season with 95.57% accuracy, with summer having the least misclassifications (1.59%) compared to fall (4.65%) or spring (22.22%). Lastly, within SEA, the model classified season with 75.57% accuracy, with fall having the least misclassifications (12.94%) compared to spring (24.82%) or summer (75.68%). Important seasonal predictors within each region varied, with C16 identified as a major seasonal predictor in PWS, C20:1n-9 in KOD, and C22:1n-9 in SEA. These results suggest that blubber FAs do exhibit regional and seasonal variation. When individual FAs were graphed seasonally over time, individual FA concentrations did change, suggesting that certain FA signatures could potentially be used as an index to monitor environmental changes.

The effect of anthropogenic disturbance in a changing environment on the lifetime reproductive success of eastern North Pacific blue whales (Balaenoptera musculus).

Animals make behavioural and reproductive decisions in the context of a variable environment that require trade-offs between survival and lifetime reproductive success. This can be formalized by modelling individuals' energy levels, which can help quantify population-level consequences of anthropogenic and environmental stressors. We developed a dynamic state variable model for the spatially explicit behaviour, physiology and reproduction of female eastern North Pacific (ENP) blue whales (*Balaenoptera musculus*). Our aim was to investigate the spatio-temporal patterns of behaviour that would maximise individuals' overall reproductive output, and to predict the effects of changing environmental conditions and increasing human disturbance on reproductive success. The baseline scenario resembled ENP blue whales' observed energy dynamics, movement patterns and reproductive strategies; over a year, lactating females had a 9% additional net loss in blubber mass compared to non-lactating females, individuals' migratory path tracked prey resources' seasonal variation, and the mean inter-birth interval was 2.42 yr, with a mean of 6.34 yr between the production of calves surviving to age one. Disturbance scenarios suggested that environmental changes could have severe consequences on reproductive success; inter-birth interval decreased to 2.26 yr due to calf abandonment, but the mean interval between the production of calves surviving to age one increased to 12.1 yr. In contrast, whales appeared to compensate for substantial levels of anthropogenic disturbance. Only year-round disturbance, or one in the summer feeding grounds, resulted in an effect size of similar magnitude to that of environmental disturbance. However, the combination of anthropogenic and environmental disturbances that individually had no impact led to small changes in female survival and small to moderate changes in reproductive success, suggesting a synergistic relationship. Across all scenarios, larger body size buffered against disturbance. Moreover, our results implied that females prioritise their survival over their current reproductive attempt, presumably because of their long lifespan.

Cetacean habitat use in the Central North Atlantic: A comparison between baleen whales and deep-diving odontocetes.

The central North Atlantic Ocean is an important feeding ground for many species of cetaceans. Six of the most commonly encountered species in this region are the balaenopterid fin, humpback, and common minke whale and the deep-diving odontocete sperm, northern bottlenose, and long-

finned pilot whale. The general distribution and abundance of these species have been documented throughout the central North Atlantic; however, little is known about the environmental features that drive their patterns of distribution. Improving understanding of this is important in the context of changes taking place in the North Atlantic as a result of climate change. Using data collected during the North Atlantic Sighting Survey 2015 and environmental covariate data for this region, habitat-use models were developed for each of the six study species, including the first of its kind for the northern bottlenose whale outside the Scotian Shelf. The baleen whales were primarily associated with dynamic variables including three-month-lagged chlorophyll concentrations, sea surface temperature, and absolute dynamic topography. The deep-diving odontocetes were associated with both dynamic and static variables, including sea surface temperature, three-month-lagged chlorophyll concentration, slope, depth, and distance to the shelf edge. The predicted high-use areas for all three baleen whales overlapped while those for the deep-divers were spatially separated. These high-use areas generally differed between the two groups, however all six species were predicted to use the waters west of Britain and Ireland. These results provide additional insights into the environmental features that influence the distribution of cetaceans in the central North Atlantic and provide valuable baseline information for studying the effects of ongoing climate change.

An interactive open-source acoustic analysis tool in R.

With the rapid development of technology, it is now possible to collect vast amounts of acoustic data both with stationary acoustic recorders and animal-borne archival tags. There is hence an increasing demand for automatic software to support scientists to understand the ocean life better. Currently there are many available tools, but many of them are written in MATLAB (which is proprietary and expensive), close or hard-to-modify source code. Our aim is to provide an alternative free and open-source solution, by developing an **interactive graphical application in R** (which can run on any operating system supporting R and Rstudio, like Windows, Mac and Linux). This can easily be extended by the user with other R-based features. This application supports basic features like current available tools, e.g. make/save/load long-term spectrograms with the ability to *process many files in parallel* (especially useful in desktop computers with many cores and a lot of memory); pre-processing by using well-known filters (Hamming, Hanning, Blackman-Harris, etc.); read/write compressed sound files such as lossless *FLAC files* directly from memory without installing any third-party tool, which saves 50-70% storage (compared to the usual WAV files) and one can embed meta-data (like date/time in headers without having to specify them in the file name). Apart from the classical Fourier spectrogram, the application supports Hilbert spectrogram and click/buzz detection using *Hilbert-Huang transform* which has been shown to perform better in low signal-to-noise ratio data compared with Fourier methods. The application can also import time-depth recorder (TDR) data as well as GPS positions allowing visualization of the detections in different datasets. Features like wavelet transforms and more complex acoustic feature recognition will be included in the future. It is user-friendly and does not require any programming skill to use, and more experienced users can adapt the open-source code for custom use.

A take on years of wrangling over a controversial taxonomy: Delphinus spp. in South African waters.

The taxonomy of common dolphins (*Delphinus* spp.) remains contentious despite much attention over the past few decades. Various techniques, such as the analysis of cranial and external morphology, postcranial material and different molecular markers, have been used to address this issue. These analyses have generated conflicting phylogenetic reconstructions, leaving taxonomic uncertainties. The situation in South African waters

is no different. We assessed the taxonomy of common dolphins on the South Africa coast using an integrative approach, combining analysis of molecular biology with cranial and external morphology. Analyses included the type specimen of *D. capensis* (BM 41.1734). Sequences were obtained from teeth in the 5' segment of the D-loop region with 458 bp. To add a global perspective, additional sequences were included from GenBank. For the morphology component, crania were photographed in both dorsal and ventral aspects, and geometric morphometric analyses conducted. Molecular and cranial analyses were performed on the same individuals. In addition, 17 external measurements from 45 individuals were analysed. Molecular phylogenetic results suggest that South African specimens belong to a single, highly variable species. The maximum likelihood phylogenetic tree showed some degree of clustering of the specimens. There were no significant differences in terms of cranial size or shape among three clusters identified by hierarchical cluster analysis of morphometric data, in both aspects. Furthermore, the results of the molecular, cranial and external morphology analyses did not show coherence, indicating that morphological variation in the sample is not a function phylogenetic affiliation. Thus, the three lines of investigation supported the presence of a single species of common dolphins in the region. This result is especially important given that South Africa is the type locality of *D. capensis*, demonstrating that further research into the relationships of these dolphins with other groups of *Delphinus* is warranted.

Humpback whale foraging in the Antarctic Summer

Humpback whales (*Megaptera novaeangliae)* arriving along the Western Antarctic Peninsula (WAP) after migrating from tropical breeding grounds are in relatively poor body condition, having fasted for several months, and must replenish energy stores rapidly. Previous work indicates that humpbacks optimize energy gain in part by increasing feeding lunges per dive as prey density increases with depth. In austral fall, whales track the vertical movement of krill and forage only at night when krill move into the upper water column, requiring less energy/time to search for and consume prey. Little information exists regarding humpback foraging behavior in early summer when light availability is consistent, and krill are more common in surface waters. We deployed high-resolution motion-sensor tags on humpbacks to test the hypothesis that during periods with extended daylight, foraging will be more consistent throughout the day and whales will increase feeding rates when diving deeper, commensurate with increases in krill density. From 2016-19, 16 tags were deployed near Anvers Island. Three-dimensional dive profiles were created and motion-sensor information was used to quantify feeding rates on a per dive basis. In 2018 (n= 6 deployments and 4,120 dives), foraging occurred during all hours of the day, however deeper dives were concurrent with hours of highest solar irradiance: 90% of dives >20 meters occurred between 0700-1900. Preliminary analyses indicate that whales feed primarily at shallow depths with only 90% of all dives being <20 m, consistent with the foraging depths of other sympatric krill predators (e.g. penguins). Our results fill a critical data gap in our knowledge of how humpback whales feed and maximize energy gain early in the feeding season and can be combined with data on body condition and demography to better understand recovery from past exploitation in a rapidly changing environment and the potential for competition among krill predators.

Thirty years of records highlight an Australian stranding hotspot for a resident community of Indo-Pacific bottlenose dolphins within a microtidal estuary

The cause of dolphin strandings is typically linked to poor health, anthropogenic impacts, navigational errors or misadventure while pursuing prey. We report on bottlenose dolphin (*Tursiops aduncus*) live stranding events in the microtidal (range < 2m) Peel-Harvey Estuary, Western Australia. The estuary is occupied by a year-round resident community of approximately 80 dolphins. Stranding information was obtained from multiple databases as well as recorded during a capture-recapture population assessment study between 2016 and 2019. Live strandings were categorized either as 'high and dry' strandings (HDS) where an individual was no longer submerged, or 'confinement' strandings (CFS) where an individual was trapped by receding tide but was still able to swim freely. Since 1985, a total of 84 stranding events involving 120 individuals were recorded, with over half of these events (n=49) identified as live strandings. All but one of the 17 live strandings (9 HDS and 8 CFS) recorded during the population study involved members of the resident community. Twenty-nine out of 105 residents have stranded at least once, some on multiple occasions. Fourteen of these showed sunburn injury indicative of HDS. All but one adult female successfully reproduced post-stranding. Although seven individuals were confirmed deceased during a live stranding or subsequently due to extensive sunburn, those who survived thrive up to 29 years post-stranding. We conclude that the live stranding events generally involve healthy resident individuals. Both HDS and CFS appear to result from individuals navigating to an area and being caught out by tide rather than individuals getting stranded during a behavioural event such as a prey chase. This study highlights the Peel-Harvey as a live stranding hotspot in Australia. Early detection, monitoring for CFS and quick rescue response for HDS are primary management goals to ensure the welfare and survival of live stranded individuals.

Spatio-temporal patterns in harbour porpoise density: Implications for conservation in UK seas.

Fisheries-induced mortality poses a threat to the conservation of small cetaceans, particularly opportunistic predators whose ranges throughout productive shelf-seas expose them to commercial activities. Harbour porpoises Phocoena phocoena are ubiquitous in UK coastal waters, but despite their prevalence, estimated levels of bycatch have given reason for concern. A deeper understanding of how distributions vary in space and time is required to assess impacts. While wide-scale distance sampling surveys are financially and temporally constrained, citizen science programs which collect standardized data aboard platforms of opportunity can help uncover density patterns to identify areas of importance. Data collected on ferries from 2006-2017 were analyzed to estimate harbour porpoise densities along routes southwest of Cornwall, the English Channel, and the North Sea. Region-specific detection functions were calculated to account for the number of individuals missed along transects and provide more accurate estimates of relative abundance. Generalized additive models (GAMs) were used to elucidate relationships between distributions and ecological covariates. The highest densities were found in the southwest (0.070 porpoises/km2), followed by routes in the North Sea (0.044 porpoises/km2), and English Channel (0.006 porpoises/km2). Average density in the North Sea appear to have increased by ~30% (95% CI ±0.015 porpoises/km2) over the study, and distributions shifted into the English Channel, suggesting new areas of relative importance. Space-use was region specific, but selected models reflect strong relationships with coastal waters, sea surface temperature, chlorophyll-a, and water column dynamics. Contrasting preferences for highly stratified waters in the North Sea and well-mixed areas in the English Channel suggest distinct foraging behavior. Hotspots in the southwest and northeast UK identify areas for mitigation efforts, especially in Cornish waters where porpoises are highly vulnerable to bycatch. The findings highlight how citizen scientists, together with robust density estimation, can contribute to the conservation management of a common, although threatened species.

A chronic problem: A 20 year summary of confirmed pinniped entanglement cases on Cape Cod, Massachusetts, USA.

Entanglements and their associated injuries are one of the leading anthropogenic causes of stranding and death for pinnipeds on Cape Cod and southeastern Massachusetts. Over the past 20 years (1999-2018), 156 confirmed cases of entangled pinnipeds have been responded to in this region. Of the 111 cases that had gear present, the majority (n=80) involved neck entanglement in monofilament netting. This type of entanglement is consistent with active gillnet fisheries due to entanglement configuration, prevalence of year-round fisheries and lack of gear fouling. Other entangling material included fishing weirs (n=4), trap/pot gear (n=7), trawl netting (n=2), other fisheries gear (n=5), marine debris (n=7) and uncategorized (n=4). The majority of these cases were gray seals (n=129), but harbor and harp seals were also affected. Out of the 76 live cases, 63% (n=48) were successfully disentangled and either transferred to a rehabilitation facility or treated and immediately released. Due to the extent of the entanglement-related injuries, 5 seals died and 3 were humanely euthanized. More than half the cases were reported dead (n=83), including 43 with gear present. Necropsies were conducted whenever logistics and carcass decomposition permitted (n=47). Significant necropsy findings in cases with chronic circumferential constricting monofilament net entanglements around the neck included severe lacerations, embedded line, sepsis, and poor body condition. Other findings of note included multiple entanglement-induced tracheotomy and large volume pyothorax. The severity of these injuries highlights the serious animal welfare concern that entanglements represent for pinnipeds. Future work should focus on the need to further understand where and how these entanglements occur in an effort to prevent them through mitigation measures.

Project: Towards sustainable coexistence of seals and humans.

The project "Towards sustainable coexistence of seals and humans, CoExist" (duration 2019-2022) is targeted to take science based actions towards human-seal coexistence in two freshwater lakes situated in Finland and NW Russia. These lakes are inhabited by two ringed seal subspecies (*Pusa hispida saimensis* and *P.h. ladogensis*). The Saimaa ringed seal is endangered (EN) with only ca. 400 seals and the Ladoga ringed seal vulnerable (VU), with population size around 5 000 seals. These seals differ by genetically, morphologically and by their behavior. Nevertheless, they share common challenges from incidental by-catch and climate change aggravated by human activities. In addition, the goals for conservation of these seals are common. This can be achieved by strengthen the Russian-Finnish cross-border cooperation and by enhancing environmental awareness among local residents, visitors, stakeholders and companies. The goals of the project are to produce and share new information on conservation biology on seals by using varied methods (e.g. photo identification and telemetry) and to develop new cost-effective monitoring tools via computer vision together with Finnish and Russian experts. We will use best practices in seal-fisheries conflict mitigation and sustainable seal tourism, and produce recommendations based on gained information. One of the aim is to involve decision-makers taking actions towards sustainable conservation of these endangered seals. University of Eastern Finland coordinates the project that is implemented together with The Finnish Association for Nature Conservation (FIN), Lappeenranta University of Technology (FIN) and Interregional charitable public organization "Biologists for nature conservation" (RUS). The project is granted by South-East Finland –Russia CBC 2014-2020 programme funded by the European Union, the Russian Federation and the Republic of Finland.

Anatomy of the kidneys of Saimaa ringed seal (Pusa hispida saimensis)

Nihtilä, Heini; Laakkonen, Juha; Jernvall, Jukka
University of Helsinki, Helsinki, Finland
Corresponding Author: heini.nihtila@helsinki.fi

The Saimaa ringed seal is an endangered subspecies that lives only in the fresh water lake Saimaa in Finland. The Saimaa ringed seals have been isolated from the Baltic and Ladoga ringed seal populations for about 9500 years, and during that time they have become genetically very different from other ringed seal subspecies. We studied the kidney anatomy of the Saimaa ringed seal and compared it to the other ringed seal subspecies in an effort to see whether the differences in water salinity are reflected in the kidney anatomy.

We collected samples from 17 Saimaa ringed seals that had been found dead. The kidneys were examined through anatomical dissection, histological stainings and silicone casts. The most notable difference we found was the number of renculi, which was smaller in Saimaa ringed seals when compared to previous studies on ringed seals.

The biggest challenge in our research was the small number of animals due to small population size of Saimaa ringed seals and number of available Baltic ringed seals. Especially in Saimaa ringed seals the age distribution was also emphasized on the sub-adult individuals, and because of the way of obtaining sample material, autolytic changes were often from moderate to severe.

Mutual interactions between Norwegian grey seals and small-scale fisheries.

Corresponding Author: kjelltn@hi.no

Grey seals in Norwegian waters are most abundant from mid-Norway to Finnmark county in the northeast. Population modelling indicated an increase from 3100 animals in the 1980ies to 8740 (95% CI: 7320–10170) grey seals in 2011 (Øigård et al. 2012). Pup counts in 2014-2018 showed a significant reduction in pup production in the most abundant grey seal area from Trøndelag to Lofoten in mid-Norway. In other less abundant grey seal areas, pup production was stable. We estimated the grey seal population to be 3850 (95% CI: 3504-4196) animals in 2018. The reduction in grey seal abundance in mid-Norway is most probably due to increase in by-catches in small-scale gillnet fisheries. Annual by-catch was estimated to be 560 grey seals, mainly in fisheries for monkfish *Lophius piscatorius* and cod *Gadus morhua*, based on data obtained from the Reference Fleet (fishing vessels hired to report on all catches by the Institute of Marine Research).

We used diet sampling and bio-energetic modeling to estimate the grey seal prey consumption along the Norwegian coast. The mean total annual consumption by 3850 grey seals was estimated to be 8084 tons (95% CI: 6166-10191) of various fishes in Norwegian waters; saithe *Pollachius virens* (3059 tons), cod (2598 tons) and wolffish *Anarchchus* spp. (1364 tons) were consumed in highest quantities. Grey seals are assumed to prey on both the coastal component of cod and the migrating Northeast Arctic cod. Norwegian annual fishery catches of coastal cod and Northeast Arctic cod were 35 000-39 000 tons and 192 000-378 000 tons, respectively, in the period 2003-2015. Leisure and tourist catch of coastal cod were estimated to be 13 000 tons in 2015. We conclude that consumption of cod by grey seals is very low compared to fishery catches.

Kinship of mass-stranded populations for Steno and Feresa.

Delphinid species have various social systems. Killer and pilot whales form stable matrilineal groups. Bottlenose dolphins show a fission-fusion social system with bisexual dispersal. However, kinship among members of a group is unknown in many Delphinid species. Mass-stranding event is one of the opportunities to gain information about their social system. Pygmy killer whales, *Feresa attenuata*, and rough-toothed dolphins, *Steno bredanensis*, are oceanic delphinids distributed in tropical and warmer waters. Here, we investigated the population genetic structure and relatedness (*r*) among individuals of mass-stranded *Feresa* and *Steno* by maternal (mtDNA control region; over 900 bp) and biparental microsatellite DNA analyses (over 10 loci). Samples were mainly from three mass-stranded events in Japan: 12 *Steno* dolphins (male 6, female 6) stranded at Tanegashima Is, Kagoshima in 2017, 6 *Feresa* whales (male 5, female 1) at Fukuoka in 2000 and 7 *Feresa* whales (male 3, female 4) at Miyazaki in 2017. These individuals were estimated to be adult based on body length and genital conditions, with exception of one sub-adult *Feresa* male (BL: 160 cm) from Fukuoka. All female individuals had identical haplotype for the *Steno* population, and males had different types for each individual except for one male. For *Feresa*, the Fukuoka and Miyazaki populations showed different haplotypes, but all members of each population had the same

haplotype. The mean value of relatedness among females are significantly higher than those of males for the *Steno* and Miyazaki *Feresa* populations. Furthermore, some male-female pairs belonging to different matrilineal groups had high *r* values for *Steno*, and the mean *r* value among males in the male-biased Fukuoka *Feresa* population was relatively high. These results suggest that both species have stable matrilineal social systems, and males migrate between matrilineal groups. Additionally, some of *Feresa* males possibly remain in their natal group.

Observations on the orbicularis oculi muscle and the facial nerve distribution of striped dolphin (Stenella coeruleoalba), Dall's porpoise (Phocoenoides dalli) and finless porpoise (Neophocaena phocaenoides).

To consider homology of facial muscles of dolphins with those of the terrestrial muscles detailed description of the facial nerve is necessary. We dissected four striped dolphins, one Dall's porpoise and two finless porpoises, either stranded or by-caught. In addition to the careful dissection of the facial muscles, the facial nerve branches were traced from the stylomastoid foramen to the antorbital notch. Dissections were made under stereo microscope when necessary.

The dorsal part of the orbicularis oculi muscle (OC) in all the samples contained an aponeurotic (tendinous) area. The forms of that area vary from species to species. Sihler's stain clearly revealed the intramuscular distribution of the facial nerve in the OC. Two branches to the OC, diverged from the facial nerve running parallel to the outer margin of the zygomatic bone, at the anterior tip of squamous bone and the palpebral fissure, distributed almost solely to the ventral part of the OC, with only a few nerve fibers to the dorsal part of the OC.

Although previous studies reported the OC formed a well-developed muscle around the eye, we confirmed the OC did not surround the dorsal part of the eye. This indicates the dorsal part of the OC is weaker and their eyelids may close from below. The difference of aponeurotic areas among species might be caused by the differences of behavior, swimming velocity or the way they use the eyes. Comparison of the mode of innervation of the OC in dolphins we observed and that of the terrestrial mammals in publications revealed that the diverging point of and the route of the branches to the muscle are different. These differences can be explained by the overlapping of the nerve paths in odontocete caused by the specific transformation of head morphology.

Factors affecting bycatch rate of harbour porpoise (Phocoena phocoena) in Swedish waters

Incidental catch (bycatch) in fisheries is one of the major threats to marine mammal populations worldwide. The harbour porpoise is one of the most common cetaceans in northern Europe. Previous studies have reported high bycatch numbers of harbour porpoises in gillnet fishing operations in the North Sea and Skagerrak Sea. With the aim of disentangling the driving factors behind bycatch of harbour porpoise, we compared bycatch rates of harbour porpoise with data on fishing operations and harbour porpoise distribution. Models were set up involving 8 explanatory variables: net soak time, net string length, net height, net mesh size, net bagginess, water depth, month of operation and porpoise density. From 1995 to 1997, data on gear characteristics and fishing operations of 952 hauls of bottom-set gillnets targeting for cod (*Gadus morhua*), pollack (*Pollachius pollachius*) and hake (*Merluccius merluccius*), operated by 28 randomly selected fishing vessels, were collected by on-board marine biologists in the Swedish Kattegat and Skagerrak Seas. During these hauls, 21 bycatch events were recorded. Data on harbour porpoise distribution was generated from daily positions of 116 individuals equipped with satellite transmitters in Danish waters from 1997 to 2016. Spatial distribution of the tracked porpoises did not show significant temporal variances between the two decades. Generalised linear models with Poisson and binomial distributions were applied to identify the relationships between the porpoise bycatch events and the explanatory variables. The model including the three significant explanatory variables net soak time, net string length and water

depth had the highest explanatory power for the occurrence of bycatch events compared to models involving any other combination of variables. The findings provide guidance for measures to adjust fishing operations and gears to reduce porpoise bycatch rates. The model can be used to predict possible spatio-temporal high risk hot spots to optimise future monitoring efforts.

Singing at Saba: Long-term acoustic monitoring provides new insights on humpback whales habitat use in the Dutch Caribbean.

We monitored the acoustic activity of humpback whales (Megaptera novaeangliae) in the Yarari Marine Mammal and Shark Sanctuary, located in the Antillean Island chain in the Caribbean.

At the Saba Bank, one Marine Acoustic Recording Unit (MARU) (2011 – 2012) and two Autonomous Multichannel Acoustic Recorders (AMAR) were deployed (2015 – 2019). The analysis of the data was performed in stages: 1. A sub-sample of the data was scrutinized to identify humpback vocalisations from spectrograms 2. These were used as reference to automatically classify humpback vocalisations in the overall dataset. 3. the performance of the automated detection process was tested with an independent sub-sample. Humpbacks were recorded during the breeding season, from end of December to April in all recording years. Most detections occurred in February and March and consisted of singing animals. This pattern was consistent between the years studied, suggesting that humpbacks return to the Saba Bank each year to breed. Humpback whales in reproductive areas tend to show exuberant surface behaviours that are hard to miss, leading to the question why, if there is indeed an returning occurrence of breeding whales, this was not described in the past. One explanation might be that Saba bank is comparatively far away from shore and has limited vessel-based tourism. In other areas those are often a source of opportunistic sightings of cetaceans. As a monitoring method, PAM can provide long-term potentially continuous data on cetacean acoustic activity in a specific location and yield valuable information on distribution patterns, habitat use, behaviour and changes thereof. In this case it has provided information that warrants a more in-depth look to determine the importance of this area as a potential breeding area for humpbacks. This is in particular relevant in the context of developing an effective cetacean management plan for the

Assessing intrinsic and seasonal variability in killer whale morphometrics, blubber thicknesses, and body condition indices via monthly assessments of trained individuals.

Recent investigations on the endangered Southern Resident killer whale population have focused on assessing body condition and health. The primary tools used to assess body condition are photogrammetry for free-ranging killer whales and extensive morphometric and blubber thickness measurements for stranded individuals. Despite the reliance on morphometric measurements to assess body condition of killer whales, no controlled studies have been conducted to assess factors (e.g., age, sex, season, water temperature) that influence killer whale body condition indices (BCIs) and blubber thickness. To address this data gap, we recorded body mass, straight body length (rostrum to fluke notch), four girth measurements (eye, anterior and posterior pectoral fin insertions, anterior dorsal fin insertion), ultrasound-measured blubber thicknesses at six sites along the body, and various BCIs (e.g., each of the four girths/body length) from 21 killer whales at three oceanaria every month for one year. Daily water temperatures were also recorded. All morphometrics and body condition indices varied by age, body length and sex. Although blubber depth varied by site, with thicknesses at the dorsal and ventral sites being greater than at the lateral site, blubber thickness at all sites increased with body length. Blubber thicknesses also varied inversely with changes in pool temperature. All

four BCIs (girth/body length) decreased linearly with total body length, yet the slopes of the regression equations were significantly different. The steepest slope was observed for the relationship between body length and eye girth/body length. This demonstrates that this BCI is most affected by growth. The smallest slope was observed for the relationship between body length and anterior dorsal fin insertion girth/body length. These results provide data to inform interpretation of measurements used to assess body condition of free-ranging killer whales and suggest that evaluations of girth/length (or width/length for photogrammetric studies) body condition indices should be age-specific.

Results of real-time passive acoustic monitoring during the 2018 Pacific Region International Survey of Marine Megafauna (PRISMM) off Western Canada

We present results for real-time passive acoustic monitoring (PAM) conducted as part of a large-scale line-transect survey of marine mammals in exclusive economic zone (EEZ) waters off the west coast of Canada. The offshore component of this, first ever, systematic survey of outer coastal waters was conducted for approximately five weeks, from July 5th to August 11, 2018, aboard the 69-meter Canadian Coast Guard Vessel, John P. Tully. This survey was conducted by Fisheries and Oceans Canada to assess the distribution and abundance of marine mammals. The real-time PAM components consisted of a four-element, towed hydrophone array and a sonobuoy system. In addition to making digital recordings, both systems were monitored 24/7 by experienced bio-acousticians. The towed array system was deployed for approximately 640 hours representing 78% of the time underway. Approximately 144 independent detections were made and classified to the highest taxonomic level possible. Sperm whales (n=53) and porpoises (n= 49) represented just over two-thirds of all detections. Localizations were made when possible, with ten localizations for sperm whales and 31 for porpoises, representing just over 60% of all (n=67) high quality localizations. Sonobuoy effort consisted of semi-systematic deployments, both during the day and night, and also during sightings of large baleen whales. Excluding three sonobuoys deployed during initial system testing, a total of 112 sonobuoys (type AN/SSQ-53F and AN/SSQ-53G) were deployed in DIFAR (i.e. directional) mode. Sixteen (14%) of sonobuoys failed for unknown reasons. Marine mammal calls were recorded on 32% (36) of sonobuoys. Detections included calls and whistles from killer whales, sperm whale clicks, dolphin clicks, fin whale calls, and blue whale calls (both B and D type calls). More detailed results will be presented with examples of acoustic detections, localizations and unusual bioacoustics signals recorded during this survey.

Marine Mammal Acoustic and Spatial Ecology (MAPS) research project: 'Physe-terrace', seasonal distribution of sperm whales (Physeter macrocephalus) in the western North Atlantic.

The Marine Mammal Acoustic and Spatial Ecology (MAPS) research project, conducted in the winter and spring of 2019, investigated the behaviour and ecology of cetaceans inhabiting the Outer Continental Shelf (OCS) of U.S. Atlantic waters. Priority species for this project were deep-diving odontocetes, including sperm whales and beaked whales, which appear to be particularly vulnerable to anthropogenic acoustic activities. Key data gaps for these cryptic species include: vocalisation rates, diving/behavioural ecology, and a regional paucity of survey effort in the winter and spring, particularly in deeper, offshore waters (>1000m). These data are required to reduce the uncertainty in analyses of occurrence and density critical to the effective management and mitigation of OCS

species by regulatory bodies such as the Bureau of Ocean Energy Management.

As visual detection of deep-diving cetacean species is constrained by the limited proportion of time spent at the surface, the MAPS surveys were conducted using both acoustic and visual techniques. R/V *Song of the Whale* was used to survey 3,000km of equal spaced, zigzag transects in each season: winter (Jan/Feb) and spring (Apr/May). This provided an acoustic coverage of 54% based on an estimated half strip width of 10km for sperm whales. Sperm whales were only encountered in waters >300m and were found between the continental slope and the furthest limits of the study area (330km offshore) in 5000m deep water. Group sizes ranged from single individuals to socialising groups of at least 16 animals; all age and size classes were represented from ~4m neonates to large, heavily scarred males. Comparison of densities suggests higher numbers of sperm whales, and larger groups, on the OCS in winter months, supporting findings from previous acoustic studies. The MAPS surveys provide substantial new datasets for the region and establish a baseline for future monitoring efforts.

Oceanographic conditions predict at-sea behavioural states in a sexually size-dimorphic marine predator: The grey seal (Halichoerus grypus).

Spatio-temporal variation in the oceanographic conditions of continental shelves results in a three-dimensionally patchy distribution of prey available to upper-trophic level predators. Although oceanographic features have been linked to the movements and foraging patterns of diverse taxa, fewer studies have used oceanographic data simultaneously collected by instrumented animals. We examined the influence of fine-scale oceanographic conditions on the foraging patterns of adult grey seals using *in situ* environmental data. To do this, we recorded data from 79 seals (20 males, 59 females) with Mk10-AF Fastloc™ GPS data-loggers during the period 2009-2015. These instruments recorded a total of 1,668,086 dives and 569,349 locations with associated water column profiles. Light level collected during the ascent phase of dives was used with a regional bio-optical model to estimate chlorophyll-*a* concentration. GPS locations were classified into two behavioural states (apparent foraging and directed movement) using the hidden Markov movement model. Using generalized linear mixed models, we examined the influence of upper-water column and bottom conditions on the behaviours of seals. In the upper-water column, season had no influence on the probability of apparent foraging behaviour, but chlorophyll-*a*, upper-water column temperature, and sex did, with females having a greater probability than males. In the bottom conditions model, again season had no influence on the probability of apparent foraging, but sex did with the odds of females foraging being more than twice that of males. There was a small effect of an increase in bottom temperature on the probability of apparent foraging in both sexes. We suggest that oceanographic features serve as an indirect proxy for the availability of prey and that grey seals may use these features to enhance foraging success.

Pathogen exposure surveillance in Southern Ocean pinnipeds

An increased pressure of human activities that can introduce new infectious agents and therefore alter host-pathogen interactions, resulting in epizootics and biodiversity loss, challenges the Southern Ocean and Antarctica. Health status information and the potential effect of disease outbreaks in Antarctic fauna is scare and evaluating the susceptibility to new infectious agents is decisive for its conservation. Herein we assess the exposure of Antarctic fur seals (AFS, *Arctocephalus gazelle*) and Southern elephant seals (SES, *Mirounga leonina*) to pathogens known to be present in pinnipeds elsewhere. AFS (n = 65) serum and swab samples and SES (n = 13) serum samples from the sub-Antarctic island of Bouvet (54º41'S, 03º29'E) were collected in two austral summers (2014-2015, 2017-2018). Sera were assayed for *Toxoplasma gondii* and smooth *Brucella* antibodies with indirect enzyme linked immunosorbent assays

(iELISAs). Three PCR protocols for parapoxvirus DNA detection amplifying the DNA Polymerase, *B2L* and *GiF* genomic regions were performed. The genomic region encoding for glycoprotein B (gB) was targeted to detect Phocine herpes virus -1 (PhHV-1) viral DNA. Antibodies against *T. gondii* or smooth *Brucella* spp. were not detected, and no PhHV-1 amplicons were generated. Amplicons of the expected size were generated for parapoxvirus in two of the 29 AFS pups (nasal swabs, 2014-2015), for the *B2L* (n=2) and DNA Polymerase (n=1) genes, whereas the *GiF* PCR did not amplify relevant sequences. Sequencing of the PCR amplicons were carried out and blasted in GenBank finding most homology with a seal parapoxvirus, confirming the presence of the virus in AFS for the first time. In general, our data indicate that these seal populations are not threatened by being exposed to the pathogens tested, although parapoxvirus infections may cause severe disease in young and stressed individuals. Further, these data serve as a baseline for its future evaluation and management.

Don't hold your breath: Limited DNA capture using non-invasive blow sampling protocol for small cetaceans.

Nuuttila, Katariina

Corresponding Author: hannanuuttila@gmail.com

Non-invasive conservation strategies currently used to monitor small cetaceans mainly focus on photo identification of individuals as a method to generate estimates of population status. With increasing anthropogenic pressures, in the form of renewable energy developments, fishing and tourism, there is the need for implementation of molecular techniques to more accurately measure population structure and health status of free-ranging cetaceans. Previous non-invasive DNA sampling has consisted of faecal, skin and exhaled breath (blow) sampling, with emphasis on the pathological information obtained particularly from sampling the blow. To date, blow sampling methodology has not been sufficiently optimised and thus scarcely applied to small cetaceans such as short-beaked common dolphin (*Delphinus delphis*) and bottlenose dolphin (*Tursiops truncatus*). In this study, we attempted to optimise a previously developed blow sampling protocol to enhance field sample collection and DNA recovery for both *D. delphis* and *T. truncatus*. Following previous recommendations, we streamlined the sampling approach to reduce the occurrence of avoidance behaviour and improve the precision for individual targeting. Overall, we collected 37 blow samples from *D. delphis* (n:30) and *T. truncatus* (n:7), however only managed to successfully extract target species DNA from one *D. delphis* sample, which is the first reported DNA detection of a small free-ranging cetacean from exhaled breath to our knowledge. Here we have highlighted the difficulty in obtaining DNA from wild cetaceans, despite improved collection success. We suggest future studies attempt to improve DNA detectability through using robust preservatives such as an ethanol-sodium acetate solution and employing adapted techniques which are compatible with the species being targeted. If this method is to be viable as a conservation tool for estimates of respiratory bacterial loads and population abundance of small cetaceans, further optimisation is required.

Fine-scale population structure and connectivity of bottlenose dolphins, Tursiops truncatus, in European waters and implications for conservation

Protecting species often involves the designation of protected areas, wherein suitable management strategies are applied either at the taxon or ecosystem level. Special Areas of Conservation (SACs) have been created in European waters under the Habitats Directive to protect bottlenose dolphins, *Tursiops truncatus*, which forms pelagic and coastal ecotypes. The SACs have been designated in coastal waters based on photo-identification studies that have indicated relatively high site fidelity to these areas. However, individuals can carry out long-distance movements which suggest potential for demographic connectivity between the SACs. Previous studies on the species in this area used different sets of genetic markers and therefore inference on the fine-scale population structure and demographic connectivity has not yet been made at a wider scale. A common set of microsatellite markers was used in this study to provide the first comprehensive estimate of genetic structure of bottlenose dolphins in European Atlantic waters. As in previous studies, a high level of genetic differentiation was found between coastal and pelagic populations. Genetic structure was defined at an unprecedented fine-scale level for coastal dolphins leading to identification of five distinct coastal populations inhabiting the following areas: Shannon estuary, west coast of Ireland, English Channel, coastal Galicia, east coast of Scotland, and Wales/West Scotland. Demographic connectivity was very low among most populations with less than 10% migration rate indicating no demographic coupling among them and suggesting that they should be monitored separately. The results of this study have the potential to be used to identify management units in this area and thus offer a significant contribution to the conservation of the species in European Atlantic waters. Future studies should prioritize obtaining biopsies from free-living dolphins from areas where only samples from stranded animals were available in order to reduce uncertainty caused by sample origin, as well as from areas not included in this study.

International efforts to advocate for the imperiled vaquita: Lessons learned.

O'Connell, Kathleen[1]; Uhlemann, Sarah[2]; Olivera, Alejandro[3]

The vaquita (*Phocoena sinus*), the world's smallest and most endangered cetacean, is endemic to Mexico's northern Gulf of California. Only 10 porpoises likely remain, and the animal's extinction is virtually assured without bold, immediate action. Vaquitas face a single threat: entanglement in illegal gillnets set for shrimp and various fish species, including endangered totoaba. Totoaba swim bladders, highly valued for their wrongly-perceived medicinal properties, are illegally exported from Mexico to China by organized criminal groups. Successive Mexican administrations failed to stop gillnet use, and the current Mexican administration's "initiative" to save the vaquita lacks the short term public policies and enforcement capability needed to address this serious issue.

A range of legal, political and consumer-oriented tools have been used to advocate for vaquita. In 2015 the Animal Welfare Institute and Center for Biological Diversity petitioned UNESCO´s World Heritage Committee (WHC) to list the Islands and Protected Areas of the Gulf of California - vaquita habitat- as "in danger" due to the site suffering a "serious decline." The WHC gave Mexico until 2019 to improve protections for the area. In 2017 a campaign was launched, encouraging retailers and consumers to choose alternatives to Mexican shrimp until gillnet use stops and the vaquita has recovered. In 2018 a lawsuit filed against the current U.S. administration for failing to fulfill its mandate under the Marine Mammal Protection Act (MMPA) resulted in a U.S. court temporarily banning the import of gillnet-caught seafood from Mexico's Upper Gulf of California. This year, the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) and the WHC are being urged to consider additional conservation measures for vaquita and totoaba.

As bycatch and illegal fishing increasingly threaten marine mammal species, this presentation will examine lessons that can be learned from efforts to save the vaquita.

Estimating the length of short-beaked common dolphins (Delphinus delphis) using laser photogrammetry off Ireland

O'Callaghan, Sean[1]; Berrow, Simon[2]

seanocallaghan212@gmail.com

Short-beaked common dolphins occur in large numbers around the coast of Ireland annually but very little is known about this species life history at sea. It is thought that the species may segregate depending on age and gender at particular times of the year based on current bycatch records.

Obtaining total length estimates from free-swimming individuals may provide an insight into the species group dynamics that are reflective of the population's dynamics and status. The dorsal fin was identified as a potentially useful and obvious feature to base total length estimates from since it displays an allometric relationship to the species overall size. An easy to use, standardised scaled image procedure was developed to enable the collection of measurable data from dead individuals with known total lengths and/or genders using citizen scientists and researchers from May 2017 – present to efficiently gather data to be measured retrospectively while avoiding observer bias that may occur between individuals taking physical measurements. Images of live dolphins were taken using a pair of lasers set to a known scale off the Southwest Irish coast to enable non-invasive laser photogrammetry to be carried out. Measurements were made of both the dorsal fin height (DH) and base length (DBL) but DH was found to be the better predictor of total length using a polynomial regression. Currently, eleven live common dolphins have been measured that displayed indicative size estimates ranging from 1.83 – 2.18 m in length using DH as a predictor from 22 dead individuals. This technique has not been applied to common dolphins previously but it may provide new insights into group composition (age class), recruitment rates (number of juvenile length individuals) and potential sexual segregations within pods to improve our current understanding of the common dolphins at sea life history to aid conservation efforts.

Non-invasive blow and aerial imagery collection for genetic and photographic comparison of putatively discrete groups of humpback whales (Megaptera novaeangliae) in northern British Columbia, Canada.

The humpback whale (*Megaptera novaeangliae*) is a panglobal balaenopterid that undertakes impressive annual migrations between seasonal breeding and feeding grounds. The North Pacific population is estimated to have surpassed pre-whaling numbers and may now find itself nearing carrying capacity, as recent studies suggest possible population stabilization or decline. Despite being one of the best studied and most successfully recovering baleen whale populations on Earth, we still lack adequate knowledge to fully assess the risks of coastal development in several remote feeding grounds where multiple breeding populations are thought to share foraging space. We have launched an effort to elucidate the population structure of a seasonally resident feeding aggregation within a fjord system in northern British Columbia, Canada, that is both proposed humpback whale critical habitat and a planned shipping lane. Long-term photo-identification surveys suggest that two separate social networks of humpback whales feed in this area using different foraging techniques in different microhabitats within the fjord system and at different times of year. We aimed to use non-invasive exhaled breath condensate (blow) collection to genetically assess which breeding population(s) contribute to this subpopulation, and to estimate the levels of interchange with feeding aggregations to the north and south. Using novel quadcopter drone technology, blow was collected for DNA extraction and LIDAR and aerial imaging was collected for ongoing assessments of whale nutrition and pregnancy rates. Here we present preliminary results on population structure, interchange, nutritional status, and demographics of these two putatively discrete feeding groups resident to the area. Deepening our understanding of this humpback whale subpopulation is particularly timely as we prepare to assess the impact of a recently approved liquefied natural gas (LNG) tanker route, which will be in daily use through the study region beginning in 2023.

Mark recapture distance sampling – new opportunities for acoustic platforms using recent advances in technology and software

Distance sampling (DS, e.g. line or point transects) is a commonly used method for estimating wildlife abundance. One critical assumption is that all animals on the line/point are detected with certainty, often referred to as $g(0)=1$, where $g(y)$ describes the detection probabilities with increasing distance y from the line/point. Mark-recapture distance sampling (MRDS) allows $g(0)$ to be estimated. Here, two observation platforms are required where for the trial configuration platform 2 sets up trials for platform 1 requiring independence of platform 1 from platform 2. For the independent observer configuration, both platforms set up trials for the other requiring independence both ways. Ensuring independence is often challenging logistically or due to observation conditions or animal behaviour. We discuss new avenues in the MRDS context for improving independence using new or existing technology and software. Two example studies serve to illustrate the methods:

- Simultaneous visual and acoustic line transect surveys for offshore dolphins where visual and acoustic platforms set up trials for each other, the latter using a towed hydrophone array. We show that during a passing mode survey in the eastern tropical Pacific, estimated probability of detecting schools of rough-toothed dolphins (*Steno bredanensis)* on the trackline for both visual and acoustic teams were imperfect and declined with increasing Beaufort sea state.
- Acoustic surveys using multiple stationary sensors where for each sensor, detections on the surrounding sensors formed the trials. We illustrate the method using the example of bowhead whales (*Balaena mysticetus*) in the Beaufort Sea where acoustic detections were made using an array of sensors mounted on the sea floor. Call detections were matched between sensors and localised if detected by more than one sensor. We demonstrate how absolute detection probabilities decrease with increasing distance around the sensors and compare these with detection probabilities estimated using conventional DS assuming $g(0)=1$.

Context of blue whale vocalizations as determined via tag-mounted accelerometers.

Blue whale calls are routinely detected via passive acoustic monitoring (PAM). At the Monterey Accelerated Research System hydrophone in Monterey Bay, for example, tens of thousands of each Northeast Pacific blue whale call type have been recorded over the last several years. However, open questions on calling rates and the behavioral context of distinct call types limit the population size and behavioral information that can be extracted from PAM datasets alone. Advances on these questions have been limited by difficulty in identifying the individuals producing acoustically-detected calls. Here, we use tag-mounted accelerometers to identify calling individuals in analysis of 41 tag deployments with simultaneous acoustics, video, and 400 Hz accelerometry on blue whales in Monterey Bay, CA from 2017-2018. The strength and consistency of calls in the accelerometer signal, plus paired whales that register calls acoustically but not on accelerometers, provides compelling evidence that accelerometry identifies calls produced by the tagged whale- however, other interpretations are also considered. 837 accelerometer-based A, B, C and D call detections were made over ~544 hours of tag deployments, including at least one detection in 12 of 41 deployments. A, B, and C calls were produced significantly more often by individuals in confirmed feeding pairs (2.52 calls/hour) than solo or presumed solo whales (0.05 calls/hour). In contrast to previous hypotheses, D calls were detected primarily at night rather than during daytime feeding bouts. Previously, A, B, and C calls have been presumed to be produced exclusively by males. Our new method provides a positive ID of the calling whale, allowing for matching the tagged whale to biopsy samples in 30 cases. The sex of these calling and non-calling animals will be reported. This individual-level analysis provides call behavioral context, calling rates, and caller sex identification- essential information for accurate interpretation of blue whale PAM.

Baleen whale faeces in the Azores

Cetacean faecal samples have been used to study diet, steroid hormones, exposure to parasites and biotoxins, individual genetic identification and assessment of microplastic ingestion in whales and dolphins. Baleen whale faecal samples are not usually easy to collect. However, as in the Azores whale watching platforms spend long time on the water and run trips year-round, they provide great opportunities to collect these samples. We review the baleen whale faeces records registered from whale watching platforms around São Miguel (Azores) between 2012 and 2018. During the seven years of the study, there have been registered 48 baleen whale faecal records, all of them between March and July. Of them, 77% were of fin whales, 17% of blue whales and only 6% of sei whales. These data support the Azores as a potential feeding ground for fin whales, blue whales and sei whales during the spring. During the spring, we have also registered krill patches on the surface in several occasions and feeding behaviour of the three species. The different colour of the faeces of each species may indicate differences in their diets: mostly red for blue whales, wider range of colour from orange, brown to red for fin whales; and even with a small number of records, yellow for sei whales. Furthermore, we create an appropriate protocol to collect and store faecal samples during the whale watching trips. In 2019 we start to use this non-invasive method as a new source of information here in the Azores. Nowadays we are looking for collaborators to go forward with the analyses of the faecal samples.

A story of how a critical habitat of an endangered species is lost: The Mediterranean monk seal in the Northeastern (NE) Mediterranean.

Ok, Meltem; Sakınan, Serdar[1]; Gücü, Ali Cemal[2]

Protecting breeding caves are of primary importance for the conservation of endangered Mediterranean monk seals (MMS). Despite this fact a large scale marine terminal serving to a cement factory was constructed just 500 meters away from a well-known MMS breeding cave in Yesilovacık bay located in the south coast of Turkey (NE Mediterranean). In this study, effect of the marine terminal on seals was evaluated by camera-trap monitoring which enable to evaluate the cave use frequency and activity pattern through pre, during and post construction periods. Results indicated that the number of seals using the cave before the construction of the terminal was dramatically reduced. Seal activity in the cave significantly decreased during the construction phase. Two whelping events occurred in the cave during the construction phase were ended by disappearance of the weaned pups and carcass of one of these two pups was found in cachectic state in the proximity of the cave. No further pupping activity has been recorded in this breeding cave since then. Considering the position of the cave with respect the marine terminal (<500 meters), the tonnage of the vessels (>30000 GRT), their speed, and given that the ships maneuver in front of the cave, the estimated noise emission (174dB) were higher than the disturbance level (120 dB) given for the pinnipeds. This can be considered as a good example of the negative effect of anthropogenic underwater noise on the pinniped. The cave may perform its function again only by; i) enforcing strict measures, such as limiting the number and tonnage (<1500 DWT GRT) of the ships; ii) declaring a traffic free buffer zone around the cave (10 km); and iii) deploying some additional noise preventive measures, such as bubble curtains, during maneuvers.

Estimating the trend in encounter rate of humpback whales in the recent years in the western waters of Okinawa (Ryukyu) Island, Japan.

Okabe, Haruna[1]; Kobayashi, Nozomi[2]; Higashi, Naoto

Humpback whales in North Pacific migrate to their feeding areas in higher latitudes in summer as well as breeding areas in lower latitudes in winter, including Okinawa, Japan. Although the increase tendency of humpback whales have been reported for recent years in North Pacific, there is also a report that the encounter rate (ER) in Hawaii and Alaska is decreasing drastically in past few years possibly because of the climate anomalies. Using the data corrected through January to March off the coast of Kerama Islands and Motobu peninsula in Okinawa from 2009 to 2018, we investigated ER for humpback whales as well as ER for mother-calf pairs for evaluating the trend in ER of humpback whales in Okinawan waters. ER for each whales were calculated by dividing a total number of whales by a total number of days of surveys. As a result, a total of 4190 whales in 2209 groups have been sighted in 381 days in Kerama and 4004 whales in 2174 groups in 314 days in Motobu, respectably. The mean ER for whales for Kerama was 10.85 when it was 12.93 for Motobu during the

survey years and there was no significant increase or decrease tendency have confirmed for past ten years. The ER for mother-calf pairs was 0.51 for Kerama when it was 0.46 for Motobu. Although there was no significant trend confirmed for ER for mother-calf pairs, it also showed gradual growth in recent few years in both areas. Despite our result indicating that there was no serious decreasing tendency occurs in Okinawan waters in recent years as confirmed in Hawaii and Alaska, continue monitoring for the population tendency in Okinawan water is needed for effective conservation plan for the humpback whale population in North Pacific.

Fin and blue whale distribution, diet and zooplankton backscatter around Isla Chañaral, Northern Chile.

Isla Chañaral is part of the Humboldt Archipelago, a chain of coastal islands off Northern Chile, and part of the Humboldt Current System (HCS), one of the most productive Large Marine Ecosystems on the planet, and one that sustains the highest fisheries catches in the world. Isla Chañaral is surrounded by a 1nm Marine Reserve and is a known feeding ground for fin whales, as well as blue and humpback whales, which also supports a growing community run whale watching industry.

This study aims to understand the spatial and temporal dynamics of fin and blue whales and their prey around Isla Chañaral, and to determine fin whale diet. Cetacean visual sighting surveys were carried out along line transects around Isla Chañaral, during February 2018 and February 2019. The survey boat was equipped with a side-mounted Acoustic Zooplankton and Fish Profiler (AZFP) sampling at 38 kHz, 125 kHz, 200 kHz and 455 kHz. We also use cetacean sighting data in and around the Marine Reserve collected by the Chilean Park Service (CONAF) between December and April, 2016 to 2018. Opportunistic fecal plume samples were collected with a dip net during focal follows of whales; these were then used for prey group identification. An Acoustic Doppler Current Profiler (ADCP) was deployed off Isla Chañaral between November 2017 and April 2019 to examine temporal variation in zooplankton backscatter. This is the first study that looks at zooplankton backscatter and whale diet off Northern Chile.

Here, we present the prey groups consumed by fin and blue whales. We show the spatial distribution of fin and blue whales in the Isla Chañaral area, with near shore and further offshore hotspots. We also present spatio-temporal dynamics of zooplankton backscatter in the Isla Chañaral area. Finally, we propose priority areas for Marine Reserve expansion.

Impact of fisheries on bottlenose dolphin behaviour in the Ría de Arousa (NW Spain).

Interaction between bottlenose dolphins and fisheries is a growing problem worldwide. The fisheries sector in the Ría de Arousa (Galicia, NW Spain) is one of the most important of Europe, however the effect of fisheries activities on the behaviour of bottlenose dolphins (*Tursiops truncatus*) remains poorly known in the area. This study is a first approach to analyze the interactions between bottlenose dolphin and two type of fisheries in the Ría de Arousa: gillnets and fishing cages. The study was conducted from direct observations by boat from May to June 2017 by coupling presence of fishing activities with bottlenose dolphin behavioural data. Over a period of two months spent in the field, 15 daily boat surveys were carried out and 54 bottlenose dolphin groups were encountered. The results of this study show that bottlenose dolphins are present in the Ría de Arousa in presence and absence of gillnets and fishing cages. In addition, when gillnets and fishing cages were present, the behaviour of bottlenose dolphins changed significantly. In the presence of gillnets and fishing cages, bottlenose dolphins tended to reduce their social and feeding activities, and to travel more. These results are not consistent with predation behaviour on nets reported by many

authors for this species. This information has important conservation implication for the bottlenose dolphins present in this area.

Population assessment of the southern sea lion in the southeast Pacific between 18° and 48°S: New information for future stock assessment report.

South American sea lion (SSL), *Otaria byronia*, range along the Pacific and Atlantic coast of South America. The species interact with the mainly export fisheries in Chile (Chilean silverside, Chilean jack mackerel, Patagonian toothfish, swordfish, hake, southern hake, Patagonian grenadier) and salmonculture (Atlantic salmon, coho salmon and rainbow trout). The aim of this study is to assess the population of SSL along the Chilean coast, for contributing to the stock assessment report associated to the Marine Mammal Protection Act and its Import Rule. During the reproductive season 2019, aerial photographic surveys were conducted between 18°S and 48°S covering more than 3400 km of coast. According to biogeographical and genetical information the population was divided in four prospective stocks: northern, central, southern and austral. In the study area a total of 242 colonies were registered, 102 in northern, 56 in central and 84 in southern Chile. The photographs are still under analysis, nevertheless based on survey data from 2012, 2013 and 2015 the population estimation was of 190,000 individuals, 95,000 in the northern, 28,000 in the central and 67,000 in southern stock. In the 3 zones the pups estimation was of 35,244 (59%); 2,063 (7%); and 22,832 (40%) respectively. This is the first time that a survey included three of the four prospective stocks in a reproductive season, so the new information will allow to calculate population trends, the Potential Biological Removal (PBR) and link this information with the bycatch for the main export fisheries to assess and reduce SSL mortality from incidental fisheries takes.

This study was supported by projects FIP 2018-54, FIP 2014-29 and FAP ID 4728-46-LP11.

From the shore to the stage: How stranded and bycatch cetaceans can provide knowledge, engage in conservation and foster awareness. The Galleria Cetacei of the Centro di Educazione Ambientale e alla Sostenibilità Laguna di Nora (Sardinia, Italy).

Cetacean museum collections represent a major attraction for the public and play a fundamental role in delivering scientific knowledge and raising awareness towards the conservation of marine mammals. Since 1993, the Centro di Educazione Ambientale e alla Sostenibilità (CEAS) Laguna di Nora is involved - through its operating arm Centro Recupero Cetacei e Tartarughe Marine (CRCTM) and the network Rete Regionale per la Conservazione della Fauna Marina of the Regione Autonoma della Sardegna - in the monitoring, investigation, rescue and museal recovery of cetaceans stranded or bycatch along the south-western coast of Sardinia. To valorize the results of its activity in the field for educational purpose, the CEAS Laguna di Nora conceived and created the "Galleria Cetacei", a permanent exhibition of cetacean osteological specimens that functions as a work-in-progress, self-implementing museal laboratory. Hanging from the roof or placed inside wood-and-glass frames under a real-size sperm whale-shaped building, skeletons of Sperm Whale (Physeter macrocephalus), Common Dolphin (Delphinus delphis), Long-finned Pilot Whale (Globicephala melas) and Risso's Dolphin (Grampus griseus), as well as skulls and disarticulated bones from Bottlenose Dolphin (Tursiops truncatus) and False Killer Whale (Pseudorca crassidens) are displayed. Every specimen is inserted in a conceptual path of narratives and materials informing on its story and educating about the species natural history and conservation status. Multi-media and instrumentations guide the visitor through an interactive process of experiential learning. Specially dedicated to school-age students, the active participation to the operational workflow that brings newly-acquired osteological specimens from the disinterment, through the assembly and then the museal display, allows first-hand interaction with the CRCTM scientists and field operators. Overall, the Galleria Cetacei provides the visitor a unique opportunity to undertake a holistic cognitive and emotional journey that can shape perspectives and behaviors into sustainable actions towards marine mammals and the entire marine environment.

Oxygenating blubber: A challenge for fat animals.

Oller, Laura[1]; Rocha, Joel[1]; McKnight, J. Chris[2]; Dagleish, Mark[3]; Bennett, Kimberley[1]

Large fat depots are associated comorbidities in humans. Biomedical studies show that tissue expansion leads to structural tissue modifications and potential hypoxia as result of low vascularity or impaired diffusion due to large adipocyte size. How blubber maintains adequate oxygenation and readjust tissue structure is unknown. Here, we examine blubber depth and fatness effects on tissue oxygenation and blubber characteristics. Blubber dissolved oxygen levels (pO_2) were measured in dorsal flank blubber on juvenile grey seals (n=10) under appropriate sedation and anaesthesia. Measurements were taken at different blubber depths, with an optical, non-consuming oxygen probe. Oxygen supply was investigated recording systemic blood saturation (SpO_2), breathing rate and oxy-haemoglobin and deoxygenated haemoglobin. The later was measured using a novel non-invasive technique: Near Infrared Spectroscopy (NIRS). Body composition and heart rate were also recorded. To examine vascularity and tissue structure changes throughout depth and fatness, full blubber depth biopsies of mother and pup pairs were taken at early and late lactation (n = 6). Biopsies were fixed in formalin, processed and stained with Masson's Trichrome. Each biopsy was divided into three sections, and five images of each section were analysed by Image J. *In vivo* oxygen measurements ranged between 11 mmHg and 59 mmHg (mean = 32 mmHg), consistent with levels on other species. Linear mixed effect analysis (LMM) showed that tissue oxygenation had a significant positive relation with SpO_2 (p-value = 0.04) and a negative relationship with depth section (p-value Inner vs Outer = 0.02; p-value Inner vs Middle = 0.17; p-value Outer vs Middle = 0.46) and fatness (p-value = 0.04), independently of the individual ($R^2_{marginal} = 0.59$, $R^2_{conditional} = 0.59$). Results show that tissue expansion is also a challenge for seals. NIRS and histology data analysis are underway to explore oxygen supply, vascularity and tissue structure role on oxygenation.

Cortisol concentrations in baleen from a suckling calf fin whale (Balaenoptera physalus)

Baleen is a keratinized structure involved in feeding that is unique to mysticetes. Previous studies have demonstrated the ability of this matrix to accumulate steroid hormones, and the retrospective information of life history that these samples could offer. Hunt et al., (2017) showed that cortisol is detectable in baleen from eight whale species, including two specimens (subadult and unknown age) of fin whale (*Balaenoptera physalus;* Conserv Physiol. 5:1-14). The main objective of the study was to determine if cortisol is detectable in baleens from a suckling calf fin whale and to assess cortisol levels variation at different locations along the baleen plate, to determine in the future whether baleen might contain a record of the physiological events. Twelve baleens with a length of 9.25 ± 0.48 cm (mean ± SD) from the dorsal plate of a dead calf fin whale were used. The baleens were divided in three sections: proximal, medial and distal to the gingiva. Samples were mechanically pulverized, afterwards cortisol was extracted by a methanol-based method and analysed by enzyme immunoassay. Results demonstrated that cortisol concentrations from the proximal sections of the baleen plate were significantly higher (0.43 ± 0.19 pgCORT/mg baleen) than those from medial (0.23 ± 0.01 pgCORT/mg; *p-value* = 0.009) and distal (0.21 ± 0.03 pgCORT/mg; *p-value* = 0.001) sections. Similar results were obtained in 11 immature and mature bowhead whales (*Balaena mysticetus*), where cortisol levels were higher in the proximal sections of the baleen plate (Hunt et al., 2014. Conserv Physiol. 2:1-12). In conclusion, the highest cortisol concentrations from baleen of a suckling calf fin whale were detected proximal to the vascularized zone. Further studies are needed to determine how cortisol is deposited in the baleen and if baleen cortisol levels can be correlated with stress responses to past physiological events.

Skin lesions on the cetacean community of the Santos Basin, Brazil

Cetaceans are indicators of environmental health. The skin condition analysis of these animals is a non-invasive tool, which enables the identification of lesions of different sources, such as intra or interspecific interactions, diseases and anthropogenic impacts. However, there are few of these studies off Brazil, especially offshore. In this study, we describe the occurrence of skin lesions on cetaceans, photographed in coastal and oceanic waters of the Santos Basin, Brazil, by Projeto de Monitoramento de Cetáceos na Bacia de Santos (PMC-BS), a project financed by PETROBRAS and demanded by IBAMA. Fourteen boat surveys were carried out from December 2015 to October 2018. We recorded skin lesions on animals from 22 species (7 mysticetes and 15 odontocetes) and classified them according to 13 appearance-based categories: nodules; open wounds; depressed round lesions; white patches; whitish velvety lesions; deformation; pox-like, lobomycosis-like, anthropogenic interaction, cookie-cutter shark interaction, ulcerative lesions, killer whale interaction and miscellaneous. The most frequent types of lesions were: cookie-cutter shark interactions (75% of the species), nodules (68%), white patches (64%), miscellaneous (64%) and open wounds (50%). The species that showed a greater variety of lesions were *Megaptera novaeangliae* (11), *Stenella frontalis* (11), *Tursiops truncatus* (10) and *Balaenoptera borealis* (8). Killer whale interactions and red patches were only recorded on *M. novaeangliae*. Lobomycosis-like lesions only occurred on *T. truncatus*. A *Stenella frontalis* had a rostral deformation of unknown etiology. Potential anthropogenic interactions were recorded for 7 species: *B. brydei*, *M. novaeangliae*, *Sotalia guianensis*, *Stenella attenuata*, *Stenella clymene*, *S. frontalis*, *Stenella longirostris* and *T. truncatus*. A Bryde´s whale had deep propeller scars on its back from a vessel collision, and at least six dolphins had their dorsal fins partially or totally mutilated by fishing gear. This study shows novel results, contributing to the health assessment of cetaceans in Brazil.

What do grey seals (halichoerus grypus) in New England really eat, and what is the best way to determine diet?

Grey seals (*Halichoerus grypus*) appear to be a species at odds with commercial fisheries no matter where they live: Europe, Canada, United States. It is imperative that their diet is clearly delineated so that the overlap with commercial fisheries is known. Researchers use a number of techniques to determine pinniped diets which utilize different types of samples that represent varied time periods, cost and labor, and each with its own benefits and restrictions. We studied several of these techniques in an attempt to determine which yielded the best estimate of the grey seals' true diet, and compared their results. Four of the techniques utilized scat samples, which do not require physical contact with the seals, but only include the last few days of feeding: hard parts, prey species specific PCR-DNA, prey species specific quantitative PCR-DNA, and next generation DNA analysis (metabarcoding). Hard parts analysis allowed quantification of prey species proportion in diet and biomass, which the other techniques generally did not. However, the DNA based techniques found prey species not detected through hard parts, and next generation DNA analysis uncovered even more previously undetected species. These DNA based techniques primarily yield frequency of occurrence in samples. Other techniques require a sample taken from a restrained or dead seal. Stable isotope analysis revealed diet over months, however, it was difficult to differentiate between species with similar isotope ratios. Fatty acid/quantitative fatty acid, and stomach content analysis have the advantage that the individual sampled is known. All of these studies have indicated that diet can vary with sampling location, season, year, sex and age of the seal. Overall, there is agreement between techniques that US grey seals eat primarily sand lance (*Ammodytidae spp.*), flatfish (Pleuronectidae), and hake (*Urophycis* spp.).

Beaked whales have gained public attention due to their involvement in mass mortality events related to naval exercises, now known to be a result of their strong behavioral responses to predator and naval sonar sounds. Limited information is available on population structure in most beaked whale species. However, local studies suggest that some live in small, seemingly isolated groups which are potentially susceptible to genetic erosion. As anthropogenic impacts continue to increase, it is vital to establish the underlying level of genetic diversity, structure, and connectivity in beaked whale populations across their geographic ranges to assess potential population-level impacts of these activities. In this study, we use double-digest restriction associated digest (ddRAD) tag sequencing to investigate population genomics of two sympatric and globally distributed species commonly associated with adverse responses to anthropogenic sound, Blainville's (*Mesoplodon densirostris,* n=43) and Cuvier's (*Ziphius cavirostris*, n=129) beaked whales.

This first analysis of genomic diversity and differentiation in these species using nuclear single nucleotide polymorphisms (SNPs; Blainville's n=13988; Cuvier's n=25059) identified from ddRAD sequences revealed hierarchical structure in both species across their global ranges using clustering algorithms (TESS3r) and population genetic statistics. In Blainville's, individuals clustered first by Atlantic and Indo-pacific basins, further subdividing into 3 populations each (observed heterozygosity: Atlantic=0.102-0.107; Indo-pacific=0.125-0.128). Cuvier's clustered by Atlantic, Indo-pacific and Mediterranean basins, further subdividing into 5, 5 and 3 populations, respectively (observed heterozygosity: Atlantic=0.118-0.128; Indo-Pacific=0.109-0.123; Mediterranean=0.081-0.092). Overall, Blainville's populations show less genetic diversity than Cuvier's, however, the lowest diversity was observed in Cuvier's from the Mediterranean Sea. Each species also had a single, genetically admixed population consisting of individuals sampled from across the North Atlantic. This evidence for significant genetic structuring supports results from photo-identification studies suggesting that these two species live in small, resident populations that are genetically discrete, substantiating the need for appropriately scaled management measures.

Individual foraging plasticity of harbour seals in a tidally energetic habitat.

Oceanography is an established driver of behaviour for multiple taxa. Features ranging from macroscale oceanic currents and fronts to microscale eddies and tidal boils have been linked to increased foraging effort. Highly dynamic marine ecosystems provide a series of relatively unique benefits (e.g. increased primary productivity and predictable prey distributions) and challenges (e.g. potentially high transport costs due to water currents) for foraging predators and they must seek to balance these to forage successfully and maintain suitable fitness for growth and reproduction. In dynamic environments, the identification of foraging behaviour is complicated due to the animal's observed movement pattern being necessarily a function of both the individual's movement and the movement of the environment immediately surrounding it. Here, we sought to investigate this by employing a discrete time, state-switching model (Hidden Markov Models) to quantify movement of harbour seals in a tidally dominated region of Scotland using GPS derived locations and tidal current corrected swimming behaviour. We combined estimates of locomotion, measured movement in both 'geo-space' and 'hydro-space', and investigated the effects of temporally dynamic environmental covariates on the probability of switching between behavioural states. We demonstrate the importance of considering temporally and spatially dynamic habitat variables when seeking to quantify animal behaviour and activity budgets in mobile environments. Further, we found significant plasticity in inferred foraging behaviour whereby seals switched between foraging tactics in increasing currents showing a) the ability of seals to respond to fine-scale changes in environmental conditions and b) the importance of these habitats as foraging areas for the study population.

Porpoise sex is literally kinky: Unique lateralized mating behavior coevolve with genital asymmetry in harbor porpoises (Phocoena phocoena).

Lateralized mating behaviors have not been reported amongst mammals with one remarkable exception. Male harbor porpoises (*Phocoena phocoena*) sexually approach females exclusively on the female's left side, breach out of the water, and hook their lengthy penis around the female to her vaginal opening. To understand the evolution of this unusual lateralized behavior, we assessed the morphological shape and symmetry of post-mortem reproductive tracts of 10 females and 3 male harbor porpoises from the same population as the behavioral observations. Two-dimensional geometric morphometrics of the vagina and 3D models of the vaginal lumen and inflated filamentous penis tip were used to characterize and quantify genital shapes and assess the influences of asymmetry on overall genital shape. There was substantial individual variation in vaginal shape in 2D, which was not correlated with total body length. The vaginas demonstrated significant directional and fluctuating asymmetry. The vaginal lumens were highly asymmetric as a result of complex 3D spirals and vaginal folds with deep recesses that may curtail the depth of penile penetration through physical obstructions. The asymmetric shapes of the excised penis tip, vaginal lumen, and penis tip of free-swimming harbor porpoises were similar. We demonstrate that the left-sided sexual approach of males is necessary for the penis to deeply penetrate the vagina, and suggest that the reproductive anatomy of both sexes and their lateral mating behavior have coevolved.

De novo genome and transcriptome assemblies of the Caspian seal

Caspian seals are an endangered landlocked, small bodied phocid that diverged from a shared ancestor with Gray seals (*Halichoerus grypus*) and Ringed seals (*Pusa hispida)* around 1-2 million years ago. However, the evolutionary history of this group is still not fully resolved. We have been working on the *de novo* genome and transcriptome assembly of the Caspian seal (*Pusa caspica*). Our datasets include short read Illumina HiSeq paired-end sequencing data (60x coverage), long read PacBio single-molecule real time (SMRT) and Oxford Nanopore real-time long read sequencing data (8x coverage and 30x coverage, respectively) in combination with Illumina HiSeq RNA-seq data from six different tissues. To date, assemblies have been produced using short-read only data which resulted in estimated genome sizes of 2.6 Gbp and N50 contig size of 3.4 Kbp, although the N50 of the assemblies is expected to increase by multiple orders of magnitude with the inclusion of the long-read data. Currently eight additional pinniped genomes are publicly available, and sequencing efforts for further seal species are underway. Together these sequencing resources will facilitate detailed analyses of the evolution and genomic basis of the highly diverse ecological and life-history traits observed within pinnipeds, with a primary focus on lactation strategies. The Caspian seal genome can be expected to provide insights into adaptations to the unique Caspian environment and, in combination with other genomes, may offer finer resolution to the evolutionary history of the *Pusa-Phoca-Halochoerus* clade. Further, effective population sizes (N_e) will be calculated from the genome assembly using Pairwise Sequentially Markovian Coalescent model (PSMC), to infer demographic variation and colonisation dates in relation to palaeoenvironmental scenarios. This presentation will report the current state of the genome and transcriptome assemblies, discussing the various pipelines implemented as well as preliminary analyses into the demographic history of Caspian seals.

Insights into the Brucella ceti genome

Brucella ceti is a dominant but poorly studied marine zoonotic organism that causes infectious diseases in marine mammals populations worldwide. B. ceti is a close relative of the pathogen B. melitensis, and constitutes the second genus, together with B. pinnipedialis, of the Brucellaceae family clade that is capable to occupy the marine environment. The increase of reported infections in cetaceans together with the need of understanding their zoonotic potential and the impact in human interventions, led us to perform a comparative analysis of B. ceti genomes. Here, the seven available B. ceti sequences were compared to 115 genomes of all Brucella available in Refseq databank. Comparative genomic analyses revealed a high degree of similarity among the marine Brucella, as well as with other terrestrial strains, with extensive pseudogenization in marine Brucella despite a global 97-99% similarity at genome level. Peculiarities of aquatic strains were found in pathways related to energy, transport of metabolites and regulation of transcription. Differences between B. ceti and B. pinnipedialis were found related to cell wall, plasmatic membrane and motility. Genomic traits potentially driving geographical strains distribution and host preference did not show clear correlations. This study provides new insight into the B. ceti genome plasticity, identifying genes that may contribute to the evolutionary success of this organism in infecting marine mammal species and spreading through the marine environment

Harbor porpoise (Phocoena phocoena) annual and seasonal distribution in Skjálfandi Bay, Iceland. Using opportunistic data over the past 10 years (2009-2018) collected from whale watching platforms.

Ortega Calvo, Marina[1]; Rasmussen, Marianne Helene[2]

The harbour porpoise (*Phocoena phocoena*) is present in Skjálfandi Bay (Iceland) all year long. Whale-watching activity reaches its highest point during the summer season due to the high

abundance of baleen whales coming into the area, with two main companies operating in the bay. Therefore, many of the studies previously conducted here over the years have focused on these other species. This study aims to gather all the data collected over the past 10 years to give an estimation of the annual and seasonal distribution of this species in the bay in relation to the survey effort carried out. Thus, the kernel distribution analysis showed a clear hotspot for harbour porpoises on the west side of the bay, which might be related to the fish abundance as this area appears to be relevant for other cetacean species too. Additionally, a correlation analysis will be carried out with environmental variables such as tide, depth, slope and day time to assess whether the presence/absence of harbour porpoises could be related to them. The outcome of these analyses would be interesting in order to conduct further studies of this species in the North of Iceland and for future conservation and managing purposes.

Cetacean abundance and distribution in the northern Gulf of Mexico after Deepwater Horizon oil spill

Line-transect vessel surveys were conducted in the oceanic northern Gulf of Mexico during 2017 and 2018 as part of the Gulf of Mexico Marine Assessment Program for Protected Species (GoMMAPPS) to obtain updated information on abundance and distribution of cetaceans. We compared data from GoMMAPPS to data from two similar surveys collected prior to the 2010 the Deepwater Horizon (DWH) oil spill. Surveys were conducted over the continental shelf and oceanic waters, from the 100m isobath to the U.S. economic exclusive zone boundary, in summers of 2003, 2009, 2017, and 2018 and winter of 2018. We pooled sightings of oceanic dolphins, primarily from the genus *Stenella*, to estimate relative abundance as the total number of individuals divided by the km of survey effort. Geographic distribution of oceanic dolphins did not change over the years; however, relative abundance decreased from an average of 0.816 individuals/km in the 2003 and 2009 cruises to 0.495 individuals/km in the 2017 and 2018 surveys. This decrease raises important questions about potential effects of the DWH spill and should be further examined. Distance-sampling analyses are being conducted to compare bias-corrected pre- and post-DWH cetacean abundance estimates.

SEAFARI: Facilitating citizen science and stranding response.

SEAFARI is a non-profit effort to encourage and facilitate public engagement in marine mammal studies and rescue. Taking advantage of the omnipresence of smart phones, SEAFARI is an app freely available for both iOS and Android. It allows users to log sightings of marine mammals anywhere in the world, and provides them with some information on the species. Information such as GPS position, behaviour, group size etc. as well as pictures can also be submitted. All sightings are then confirmed manually by the app administrator. All data collected via the app are freely available to researchers upon request. No personal information on the users is shared, but should there be a need to contact a particular user then this request can be made with the administrators. SEAFARI was created in South Africa, and best covers local species, but new species descriptions are being added and we do encourage users to submit sightings from all over the world. Currently a large effort is put into developing an easy way to report stranding and entanglement. The new function will provide a fast way to put users and local stranding response networks in touch, and hopefully improve the response. Taking advantage of the growing public interest in marine wildlife, this can be a great addition to costly fieldwork and help in the conservation of our megafauna.

Species-specific whistles in Delphinus delphis and D. capensis enable passive acoustic species identification.

Short- and long-beaked common dolphins (*Delphinus delphis* and *D. capensis*) are sympatric species in the eastern north Pacific. These species are highly vocal and passive acoustic monitoring can be an effective tool for investigating their occurrence and behaviour. However, acoustic identification is challenging for these species, in large part because their whistles overlap in many time-frequency characteristics. In this study we analysed whistles from single-species acoustic recordings of *D. delphis* and *D. capensis* in Southern California. Recordings were made using floating buoys surrounding schools (sampling rate = 48 kHz). Species identification, school composition and school size were confirmed by visual observers, drone footage and biopsy samples. We extracted whistle contours and measured 52 variables from a random subset of whistles (*D. delphis* = 425 whistles, 9 schools, *D. capensis* = 464 whistles, 5 schools). Whistle contours were categorized based on frequency content and shape using dynamic time warping and artificial neural networks in ARTwarp. This analysis resulted in 212 whistle types, with 42% of these being shared between species. Of the whistle types that were produced by only one species, 23% (n=27) were recorded from more than one school and are likely to represent species-specific whistle types. Permutation tests showed that the proportion of species-specific whistle types was significantly greater than their proportion if sampled by chance from an assumed shared repertoire ($p<0.001$). Random forest analysis using a random subsample of all recorded whistles (n=425 per species) classified 68% of whistles to the correct species. Random forest analysis using only species-specific whistles (n=31 whistles per species) correctly classified 89% of whistles, suggesting that these whistles carry more species-specific information than others. This shows that species-specificity in whistles may be expressed by unique contours or parts thereof and may be missed by traditional global parameter measurements commonly used in acoustic classifiers.

The intestinal microbiota is essential for the metabolism in herbivorous mammals, releasing simple sugars from the complex plant polysaccharides, as is the case of cellulose (which comprises 70% of plant biomass). The crystalline structure of cellulose makes it resilient to biological hydrolysis, but certain bacteria and fungi in the microbiota are able to hydrolyze it through cellulases activities. With the notable exception of ruminants, little is known about the intestinal microbial diversity from herbivorous vertebrates. In this study, we characterized the intestinal microbiome of the West Indian manatee *Trichechus manatus*, a strictly herbivorous aquatic mammal. Fecal samples were obtained from two manatees under human care. Half of each sample was diluted and cultured to isolate cellulose-degrading bacteria. The other half was used for total DNA extraction and shotgun genomic sequencing, as well as 16s amplification, followed by DGGE, run for band cutting and direct sequencing. Amplification and sequencing of the 16s established the presence of phylum Firmicutes genera, followed by Proteobacteria and Actinobacteria. Shotgun genomic sequencing resulted in 11.676.441 unique reads among all four samples, from which, 454 OTUs were identified. Bacteria and 21% as Archaea were identified from 79% of the readings. Firmicutes were confirmed as the most abundant phylum, with 58% of the total readings, followed by 21% of the Archaea phylum Euryarchaeota, 13% to Proteobacteria, 5% to Actinobacteria, and less than 1% as Bacteroidetes and Verrucomicrobia. Alpha Diversity indexes were consistent with those reported from terrestrial herbivores (Shannon = 6.079 ± 0.06; Simpson = 0.04 ± 0.015) but the Chao Abundance Index was higher (Chao = 2489 ± 780). From the cultured portion of the microbiome, four strains with cellulolytic activity in CMC agar were isolated and identified as members of the genus *Klebsiella,* for which cellulolytic capacity has been previously reported.

Micro-anatomical and immunohistochemical characterization of the terminal portions of the lung in the sperm whale (Physeter macrocephalus), the fin whale (Balaenoptera physalus), and the bottlenose dolphin (Tursiops

truncatus)

The lungs of cetaceans underwent physiological and anatomical adaptations that facilitate extended breath-holding during the dives, including the long and deep ones. On the contrary, the time spent at the surface for gas exchange is very short. Here we present our results on the relatively unknown micro-anatomy of the terminal portions of the lungs of fin (*Balaenoptera physalus*) and sperm (*Physeter macrocephalus*) whales. For comparison we examined also the most investigated lungs of the bottlenose dolphin (*Tursiops truncatus*). Our study focuses on small bronchioles, cartilage rings and alveoli. For this purpose, we executed routine histological techniques, and performed both an in-depth immunohistochemical (IHC) characterization, and a morphometric analysis of the terminal portions of the lung. For the IHC analyses, we employed commercial anti-human antibodies (Abs) against *i*) smooth muscle actin; *ii*) smooth muscle myosin; and *iii*) desmin. Results revealed that, in the bottlenose dolphin, a system of myo-elastic sphincters (MESs) is present up to the alveolar end of the terminal bronchioles. This MESs system consists of a series of sphincters placed at short intervals that constrict the lumen and divide the airways in chambers. In fin and sperm whales, smooth muscle bundles (SMB) were observed throughout the terminal bronchioles until the entrance of the alveolar sacs. However, contrarily to the MESs system, these latter structures do not constrict the lumen. Cartilage rings were present until the level of the entrance to the alveoli in the lungs of all the species. On the other hand, the alveolar size and wall thickness varied greatly. All the Abs used showed positive immunolabeling in all species sections, except for the smooth muscle myosin, which was not detectable in the sperm whale tissues. The present study provides the first IHC and quantitative morphometric analyses of the terminal portion of the lungs in selected cetacean species.

Hair testosterone levels of Northern fur seals correlate with month and testicular morphometric parameters.

Hair samples can be used as endocrine markers to assess the reproductive status of animals, as hair is known to reflect endocrine activities spanning several weeks or months prior to the time of collection. However, it is unknown whether pinniped reproductive status can be assessed from hair samples. Northern fur seals (*Callorhinus ursinus*) are found off Hokkaido, Japan during non-breeding season. Knowledge about the reproductive statuses of free-ranging seals provides important data to inform population dynamics analyses. Here, we show that sexual maturity of northern fur seal males during the non-breeding season off Hokkaido can be distinguished using hair testosterone levels. A total of 57 male fur seal hair were collected during the non-breeding seasons of 2011-2018. Time-resolved fluoroimmunoassays were validated for testosterone through parallelism and gas chromatography. We found that the testosterone levels of juvenile seals (age < 4) were significantly lower than those of mature seals (age ≥ 4). Elongated spermatids, the final phase of spermatogenesis, were present in the seals collected between April and June. The seals collected in May, as spermatogenesis progresses, showed the highest testosterone levels. Our overall model revealed that testis weight and month were significant predictors of hair testosterone levels. Our results demonstrate that the juveniles can be distinguished from mature males using hair testosterone levels in May, preceding breeding season. Hair testosterone levels of seals, thus, likely reflect endocrine activity at approximately the time of sampling. Data on male reproductive status enhances our understanding of fur seal ecology, such as distribution of the seals off Hokkaido during the non-breeding season, and clarifies the connection between non-breeding and breeding seasons. This method can be applied in various species of pinnipeds, and is especially useful for those that spend time offshore during the non-breeding season, since hair can be biopsied.

A review of Balaenoptera strandings in the East coast of South America

The genus *Balaenoptera* comprises seven species and 15 subspecies with conservation status ranging from "Endangered" to "Least Concern" and "Data Deficient". Despite data from whaling and offshore cruises, much of information related to seasonal distribution and ecology of these whales in the southwestern Atlantic Ocean (SWAO) comes from analysis of beached carcasses. A review of published and unpublished confirmed records on *Balaenoptera* strandings along the east coast of South America (from ~12ºN to 55ºS), comprising six countries (Argentina, Brazil, Chile, Suriname, Uruguay, Venezuela) and the Falkland/Malvinas Islands was used to evaluate spatio-temporal ecological and habitat use patterns of these whales. A total of 196 strandings from the seven species were documented from 1865 to 2018. Records varied largely across species: *B. edeni*/*brydei* (n=81), B. *acutorostrata* (n=45), *B. bonaerensis* (n=23), *B. borealis* (n=19), *B. physalus* (n=18), *B. musculus* (n=9), and *B. omurai* (n=1). As expected, most of the species occur in higher numbers during winter and spring migration season to/from low latitudes. When all records were gathered, the permanence of *B. edeni*/*brydei* and some individuals of *B. acutorostrata* in the Brazilian coast year-round became more evident than previously. Moreover, analysis of a greater number of studies brought strength to different theories, such as a possible latitudinal sexual segregation of *B. bonaerensis* (especially of pregnant females) and a calving area of *B. borealis* in mid-latitude waters of the SWAO. Also, a hypothesis of a larger calving area (from ~17ºS to 35ºS) than previously expected for *B. acutorostrata* emerged from the compiled data. Finally, although stock structure and taxonomy still need to be better resolved for different species, the information about *Balaenoptera* strandings are now comprehensively organized and exposed considering a greater dataset than any previous review in the east coast of South America.

Gollum is dead: Presentation of a cetacean online relational database under a Creative Commons license.

Databases are a key aspect of scientific research. They are of capital importance not only to store and organize data but to analyze and design long term research plans. Relational databases are of special interest as they are structured in different tables that are connected with each other. This fact allows an effective way of performing the CRUD (Create, Read, Update and Delete) operations using the Structured Query Language (SQL). Here we present a marine survey online relational database structure implemented in PostgreSQL, an open source database management system. It is hosted in an online server provided by ElephantSQL, allowing the CRUD operations to be executed from any device around the world using the SQL language. The online database can be connected to R statistical software through the server credentials (username, password, and server name), a fact that allows an easy and effective way to import and analyze the data. The database is structured in more than 50 tables and contains more than 20 years of data on cetaceans and birds from the Mediterranean and North Atlantic. This point makes it not easy to interact with the database structure directly so an interactive way of making the CRUD operations is also presented using the Shiny package from R Studio. The database and the data included are under a Creative Commons license, allowing its use by anyone.

Living together yet a life apart: The behavior, distribution and abundance of sympatric inshore bottlenose dolphin and pantropical spotted dolphin in Golfo Dulce, Costa Rica.

Oviedo, Lenin[1]; Herra-Miranda, David[2]; Pacheco-Polanco, Juan Diego[2]

In sympatric predators, range overlap is frequently assumed as a potential for competition. However, co-occurring organisms could have different ecomorphology and niche preferences, thereby minimizing competitive interactions and coexisting. This study analyzed the ecological characteristics (abundance, distribution and behavior) of inshore bottlenose dolphin and pantropical spotted dolphin in Golfo Dulce (Costa Rica), identifying patterns-processes that enable the

mechanisms leading to coexistence. Mark-recapture analysis was performed using four years (2011–2015: eight rainy-dry seasons) of photo-identification data collected systematically for bottlenose dolphins and three years (2011–2014: six rainy-dry seasons) for pantropical spotted dolphins. Under the most parsimonious and best-fitted model of Pollock's robust-design, which included the effects of temporary emigration, the estimate of apparent survival was higher for pantropical spotted dolphins (S≈1, 95% CI: 0.99–1), than for inshore bottlenose dolphins (S=0.90, 95% CI:0.85–0.92). Both dolphin species evidenced random temporal emigration pattern with no seasonal effect. Total abundance estimates were relatively more precise for spotted dolphins (highest coefficient of variation was 0.10) and did not exceed 400 individuals, than for the small local population of inshore bottlenose dolphin (highest coefficient of variation = 0.24, total population < 120). There are important differences in foraging strategies between species in terms of depths: individual foraging in shallow waters for bottlenose dolphins and deep waters for cooperative foraging of spotted dolphin, which provided insights on potential dissimilarities in prey captured - consumed. The latter agreed with the pattern of distribution of both species and the resource partitioning evidenced in the species distribution models. The coexistence of both predators in Golfo Dulce is linked to habitat heterogeneity, where critical habitats are spatially differentiated. The lack of fine-scale spatial overlap, highlights a process of coexistence for dolphins that are sympatric at the scale of Golfo Dulce, but within the Gulf there is fine-scale allopatry.

"Dolphin dictionary": Using a self-organizing map to categorize the whistle repertoire of a group of bottlenose dolphins and identify signature whistles.

Defining the repertoire of a species is important in understanding its communication system. While delphinids generally have complex acoustic communication, the consistent and repeatable categorization of their vocalizations is difficult. In this study, we define the whistle repertoire of 11 wild Indo-Pacific bottlenose dolphins (*Tursiops aduncus*) and identify individually distinctive signature whistles (SW) within it. We recorded vocalizations of provisioned wild dolphins at Tangalooma, Australia. Recordings from a hydrophone array were used with video footage and photographs to localize whistles and identify the vocalizing individual(s). We used a self-organizing map (SOM) to create an automated categorization of dolphin whistles and tested its performance in clustering whistles from individuals. A number of tests were performed to identify the optimal parameters for the SOM resulting in a map with 64 whistle categories. These were assessed using a method for identification of SW by their temporal production (SIGID), identifying those containing potential SW. Visual assessment of the categories was also performed to subjectively evaluate the similarity of whistle contours within each category. Categories with potential SW were confirmed as belonging to the same animal by localizing whistles from them consistently to one dolphin. The SOM performed well in clustering similar whistles together. However, due to an overrepresentation of some SWs, these were split across several categories. Out of the 64 categories, 27 were identified as containing SWs. In three of these categories, less than 75% of whistles were correctly assigned, based on visual assessment. Other categories, however, had an average of 96% accuracy. The SOM was found to be a suitable method for mass categorization of the dolphins' repertoire and assisted in further fine-scale SW identification. It provided a valuable first step in reducing the number of categories to be tested, while the definitive identification of SW could be achieved using other methods.

Wake up and smell the krill: Is fine-scale dimethyl sulfide (DMS) concentration correlated to prey quality or humpback whale distribution?

Finding prey is essential to the survival of all animals. Phytoplankton produce dimethylsulfoniopropionate (DMSP) and when krill and other grazers consume phytoplankton, DMSP is released and breaks down into dimethyl sulfide (DMS). Some krill predators, such as seabirds, have been shown to be attracted to DMS, likely relying on it for navigation and locating krill patches in the ocean. However, much of the research on attraction to DMS has occurred with captive animals or at breeding colonies. Studies at sea have released DMS to determine whether a species shows a positive response towards the chemical. It is unknown whether natural gradients of DMS correlate with prey abundance or predator distribution, or whether baleen whales use DMS to locate prey. Baleen whales are thought to have retained their sense of smell, suggesting that DMS concentration in the air is a possible foraging cue. We used a newly developed analytical chemistry instrument to measure the concentration of DMS at a fine-scale (temporal = continuous to 10 minutes; spatial = continuous to 1000 m) in both air and water. We examined whether DMS concentration was correlated to prey distribution and quality (patch size and density) or to the distribution of humpback whales (*Megaptera novaeangliae*). This study is the first to directly assess the relationship between natural gradients of DMS concentration and whale prey distribution, providing an indication of whether DMS gradients are likely to be a reliable foraging cue for predators to locate high quality prey patches. In addition, we assess whether humpback whale distribution on a feeding ground is more strongly correlated to air-based or water-based chemical signals. Given the role of DMS in global climate regulation, understanding its impact on predator foraging behaviour will provide a mechanistic understanding of how species will respond to future changes in the ocean.

Preliminary investigation of humpback whales (Megaptera novaeangliae) in the Bazaruto Archipelago, Mozambique

During September 2018, an Israeli research team of biologists and acousticians set out to survey the humpback whale (*Megaptera novaeangliae*) population around the Bazaruto Archipelago, off the coast of central Mozambique. The entire Mozambique and Madagascar region serves as breeding grounds for southern hemisphere hupback whales of 'Breeding Stock C', through 3 different migration routes, during the austral winter, with the population in question belonging to the 'C1S Breeding Sub-stock'. The project's main goal was to observe mother-calf interactions and record vocalizations between them. Surveys were carried out over 13 days and the team collected 872 images for photo identification, enabling the identification of 63 individuals, including 11 mother-calf pairs, as well as videos, both above and below water, for behavioral analysis. Upon reviewing the photos, an peculiar pattern emerged: 8 mature individuals (4 of them mothers) with fresh cuts on one or the other side, just below and behind their dorsal fins. Repetative abrasions at this body location have not been documented in other humpback populations and it is possible that this stock exhibits a unique behavior that causes the cuts. This expedition also preformed the first acoustic recordings for the C1S Breeding Sub-stock, distinguishing between two types of communication: male songs and social-calls, the latter for both mother-calf and competitive group interactions. As part of the project, an open-source Matlab toolbox for bio-acoustic data analysis and denoising was developed, available at https://github.com/mosheman5/deep_voice. This project comprises preliminary research on a unique and scarcely documented region, seting a baseline for future studies in this area, so as to gain insight into the social dynamics of the humpback whale population around this archipelago and in the Mozambique region in general.

Cetacean stranding records on the central Turkish Black Sea coast in May 2017 - April 2019

Ozsandikci, Ugur[1]; Tonay, Arda M.[2]; Danyer, Erdem[3]; Dede, Ayhan[4]

ozsandikciugur@gmail.com

Between May 2017 and April 2019, monthly stranding surveys were conducted along the coasts of Sinop Province in the central southern Black Sea. The study is the first regular stranding survey on the central coasts of the Turkish Black Sea, which is known for intense artisanal and industrial fishing activities. During the study, the sandy beaches of the total length of 14.5 km were surveyed within the 63 km-long coastline. Stranded cetaceans were recorded, photographed and measured. Beside the surveys, media and citizen reports were analyzed, which constituted 28.5% of all records. In total, 42 stranded cetaceans of three species living in the Black Sea were found –23 common dolphins (55%), 15 harbour porpoises (36%), 3 bottlenose dolphins (8%) and 1 unidentified specimen. The highest number of strandings was recorded in spring, that is, in April (50%), followed by May (21.4%) and March (19%). The number of stranded individuals per km in spring months were as follows: 0.62 in May 2017, 0.55 in March 2018, 1.24 in April 2018 and 0.21 in April 2019. After spring, most of the strandings were seen in autumn (7.14%). More than half of the strandings were at an advanced stage of decomposition (stage 4 and 5, 60%), which made it impossible to determine the cause of death. In total, 13 individuals (31%), all of which were recorded in spring (9 common dolphins, 2 harbour porpoises, 2 bottlenose dolphins), were considered to be incidentally caught due to net marks on their bodies and missing fins/tail flukes. High number of stranded cetaceans in spring, especially in April, is considered to be related to the increased use of turbot gillnets in these months. Additionally, in spring being the ending period of industrial fishing season, purse seiners may also be another cause of mortality for those cetaceans.

Be prepared for muddled messages when monitoring management effectiveness in the face of sample noise and a changing environment

Pace, III, Richard M[1]; Robbins, Jooke[2]

Corresponding Author: richard.pace@noaa.gov

North Atlantic right (Eubalaena glacialis, NARW) and humpback whales (Megaptera novaeangliae) are vulnerable to human impacts along the East Coast of the United States, The NARW population is in decline, both in abundance and divergence in sex ratio with males becoming more numerous than females. Humpback whale population growth in the Gulf of Maine has declined and is among the lowest rates on record for the species. The U.S. National Marine Fisheries Service has implemented a series of mitigation measures to try to reduce the impact of commercial fishing activities on the recovery potential of these species. Most notably, federal rules in 2009 and 2015 aimed to reduce the profile of ground line and the number of vertical lines in the water column, respectively. Stakeholders, including the fishing industry, scientists, conservation groups, and the agency itself are highly interested in the effectiveness of these actions. A metric frequently chosen to evaluate the effectiveness of rules for reducing serious injuries and mortalities due to gear entanglement (SIME) has been the annual count of observed events. Unfortunately, these count data are often viewed without regard to the sampling and stochastic processes that generate them. Herein, we evaluate the SIME counts, as well as vessel-strike related SIM, in a common framework for accounting for their inherent noisiness. We show that the signal in these data to date is inconsistent with the desired goal of reducing entanglement mortality and serious injuries since the ground line and subsequent rules were established. For right whales, these data actually imply that SIME has increased over time. We use this observation as a springboard to pontificate on the perils of attempting to gauge effectiveness in a setting that lacks replicates and controls of influences unrelated to the management action.

Diet shape the gut microbial composition of the Pacific harbor seal (Phoca vitulina richardii).

Diet is a primary driver of the gut microbial composition and is considered one of the main routes of microbial colonization. Prey identification is fundamental to correlate the diet with the presence of particular microbial groups. This study examined how diet influenced the gut microbial composition and function of the Pacific harbor seal (*Phoca vitulina richardii*), a pinniped that predominantly consumes fish and cephalopods. The aim of the study was to understand the role of prey consumption on shaping the gut microbiota of harbor seals.

Twenty fecal samples were collected from five harbor seal colonies located in Baja California, Mexico. The V4 region of microbial 16S rRNA genes was amplified and sequenced using the Illumina MiSeq platform. DNA metabarcoding of the fecal samples was used to identify the preys

consumed by harbor seals. The gut microbiota of harbor seals was dominated by the phyla Firmicutes (37%), Bacteroidetes (26%) and Fusobacteria (26%). There were significant differences in the gut microbiota composition between the harbor seal colonies. PICRUSt was used to predict gene content in the gut microbiome and suggest a high content of routes involved in the metabolism of organic molecules. All harbor seal colonies presented routes related to the degradation of persistent environmental pollutants. Functional redundancy in the seal gut microbiota was observed regardless of diet or location.

There was a significant relationship between the diet and the gut microbiota composition and also with OTUs assigned to a particular metabolic pathway. The results of our study indicate that the frequency of occurrence of specific preys plays an important role in shaping the gut microbial composition of harbor seals by influencing the relative abundance of specific genera and phyla of gut microorganisms.

Energetic budgets of gray whale mother-calf pairs on their breeding ground in San Ignacio Lagoon, Mexico.

In order to optimize the conservation of a species, it is important to understand how individuals allocate energy to the various phases of their life cycle. In the case of mysticetes, migration and breeding are taxing on females and quantifying the energetic costs associated with these behaviors can help inform management on the importance of certain habitats. Gray whales (*Eschrichtius robustus*) carry out some of the longest migrations ever recorded. This project aims at quantifying the energetic budget of female gray whales and their calves on their breeding ground in San Ignacio Lagoon, Baja California, Mexico. Non-invasive archival tags (DTAGs) were deployed on both females and their calves to quantify diving behavior, acoustics and energetic expenditure using respiration rates as a proxy. A total of 10 tags were deployed: five on adult females and five on calves. A total of 70 hours of recording were collected and focal follows on two mother/calf pairs were conducted for a total of seven hours. We present preliminary results on dive profiles, minimum specific acceleration (MSA) and acoustic behavior of these animals. Results will be compared to available and equivalent datasets from humpback whale (*Megaptera novaeangliae*) and southern right whale (*Eubalaena australis*) breeding grounds, thereby providing insights on the importance of these areas across mysticete species. In addition, results will provide a better understanding of the specific adaptations to long distance migration and gray whales' resilience to anthropogenic stressors.

First comparisons of testosterone levels in male humpback whales (Megaptera novaeangliae) of different behavioral roles and body sizes in the breeding grounds

In the animal kingdom, a direct relationship between male testosterone and dominance appears complex, having been demonstrated in some species but not in others. It is well known that male humpback whales in the breeding grounds engage in physical contest competition for access to individual females. Within these competitive groups, the male successfully defending the position closest to the female (the principal escort) tends to be larger than other "secondary escort" males, and thus may be considered to be in a position of at least temporary dominance. However, whether the advantages of the principal escort role are also reflected in testosterone level is unknown. We measured testosterone in blubber samples obtained using biopsy techniques from 161 male humpback whales in various behavioral roles including 20 principal escorts (PE) and 47 secondary escorts (SE) in waters off Maui from 2004-2006 (Range = 0.30-4.31ng/g). There was a significant reduction in testosterone for both PE ($r = -0.60$, $p=0.005$) and

SE (r = -0.36, p=0.012) across the breeding season. Given this trend, we compared testosterone levels early in the season (Jan-Feb) from PE (Median = 1.13ng/g, IQR = 0.77) versus SE (Median = 1.17ng/g, IQR = 1.08), and also late in the season from PE (Median = 0.34ng/g, IQR = 0.49) versus SE (Median = 0.75ng/g, IQR = 0.77), and found a significant difference only late in the season (Mann-Whitney U, Z = -2.37, p=0.018). However, for five males in different behavioral roles sampled early in the season in which both testosterone (Range = 0.52-1.14ng/g) and body length (Range = 10.90-13.29m) were measured, the two were significantly positively correlated (r = 0.85, p=0.034, one-tailed). Taken together, these findings suggest that blubber testosterone may be reflective of male body size, but alone, may be a more subtle predictor of male dominance than size.

Regional differences in the cranial morphometry of adult male Galapagos sea lion

The skull is useful tool that shows adaptation effects of species to different ecological and environmental influences. Based on the fact that the food available affects the somatic growth of the otariids, it was hypothesized that there could be regional differences between rookeries of Galapagos sea lion (GSL) as a result of the trophic recourses availability and the ecosystem variability in Galapagos Islands. Based on this, we used associated measures: (a) size, sections that define growth only; and (b) aggressiveness, specific sections of the skull that the individual uses in their antagonistic behavior. In this context, 34 linear measures, 20 in size and 14 in aggressiveness, were taken on 48 adult male skulls of GSL. Based in ecological information, the study area was divided into three bioregions: (a) Southeast (n = 15), (b) Center-North (n = 17) and (c) West (n = 16). Regional differences were observed, where the length of the nasal bone (p = 0.031), the width of mesodistal orbital (p = 0.022) and the width of occipital condyle (p = 0.025) were smaller in the western region. The length of the nasal, and the width of mesodistal orbital bone were associated to an increase in size, while the width of occipital condyle to a greater defense or aggressiveness of the males. The regional differences suggest a greater size and aggressiveness in the rookeries of the western region, which could be associated with a greater availability of resources and greater competition given the high variability of the ecosystem in the western region. The information generated in this work is important to understand the trends in the life history of the species, its opportunities and threats. Aspects that could be the basis to develop management measures for the conservation of this species.

The genetic legacy of extreme exploitation in a polar vertebrate

Human exploitation is one of the greatest threats to global biodiversity. It is crucial to understand the consequences of human-induced declines on the demography and genetic composition of wild populations to predict species persistence and adaptive potential. We investigated the genetic legacy of large-scale commercial harvesting by reconstructing on a global scale the recent demographic history of the Antarctic fur seal (Genus). This species was hunted to the brink of extinction by 18th and 19th century sealers across their entire circumpolar distribution. Molecular genetic data from over 2,000 individuals sampled from all major breeding colonies show that at least four relict populations survived commercial exploitation around Antarctica. We used a coalescent-based approximate Bayesian computation framework to reconstruct this species' recent demographic histories and found that all of the populations experienced severe bottlenecks down to effective population sizes of around 200 to 300 individuals. Relatively high levels of neutral genetic variability of the Antarctic fur seal in

comparison to other Otariid species suggest that the inferred declines may not have been strong enough to have reduced allelic richness by more than around 15%. Our results indicate that the species as a whole was more resilient to hunting than suggested by historical accounts. Furthermore, the assertion is supported that only the strongest bottlenecks lead to major losses of diversity, and highlight the importance of relict populations to species recovery and the maintenance of genetic variation.

Harbour porpoise (Phocoena phocoena) mother-calf behaviour revealed by drone observations

Due to their aquatic lifestyle and wide distribution, studying cetacean behaviours in the wild is difficult, especially when it comes to understanding their group structure and social behaviour. One of the less known species is the harbour porpoise (*Phocoena phocoena*). Despite being Denmark's only year-around whale, significant gaps still remain in our understanding of the behaviour and development of the species. Most of our knowledge comes from studies performed in captivity, and almost nothing is known about their social lives, group structure and bonds between conspecifics in the wild. Such information is of great importance for protecting porpoises, known to be vulnerable to by-catch and different types of pollutants, especially calves during the most vulnerable period of their life cycle. Unmanned aerial vehicles or drones represent an innovative and effective way to observe cetaceans in their natural environment. The aim of this study was to assess the affiliative relationship of mother-calf pairs by measuring the length and relationship (in terms of distances) between the mother and her calf in two different periods of the neonate's life cycle. Data analysis was performed from drone-based video recordings with the help of a new computer software developed at the University of Southern Denmark. During the first months after birth, calves stayed significantly closer to their mother and synchronized their breathing with her more often than during the final part of the lactation period. This shows that the bond between the mother and the calf is stronger during the first months after birth and gradually decrease during lactation. This has important implications for our understanding of harbour porpoise behaviour and how to design relevant and adequate conservation measures.

Applications of a new satellite-linked tag for long-term monitoring of large whale movements, diving, and feeding behavior.

Despite spending much of their time on activities at depth, the technology in use to track whales over large geographic ranges via satellite has been largely limited to locational data, and most applications have focused on describing their horizontal movements, ignoring the vertical dimension. We describe the development of a new satellite telemetry device for tracking the movements and dive behavior of large whales over several months without requiring recovery. The tag incorporates sensors and software to detect dives and create per-dive summaries for transmission via the Argos System, and reports dive duration from a saltwater conductivity switch, maximum dive depth from a pressure transducer, and feeding events from a tri-axial accelerometer. Through three case studies involving humpback whales (*Megaptera novaeangliae*) and blue whales (*Balaenoptera musculus*) tracked while in their feeding areas as well as during migration, we demonstrate a variety of applications of the tag. We derived a suite of dive metrics from the dive summaries transmitted by the tags and documented diel and longer-term variability in diving and feeding behavior over tracking periods of up to 76 d. The results showed marked differences within and among individuals tracked contemporaneously, and provided some of the first assessments of previously unobservable behaviors in the context of movement across entire geographical ranges. This information has relevance to studies attempting to assess risk of exposure and response to anthropogenic noise and ship traffic and their relation to the animals' behavioral context. We conclude with a discussion of some of the tag's current limitations, including the importance of validation.

Ecological drivers of reproductive rates in humpback whales along the Western Antarctic Peninsula.

Antarctic humpback whale populations are recovering after intense commercial whaling in the 20th century. Along the Western Antarctic Peninsula (WAP) this recovery is occurring in a rapidly warming environment. To fully assess the recovery of these whales, understanding the effects of environmental drivers on their demography is critical. Since the 1990s, biological and physical variability in this marine ecosystem have been described as part of the National Science Foundation's Long Term Ecological Research program. As part of this program, we have collected skin and blubber biopsy samples from humpbacks since 2010. We assessed pregnancy, via blubber progesterone concentrations, in 266 female humpbacks during the austral feeding season between 2010-2016. Using a Pearson's time series correlation, we found a strong positive relationship between pregnancy rates (year of birth) and the extent of summer sea ice in the same year ($r = 0.87$, $n = 5$, $p = 0.04$) and local krill abundance in the year of conception, i.e., one year prior to pregnancy ($r = 0.67$, $n = 5$, $p < 0.05$). These results are similar to observations made from other Antarctic krill predators (southern right whales and gentoo penguins) and reveal linkages between variation in the Antarctic climate and the biological processes driving humpback whale population dynamics along the WAP. These are some of the first quantitative observations linking the recovery of a baleen whale to ecological drivers in the Antarctic. Our results contribute to a better understanding of the effects of climatic change on whales and other large marine predators in the Southern Ocean.

The spatio-demographic trends of sperm whale (Physeter macrocephalus) strandings in New Zealand: A review.

Despite the frequent sperm whale (Physeter macrocephalus) strandings in New Zealand waters, to date, there has been no review of their spatio-demographic trends. We used historical stranding records to assess spatio-temporal patterns of strandings on the New Zealand coast between 1873 and 2018. A total of 591 sperm whales stranded during 277 independent events. Using sex, age class, season and location, potential spatio-demographic trends were evaluated. Both sexes strand throughout all austral seasons and along all coast lines of New Zealand, in addition to two offshore islands. The majority of single stranded females occurred north of 44º S, which supports anecdotal distribution records of sperm whales within New Zealand. Of the strandings for which sex was determined (n=140), single strandings consisted of 39 females and 101 males (1:2.6). Austral summer (Dec-Feb) exhibited the highest (n=98) number of single stranding events. Across all seasons, the west coast had the highest number of single stranding events (n=111), followed by the east coast (n=94) and Stewart and Chatham Islands (n=24). All mass stranding events (n=23) occurred north of 44º S or on Chatham Islands (44.02º S). Mass stranding events for which group type was determined (n=18) consisted of 11 bachelor pods and seven matriline groups. Austral spring (Sep-Nov) displayed the largest number of mass strandings events (n=8) whereas austral autumn (Mar-May) had the greatest number of individuals stranding (n=151). The west coast recorded the highest number of mass stranding events (n=13), with eight of the 11 bachelor pods stranding on the west coast. Our preliminary findings suggest most live strandings included adult females. This is contrary to previous studies which indicate the New Zealand population consists predominantly of bachelor pods. Here, strandings data provide an invaluable resource to gain critical information about populations and species for which little is known.

Fine-scale movements of small cetaceans around an operational tidal turbine.

The offshore renewable energy sector is expanding in order to fulfil ambitious national and international green energy targets in response to climate change. Tidal turbines harness energy from water currents and can provide more stable, predictable energy generation than wind or solar. However, there is increasing evidence that tidally energetic sites are important for marine mammals, leading to concern about potential collisions with turbine blades. To-date, there is a general paucity of information on the fine-scale movement behaviour of marine mammals around operational turbines to inform whether this concern is valid. This information is critical for regulators looking to effectively manage marine mammal populations whilst making consenting decisions about the tidal industry as it looks to develop from small, demonstration arrays to commercial scales. Here, we present results from a long-term (>1 year) passive acoustic tracking study of small cetaceans around an operational tidal turbine in the UK. A system of 12 synchronised hydrophones sampling at 500 kHz allowed fine-scale, 3-dimensional tracking of harbour porpoises (*Phocoena phocoena*) and dolphins. Real-time processing in PAMGuard reduced 365 TB of raw data to 1.2 TB of stored detection data. Twenty-seven dolphin and 571 porpoise encounters (>= 30 echolocation clicks) occurred in 12 months of monitoring. Marked seasonality in porpoise occurrence was evident; the highest detection rates occurred in December 2017 (mean = 3.1/day) and the lowest occurred in May and June 2018 (mean = 0.3/day). Porpoise detections occurred at all tidal states and during periods when the turbine was operational and non-operational. Preliminary tracking results indicate that between October 2017 and September 2018, 132 porpoise tracks came within 10 m of the turbine. We present the most comprehensive record to-date of 3D porpoise movements close to an operating turbine and discuss implications for collision-risk, and future management and monitoring.

Look up: Potential impacts of UAVs on Arctic Marine Mammals.

The impact of UAV technology on marine mammals remains poorly documented despite the increase in their use for ecological studies. In polar regions such as the High-Arctic Archipelago of Svalbard, marine mammals are facing increasing pressure from the coupled effects of climate modification and an expanding tourism industry. Our study focussed on assessing UAV disturbance effects on marine mammals, conducting disturbance experiments to provide science-based management advice using a novel approach. We included a behaviour control period before and after experimentation which involved flying sets of profiles over a range of altitudes and approach strategies, using UAV models with varying acoustic profiles. Adult female polar bears responded to the take-off of UAVs even at ranges exceeding 200m, however response levels were relatively low and remained so even at 60m. Experimental flights over harbour seals during the pre-breeding and moulting seasons and over adult male walruses during summer aggregations yielded contrasting results. Pre-breeding harbour seals were the most reactive to UAV distance. Pre-experiment activity levels of walruses seemed to be the major factor influencing whether or not they were disturbed; when they did respond, young animals were the first to react, triggering a flee response of the whole herd. Adult female polar bears responded to the acoustic signature of the drone from the launch point over 200m away, but exhibited a weaker response at closer range than seals. For pinnipeds, vertical descent was the approach strategy that caused the greatest impact. The alertness level of animals prior to operations appears to be a major factor determining sensitivity to UAV disturbance, and larger UAV models do not cause more disturbance when flying pre-set smooth horizontal profiles. We suggest that footage obtained from 80m has a high enough resolution for most scientific purposes.

Temporal patterns of a low-frequency baleen whale call from Diego Garcia waters in the Indian Ocean.

Corresponding Author: divya145@gmail.com

Passive acoustic monitoring provides a window into understanding the occurrence and seasonality of cetaceans in remote regions by studying their vocalizations. The Diego Garcia downsweep (DGD) described first by Sousa and Harris (2015) is a dominant baleen whale call type in the 18-50 Hz band recorded from hydrophones that are part of the Comprehensive Nuclear-Test-Ban Treaty off Diego Garcia Atoll. This study uses a decade of data (2008-2018) from these hydrophones to examine potential species identity of the signal and report on the inter-annual, seasonal, and diel

patterns of this call off Diego Garcia Atoll. Based on comparisons with recordings from Madagascar and western Australia, we believe these signals to be produced by Omura's whale (*Balaenoptera omurai*). The other possibility is Bryde's whale (*B. edeni*). Long-term spectral averages were used to examine annual and seasonal patterns from 2010-2017 and 2010-2014 at the southern and northern hydrophone which monitor the southern and north western Indian Ocean, respectively. Spectrogram correlation was used to build a detector that identified DGD calls from the time series. Parametric statistics using model approaches was used to examine predictors (e.g. year, season, time of day and interactions) of call detections. In general, detections peaked in austral winter on the southern hydrophone but austral summer on the northern hydrophone. There was significant interannual variability in the number and timing of call detections. This study provides new information on a (likely) recently described species of whale over a long time-series in the northern and equatorial Indian ocean region where visual surveys and information on baleen whale ecology are wanting.

The ACCOBAMS Survey Initiative - a tool to facilitate conservation effort across cultural, social and political boundaries.

Panigada, Simone

The "ACCOBAMS Survey Initiative" (ASI) is a pilot programme aimed at establishing an integrated and coordinated monitoring system for cetaceans throughout the entire ACCOBAMS area. Conducted in coordination with riparian countries, it supports the implementation of European and regional policies, in particular the Marine Strategy Framework Directive (MSFD-EU) and the Ecosystem Approach process (Barcelona Convention UNEP/MAP).

In summer 2018, a synoptic survey was carried out across the Mediterranean Sea and contiguous Atlantic area, combining visual methods (aerial surveys) and visual and passive acoustic monitoring (PAM) from vessels (focused primarily on deep diving species and areas where aerial surveys were not possible). Line-transect sampling methodology was applied and density and abundance estimated through design-based and model-based approaches.

Uncorrected for availability and/or perception biases, design-based estimates are available for the areas covered by aerial surveys, including: fin whales (N=1769, CV=0.28), sperm whales (N=1448, CV=0.51), Risso´s dolphins (N=26,659, CV=0.29), bottlenose dolphins (N=75,762, CV=0.21), long-finned pilot whales (N=5866, CV=0.41), striped dolphins (N=418,589, CV=0.14), common dolphins (N=65,925, CV=0.40), and a merged category of either striped or common dolphins (N=218,289, CV=0.27).

To continue this pivotal research effort, an equivalent aerial survey is planned for summer 2019 in the Black Sea in relation to the MSFD.

The 2018-2019 effort will provide an overall picture of the distribution and abundance of cetaceans throughout the ACCOBAMS area,

providing robust estimates to be considered as a baseline for further regional systematic monitoring programmes, coordinated and comparable amongst all areas. These data will improve the current knowledge on cetacean status, facilitate the development of targeted conservation and mitigation measures and allow for the follow-up to international obligations (EU, UNEP-MAP). Moreover, they will be used to support both place- and threat-based conservation efforts in the Agreement area, with the identification of Important Marine Mammal Areas (IMMAs) and Cetacean Critical Habitats (CCHs), respectively.

Mediterranean monk seal habitat use in the Central Ionian, Greece

Panou, Aliki[1]; Bundone, Luigi[2]; Aravantinos, Panagis

Projects for the conservation of the Mediterranean monk seal in the Ionian Islands of Kefalonia, Ithaca and the islets of Atokos, Formicula, Kalamos, Kastos and Meganisi started in 1985 and were regularly carried out until 2002. Over that period, 140 marine caves/overhangs were registered and were surveyed on a regular basis with respect to habitat availability and the use by monk seals. A total of 40 caves/overhangs were found to be used at least once: 16 caves were regularly used, in 5 of which pupping was registered. In 2018, a photo-identification project was launched in this area aiming at (a) establishing actual seal numbers and (b) updating the use of caves. After thorough cave surveys (continued throughout the project), in May 2018 infrared cameras were installed in 8 caves out of those used most frequently in 1985-2002 including 4 of the 5 pupping caves, thereby strategically covering the entire study area. Up to November 2018, evidence of use was registered in 7 out of the 8 caves monitored. Thus, the general pattern of cave usage has not changed substantially since the aforementioned early studies, contrary to information on the situation from other parts of Greece. Only in 4 out of the aforementioned 16 caves, no evidence of seal use was recorded, all of them in W. Ithaca where coastal development/tourism have significantly increased compared to the past. Three out of the five known pupping sites were found to be still used for pupping including one cave not monitored by cameras. Up to six animals were recorded together in the same cave while previously only up to three seals were recorded simultaneously in a cave. These findings highlight the crucial importance of this area in the overall conservation and recovery of the species, particularly with respect to the Adriatic-Ionian region.

Acoustic response of bottlenose dolphins (Tursiops truncatus) to airgun noise in the Adriatic Sea (Italy)

Underwater airgun impulses can generate both acute effects, such as temporary/permanent threshold shift in marine mammals hearing, and behavioral reactions. Dolphins are able to adjust their communication signals in relation to fluctuating noise from natural or anthropogenic sources; however, little is known about the variation of communication signals during prolonged exposures to airgun impulses. This work aimed at evaluating the acoustic response of bottlenose dolphins to a continuous low frequency airgun emission in the Adriatic Sea (Italy). We examined 37dolphins' acoustic detections, 10 of which, corresponding to 10.3 hours, were recorded during 87 hours of airgun activity, occurred at about 180 km in Montenegrin waters, from 21th to 27th November 2018. 3D seismic surveys began off the coast of Montenegro on November 11th and ended on December 19th, 2018, using airguns firing approximately every 8 seconds at a depth range of 50–100m. Whistles occurrence and acoustic structure in presence of airgun noise were analyzed in 6 detections and compared to the ones collected in its acoustic absence, during the days before and after the emissions recorded. Whistles frequency parameters were modeled as a function of the intensity of airgun impulses. A higher whistles' occurrence was documented during airgun activities than in their absence, as well as the presence of different signature whistles, a greater whistles' modulation and diversity. These findings seem to indicate an increased communication effort by bottlenose dolphins, outlining a way airguns could potentially affect species' sociality and ecology through direct/indirect paths. The behavioral

responses of dolphins to acoustic stimuli vary widely depending on species, context, and properties of the stimuli. This study could help to better understand the extent to which bottlenose dolphins alter their vocalizations in the presence of airguns and provide evidences for predicting its potential effects on populations.

What whales say at night: Diel trends in the acoustic behavior of humpback whales on the North Atlantic feeding grounds.

Humpback whales are known for their diverse acoustic repertoire. Numerous studies have explored the spatial and temporal production of song by this species. Less is known about the non-song vocalizations used in social interactions on the feeding grounds. Significant diel trends in sound production have been described in many other baleen whale species, yet little is known regarding these temporal trends in social sounds produced by humpback whales in the North Atlantic, highlighting an important gap in our understanding of their acoustic behavior with relevance to passive acoustic detection. Previous studies have described primarily daytime acoustic signal production, with identification of two novel signal types recorded on some night tag data from the Gulf of Maine. In this study, we use suction-cup attached acoustic recording tags (DTAGs) to characterize the diel trends in acoustic repertoire usage of humpback whales in the Western North Atlantic on the feeding grounds off the coast of Massachusetts in the United States between 2016-2019. These tags record sensor and GPS data to provide temporal and spatial context to sounds produced by the tagged whale, combined with data on the acoustic environment experienced by the whales. We collected data including both day and night-time data from 8 humpback whales (19-45h recording duration) between 2016-2018, with additional deployments planned for the summer of 2019. We present an analysis of the acoustic repertoire by behavioral state recorded on the tags and assess the spatial and temporal trends in sound production in this habitat to explore variation in the acoustic behavior between day and night time periods.

Close-range received levels of Hawaiian monk seal (Neomonachus schauinslandi) underwater calls

Corresponding Author: keparnel@hawaii.edu

Aquatically mating phocids are known to produce underwater vocalizations during the breeding season. However, for the tropical Hawaiian monk seal (*Neomonachus schauinslandi*), the breeding season is protracted and underwater sound production has only recently been documented. This study provides the first amplitude estimates of underwater calls produced by a male Hawaiian monk seal. Spontaneous underwater vocalizations were recorded year-round from an adult male Hawaiian monk seal living in human care at Long Marine Laboratory, Santa Cruz, CA, USA. Six call types were identified. These were generally low-frequency, short-duration sounds with average peak frequencies ranging from 48 Hz to 292 Hz. Sound pressure level (SPL) was measured over the 90% duration of 20 to 40 calls of each type. Received levels at distances of 0 to 7 m ranged from 123 to 169 dBre 1 µPa. Mean SPL values per call type at distances of 0 to 7 m ranged from 137 to 153 dBre 1 µPa. Call types with relatively brief durations (< 600 ms) tended to have higher SPLs than the call types with longer durations (> 1300 ms). These bioacoustic data for Hawaiian monk seals can be used to determine upper boundaries of intraspecific communication ranges for these seals in different ambient noise conditions, and have implications for potential conservation and monitoring efforts using passive acoustics.

Assortative interactions revealed in a fission–fusion society of Australian humpback dolphins.

Understanding individual interactions within a community or population provides valuable

insight into its social system, ecology, and, ultimately, resilience against external stimuli. Here, we used photo-identification data, generalized affiliation indices, and social network analyses to investigate dyadic relationships, assortative interactions, and social clustering in the Australian humpback dolphin (*Sousa sahulensis*). Boat-based surveys were conducted between May 2013 and October 2015 around the North West Cape, Western Australia. Our results indicated a fission–fusion society, characterized by nonrandom dyadic relationships. Assortative interactions were identified both within and between sexes and were higher among members of the same sex, indicating same-sex preferred affiliations and sexual segregation. Assortative interactions by geographic locations were also identified, but with no evidence of distinct social communities or clusters or affiliations based on residency patterns. We noted high residency among females. Models of temporal patterns of association demonstrated variable levels of stability, including stable (preferred companionships) and fluid (casual acquaintances) associations. We also demonstrated some social avoidance. Our results point to greater social complexity than previously recognized for humpback dolphins and, along with knowledge of population size and habitat use, provide the necessary baseline upon which to assess the influence of increasing human activities on this endemic, Vulnerable species.

Population identity and occupancy characteristics of humpback whales (Megaptera novaeangliae) in the New York Bight apex

Cetacean research has historically been limited in the New York Bight apex (NYBA), which includes the Port of New York and New Jersey and adjacent waters. However, increased sightings, documented mortalities, and high levels of commercial and recreational activity suggest the need for a better understanding of humpback whales in this area. Opportunistic sightings and photo-identification data for 54 individuals from the New York City Humpback Whale Catalog were used to determine occupancy, occurrence, and annual return in the NYBA. Photographs were also shared with regional and basin-wide catalogs to determine the origins of these individuals and their exchange with other areas. Mean occupancy length in the NYBA was 30.5 days, mean occurrence was 2.3 days, and mean rate of return was 39.1%. Individuals photographed in the NYBA had sighting histories in the greater New York Bight area (Cape May, NJ and Montauk, NY) and in the greater mid-Atlantic region (Virginia). There were also matches to primary feeding grounds, including 36% (n=18) to the Gulf of Maine and 2% (n=1) to Newfoundland. Sighting records suggest that most individuals were immature when seen in the NYBA. There were within-season sightings with both Montauk and Cape May suggesting that individuals may utilize the entire New York Bight during the feeding season. The NYBA may be of increasing importance to juvenile humpback whales as a supplementary feeding ground.

The age of epigenetics: A molecular biomarker for ageing killer whales using DNA methylation patterns from skin.

Age is a key piece of demographic data contributing to an understanding of the age structure of populations, and critical for interpreting the behavior, ecology and health of individuals. Accurate chronological age estimates improve our ability to parameterize population dynamic models, infer individual and population-level effects from contaminants data, and predict disease impacts across the population as a whole. Common approaches for wildlife age estimation include counting patterns of annually accrued cemental deposition in mammal teeth and wax in ear plugs for mysticete cetaceans. More recently, acid racemization of the eye lens has been used to estimate ages of balenopterids. Unfortunately, these methods rely on tissues collected during necropsy or post-mortem processing. Attempts to age marine mammals from skin samples using changes in telomere length over time has been filled with both promise and pitfalls, and the relationship between telomere length and age has been found to be very weak in many species. Development of molecular biomarkers of age that could be applied to tissue biopsies would be beneficial for a variety of applications. DNA methylation (DNAm) is involved in gene expression, and age effects on DNAm have been documented in humans, humpback whales and other mammals. Age-related patterns of DNA methylation (DNAm) can be used to construct so-called "DNAm clocks" to quantify these changes in methylation patterns at specific CpG sites across the epigenome. Using skin biopsies, we developed a DNAm clock for killer whales based on 111 samples from the endangered Southern Resident killer whale population, including 90 known age killer whales born since 1971. Based on 100s of CpG sites, we built a regression model that is able to predict the age of an individual with a precision of 2.42 yrs. This species-specific model demonstrates the potential of DNAm as a molecular biomarker for aging living cetaceans.

Examination of combined isotopic signals as evidence for oceanographic regime shift within the Gulf of Maine.

Within the past fifteen years, the Gulf of Maine has experienced dramatic increases in temperature and impacts to the Gulf's marine ecosystem—including its population of baleen whales—are not yet fully understood. One hypothesis suggests that increases in temperature have reduced productivity, affecting prey distribution. Tracking changes in resulting prey choice is challenging; however, analytical methods such as stable isotope analysis (SIA) allow researchers to examine trophic dynamics in consumers over various time scales and assess ecological impact of possible oceanographic regime shifts. Here, we report the results of the first year of a five-year SIA study to examine the trophic dynamics of humpback (*Megaptera novaeangliae*) and fin (*Balaenotera physalus*) whales using samples collected *in situ* via a crossbow-delivered biopsy dart. The results were compared to those from a similar study, completed in 2003, prior to the latest warming period.

A multivariate analysis of our 2018 data suggests that fin whales (n = 2) have a lower trophic level signature in comparison to humpbacks (n = 13), similar to findings from prior to the warming period ($p < 0.0148$), specifically due to differences in $\delta^{13}C$ values ($p = 0.0384$). Although more samples are needed to increase statistical power, the 2018 isotopic signature for fin whales appears not to have changed since 2003. However, the 2018 isotopic signature for humpbacks appears to have shifted—specifically, $\delta^{13}C$ values have become significantly more negative ($p = 0.0002$), while $\delta^{15}N$ values have remained statistically similar. Using isotopic fractionation enrichment constants, humpback isotopic values map well to contemporary samples of Atlantic herring (*Clupea harengus*). Thus, we find that humpback isotopic values have changed to some extent over the past fifteen years. This may be because of changes in diet, or because of changes in prey isotopic values.

Social structure of bottlenose dolphins in the Hauraki Gulf, New Zealand

Patiño-Perez, Jessica[1]; Brunton, Dianne H.[2]

Corresponding Author: jjessicap@gmail.com

The social structure of a population has been described as the content, quality and patterning of relationships among individuals within a group. It is a synthesis of how individuals interact with each

other and is an important determinant of the biology of the population, influencing fitness, gene flow, and spatial patterns. Dolphins are gregarious animals that form complex social structures, from fission-fusion societies to social alliances. The North Island population of bottlenose dolphins in New Zealand was thought to be restricted to a single location; where the dolphins have been intensively studied. Recent studies have shown that the Hauraki Gulf, south of this location, it is also an important area for them. For the first time, we examined the association patterns among individually identifiable bottlenose dolphins in the Hauraki Gulf and therefore the social network structure of the dolphins frequenting this area. Data for this study were obtained from the Hauraki Gulf bottlenose dolphin catalogue between 2008-2013. We (i) describe the social structure of bottlenose dolphin in the area, (ii) determine the duration of association among individuals, and (iii) assess preferred/avoided companions among individuals. Results showed that of the 159 dolphins photo-identified in the study area, all were linked by association in one large social network. In general, dolphins exhibit weak associations (Mean HWI= 0.30 [SD=0.14]); however, some dolphins can associate with particular dolphins in this area (Max. HWI= 0.81 [SD= 0.16]). The associations in this area appear stable in the first 50 days, slightly decreasing after 110 days, but dolphins can have long-lasting preferred companionship in this area. The best fitting model for preferred/avoided companionships was casual (short-term) acquaintances and constant (long-term) companions. In this area, 44% of the dolphins observed at a specific time with a given dolphin will form long-term associations.

Can sustainable whale watching update on occurance of protected species? The common bottlenose dolphin (Tursiops truncatus) case in Maltese waters.

patrizia@ecomarinemalta.com.mt

The Maltese Channel above the Tunisian plateau is known to be of high ecological importance in the Mediterranean region (Notarbartolo di Sciara, *et al*. 2017). EcoMarine Malta has been performing the first 'whale' watching activities in Maltese waters with the aims of sustainable tourism and collection of scientific data on protected marine species (listed in the Habitat Directive and other multilateral environment agreements).

Visual and acoustic surveys were conducted in 2017 and 2018 (between May and September) in territorial waters, in bathymetry of 100 and 1,000 meters and an approximate area of 366 Km^2. Daily tours covered circa 32 nautical miles and included both the northern and southern coastal areas. During the surveys, the species sighted is the bottlenose dolphin (*Tursiops truncatus*) (N=10, 100% of the sightings). 80 % of the sightings occurred around the south-east fish farms. No sightings were however recorded during the above-mentioned tours, near the northeast fish farms. Fishermen's interviews confirm the presence of the species in the southern area also in winter. In contrast, in the north-west, where no fish farms are present, bottlenose dolphins are observed further off-shore, at a distance of about 6 nautical miles from the shore.

This preliminary data further confirm the attractiveness of fish farms for this species, as was observed in other Mediterranean areas. Further investigations are necessary to correlate species occurrence with different ecological features and human interactions, to better understand the species habitat selection around Maltese waters and aid the development of appropriate management strategies.

Counting what we cannot see: Estimating humpback whale availability bias using UAV.

Estimates of cetacean population size using counting or distance sampling methods require accounting for the proportion of animals that are unavailable to be detected at the time of the survey by surface-based observers. It is especially important for aerial estimates where aircraft speed leads to a short sampling window. To incorporate the so-called availability bias, land-based and more recently telemetry data have been used. From these data, the modelling of time an individual spends over and under sea surface can be used to adjust estimates of abundance. As an alternative to these approaches, we implemented UAV surveys to conduct focal observation of humpback whale groups off the Southwestern Atlantic Ocean during

the 2018 breeding season. Availability bias is estimated using Markov modelling, and the resulting estimate of bias is used to correct abundance estimates from an aerial line transect survey. Preliminary results indicate how important it is to model the same object unit as in the distance sampling survey (i.e., groups or individuals), the financial and analytical advantages of using only UAV data to estimate availability bias for short-dive cetaceans; and the potential of using UAV data to obtain unbiased estimates of group size. The main advantage of using focal follows is that UAVs have similar perspectives to that achieved from aerial surveys. In contrast, telemetry data can only inform us to whether an animal is at surface or not, but is unable to evaluate its availability since animals can be detected even when they are subsurface. This has the potential to underestimate availability bias which leads to overestimation of abundance. We argue that UAVs are a more realistic method to generate data for availability correction compared to the current methods in use.

Investigating the habitat use of coastal bottlenose dolphins (Tursiops truncatus) in response to a major hurricane

Extreme events provide a unique opportunity to understand how sudden changes in the environment can impact species and ecosystem processes. Hurricanes can cause drastic changes to aquatic ecosystems, with possible short-term changes to salinity, hypoxia, mangrove and seagrass loss, for example. In addition to the immediate changes to the environment, hurricanes leave lasting demographic effects on coastal populations. Studies in the coastal waters of the Gulf of Mexico and the Bahamas have shown that hurricane events caused changes in social structure, demography, and reproductive success of coastal bottlenose dolphins (*Tursiops truncatus*). There are, however, few studies that have investigated how behavior and habitat use might change immediately before and after a storm. In September 2017, Hurricane Irma, a category 4 storm, made landfall in South Florida, USA. Our study site, the Florida Coastal Everglades (FCE), recorded a storm surge of over 10ft at the mouth of the Shark River Estuary. Five CPOD (Chelonia Ltd., Cornwall, U.K.) passive acoustic monitors have been deployed as part of a Long-Term Ecological Research (FCE-LTER) to investigate the habitat use of bottlenose dolphins. CPODS were deployed across the Shark River estuary, from the mouth to upstream brackish waters, and were used to investigate how environmental conditions (pressure levels, wind speed, temperature, salinity, water levels) correlated with detections of dolphins at a fine scale (hourly) throughout the Shark River Estuary. Dolphin detections per minute (DPM) increased up to 4-fold in the upstream locations, starting two days following the hurricane landfall, and continuing up to two weeks. Investigating the immediate effects of hurricanes on habitat use of coastal species may provide insight on the magnitude of disturbance and how that may affect populations.

Translating the science of oceanic blue carbon into policy action to promote marine mammal conservation and climate change mitigation.

Corresponding Author: hcpearson@alaska.edu

Oceanic blue carbon refers to the natural processes whereby marine vertebrates trap carbon. We have identified nine mechanisms whereby marine vertebrates can store and sequester carbon. Marine mammals spanning all three taxonomic orders are involved in seven of these mechanisms. They include: 1) storing carbon in living and dead bodies; 2) stimulating nutrient flux to surface waters via excretion of waste products and mixing the surface layer, thus spurring phytoplankton growth; and 3) promoting kelp forest and seagrass growth. Recognizing the role of marine mammals in the carbon cycle is a potentially innovative and important strategy for combating climate change yet it has been overlooked in climate change mitigation strategies. If we can recognize the value of marine vertebrate carbon, many existing marine mammal conservation and management policies (e.g., establishment of marine protected areas, bycatch reduction, hunting and whaling regulations) could qualify as climate change mitigation strategies. With the recent passage of two International Whaling Commission resolutions recognizing the value of whales in ocean carbon storage, a global precedent has already been established. We present the latest state of knowledge on the role of marine mammals in oceanic blue carbon, including quantification of carbon storage and sequestration values. We identify knowledge gaps and future research needs. We discuss strategies for translating the science of oceanic blue carbon into national and international policy actions. A concerted effort by the marine mammal science community that includes integration of oceanic blue carbon data collection within current and future research programs, in addition to timely and effective

communication with policy makers and the public, could be pivotal in stimulating climate change mitigation action.

BaitSTR facilitates simultaneous large scale genotyping of STR loci in non-model organisms – a test case in deep-pedigree reconstruction of Indo-Pacific bottlenose dolphins

Increasingly accessible next-generation sequencing technologies have enabled genome-scale analysis of non-model species. Most studies that use next-generation sequencing focus on single-nucleotide polymorphisms (SNPs). However, for many questions in population genetics, SNPs are an insufficient or inefficient marker choice, particularly when studying short-term population-level events or when species show low genetic variation. Conversely, short-tandem repeats (STR) offer fine-scale resolution of recent demographic events and have a much higher information content per locus. The recently developed 'BaitSTR' approach facilitates the identification, development, and genotyping of thousands of STR loci through target capture and massively parallel sequencing. This method does not require a reference genome and is therefore highly amenable to use in non-model species. BaitSTR offers a data-dense and cost-effective solution to the impracticality of genome-scale analysis in natural populations. However, it has yet to be applied to population-scale data and still requires robust validation of genotype calls. We will evaluate the feasibility and accuracy of this approach through deep-pedigree reconstruction in a natural population of Indo-Pacific bottlenose dolphins (*Tursiops aduncus*) in Shark Bay (Western Australia). Pedigrees allow robust evaluation of population parameters, assessment of selective events, determination of the genetic basis of traits, and are a strong complement to behaviour data. We will provide genotypic data on 80 *T. aduncus* from a long-term study population with known relationships using a repurposed panel of 2499 STR loci developed with BaitSTR for Australian humpback dolphins (*Sousa sahulensis*). Ultimately, we posit that through pedigree reconstruction and comparison to known pedigrees, we can broadly assess the power and practicality of employing BaitSTR as the genetic tool of choice in non-model population studies

Acoustic communication is cheap in whistling dolphins

Toothed whales depend on sound for communication and foraging, which makes them potentially vulnerable to increases in anthropogenic noise. Some noise effects may be ameliorated by increases in amplitude or rate of calling, but such acoustic compensation mechanisms may incur energetic costs. Costs of whistling in the bottlenose dolphin (*Tursiops truncatus*) have been reported to be high (20-50% of resting metabolic rate) despite theoretical estimations (0.5-1% of resting metabolic rate). Here we investigated these contrasting claims by testing the hypothesis that whistling is metabolically expensive for bottlenose dolphins. We did this by measuring the change in metabolic rate in voluntarily participating fasted bottlenose dolphins during whistling and silent trials. The experimental protocol consisted of a two-minute baseline period to establish resting metabolic rate, followed by a two-minute static surface apnea, with or without whistling as cued by the trainers, followed by a five-minute resting period to measure recovery costs. Metabolic rate was measured using a custom-made breath-by-breath respirometer, and acoustic output energy was quantified using two calibrated hydrophones in front of the stationed animal. Daily fluctuations in metabolic rate were accounted for by subtracting the baseline metabolic rate from the recovery costs to estimate the cost of apnea with and without whistles relative to resting metabolic rate. A total of 52 sessions containing 1162 whistles were analyzed. We show that whistling added no significant metabolic cost (4.2 ± 6.9%) compared to that accrued during the static surface apnea control (-0.5 ± 5.9%), and these changes were significantly lower than the previously proposed 20% increase in metabolic rate. Thus, we reject the hypothesis that whistling is metabolically costly for bottlenose dolphins and conclude that vocal

adjustments such as the Lombard response to noise are unlikely to represent large energetic costs for communicating toothed whales.

"Measuring Glacial Ice Castles from the Sky" Using drones to quantify glacial ice habitats used by pinnipeds in Alaska

Pegus, Courtney[1]; Atkinson DeMaster, Shannon[1]; Quinn, Terry[2]; Pyare, Sanjay[3]
(1) University of Alaska Fairbanks

Corresponding Author: ccpegus@alaska.edu

Harbor seal (*Phoca vitulina*) populations have experienced significant declines which might be related to climate-driven changes to habitat. Approximately 10-15% of harbor seals in Alaska use tidewater glacial ice as substrate for pupping, molting, and resting, but these habitats are disappearing due to warming temperatures. Little is known about the fine-scale characteristics of glacial habitats used by these animals, making it difficult to identify and quantify habitat changes over temporal and spatial scales. The present study 1) evaluates the accuracy of using unmanned aerial systems (drones) to measure fine-scale dimensional characteristics of floating objects 2) evaluates the accuracy of using cameras mounted to electronic gimbal systems to measure fine-scale dimensional characteristics of glacial ice. Height measurements of objects were obtained from images captured from land, water, and air platforms, and statistically compared with the true heights of objects. There were no statistical differences between the true heights of objects placed on land or water surfaces and the calculated heights of these objects from images that were captured from the airborne UAS (χ2range1.8-0.39;n=;df=9;p=0.98), or the UAS placed on either water (χ2range10.8-1.89;n=5;df=9;p=0.98), or land surfaces (χ2=1.41;n=9;p=0.98). There were significant differences ($p<0.00001$;F=46.18) in the mean error ratios of measurements made for different surfaces. Images of objects (n=5) that were placed on land surfaces and captured from an air platform had the least mean error ratio (-0.009±0.01) compared to objects (n=5) placed on water surfaces and captured from the camera placed on a water platform (0.013±0.019) and objects (n=5) placed on a land surface and captured from a land platform (-0.022±0.024). Our study indicates that remote sensing is a highly accurate method to estimate measurements, but the platform type used to capture the images (F-Distribution(1,24)=33.68) as well as the distance between the object and image (F-Distribution(2,24)=11.32) had significant effects on the error ratio.

Can modelling the drift of bycaught dolphin stranded carcasses help identify involved fisheries? An exploratory study.

Between the 1st of February 2017 and the 31st of March, 793 cetaceans were found stranded along the French Atlantic coasts. 84% of them were common dolphins, and most of them presented evidences of death in fishing gears. The aim of this work is to test an approach that would help to identify the fisheries potentially involved in any given stranding events. To do this we examined how the likely distributions of mortality of bycaught dolphins inferred from carcass drift modelling coincide with fishing effort statistics in the same area at the same dates for different fleets, generated from the Vessel Monitoring System. Using reverse drift modelling, two main mortality areas were identify during these events, and 3 690 common dolphins (IC95% [2 230; 6 900]) were estimated to have died in fishing gears of the Bay of Biscay during February and March 2017. The relationship between origin of stranded bycaught dolphins and fishing effort distribution during the different stranding events was strongly positive for French midwater pair trawlers, Spanish otter bottom trawlers and French Danish seiners. Co-occurrence highlights a risk but does not presume of interaction of fishing effort on common dolphins nor its intensity. Beyond this diversity of gears, two characteristics appeared to be shared: targeting predatory fishes in winter (sea bass and hake) in winter and using high vertical opening gears.

Inferring the distribution of cetacean species in deep waters of Gabon. The potential of seismic prospecting surveys as a source of marine mammals data in data-scarce regions.

Pena, Ursula[1]; Vilela, Raul[2]; Bachl, Fabian
(1) Oceansea Conservación del Medio Marino

Corresponding Author: ursulapena@gmail.com

Gabon has recently approved the biggest network of marine protected areas in Central Africa. However, to date there have been no focused surveys of cetaceans outside the coastal zone. This information gap can be filled using data collected by marine mammal observers during seismic surveys in deep waters. Between 2013 and 2017, 13 surveys were conducted in Gabonese deep waters. A first estimation of cetacean distribution has been estimated for the region based on visual sightings and acoustic detections, combined with corresponding effort data. To this end, we assumed the spatial location of cetacean occurrences as a point process to propose a model-based inference using a spatial log-Gaussian Cox process. The method adopts a flexible stochastic partial differential equation (SPDE) approach to model spatial structure in density and Integrated Nested Laplace Approximation (INLA) for Bayesian inference. It allows simultaneous fitting of detection and density models and permits prediction of density at fine scale while specifically accounting for distance sampling and the local-scale dependence structure of the data. This methodology can be used to develop informed management plans and give insights of species distribution in data-scarce regions where offshore seismic surveys are available.

Entanglements Of North Atlantic right whales increase as their distribution shifts in response to climate change: The need for a new management paradigm.

Since 1980, the leading causes of mortality in North Atlantic right whales (*Eubalaena glacialis*) have been collisions with ships and entanglements in fishing gear, which combined caused an estimated 50% of all detected right whale deaths. In addition, 83% of all right whales display scars or carry ropes indicative of past entanglements in fixed fishing gear. Deaths from vessel strikes have declined as a result of recent legislation to reduce vessel speeds in right whale coastal habitats. However, despite a nearly 20-year effort by the U.S. National Marine Fisheries Service to reduce accidental kills of whales in fishing gear, no improvements in these rates of entanglement have been detected. In the present study, we used the North Atlantic Right Whale Catalog Photo-Identification Database to identify records of serious injury and mortality from entanglement. We found that entanglements increased significantly over a 35-year period, especially in the most recent decade. Since about 2009 the migratory phenology of right whales has changed dramatically. Right whales are no longer aggregating in most of their traditional feeding grounds during the expected times of year. Historic right whale habitats in the Gulf of Maine have warmed at an unprecedented rate. Changes in temperature and circulation have been linked to reductions in *Calanus finmarchicus*, the primary prey of right whales, and declines in residency patterns of right whales. Right whales are responding to a rapidly changing climate in realtime. In contrast, the resource management structure has not adapted to these changes. This phenological mismatch between humans and whales highlights the need for industry-wide blanket protective measures that will reduce or eliminate entanglement altogether. Reduced breaking strength ropes, ropeless fishing, and effort reduction are all options that should be considered throughout their range from Florida to Iceland.

Frequency patterns in humpback whale (Megaptera novaeangliae) song.

Corresponding Author: cperazio@buffalo.edu

Acoustic signals are a primary mode of communication for species in a variety of terrestrial and aquatic habitats. The need to exchange signals with conspecifics beyond visual proximity is especially important across large territories or home ranges, or for migrating species. Humpback whales produce songs that are highly structured. Despite the wide range of frequencies produced by humpback whale singers, and the fact that signal frequency determines how far sounds propagate underwater, little attention has been given to how singers organize their use of sound frequencies within songs. Based on the distances over which songs travel, we predicted that singing humpback whales consistently produce units with energy

focused in one or more specific frequency bands to maximize transmission efficacy. Songs recorded from 2013-2016 in the Gulf of Tribugá, Colombian Pacific suggest that not only do singers favor specific frequencies, but that they consistently concentrate their sound production within three frequency bands across years. One band spanning frequencies between 250-475 Hz is the most stable and consistently used band. Further analyses revealed that singers often cycle through predictable sequences of frequencies within song sessions. Transition probabilities between frequency bands show that singers commonly switch between medium and low bands, but not between low and high bands. Collectively, these findings suggest that singing humpback whales produce sequences of peak frequencies that are as predictable, and perhaps even more predictable, than the pattern sequences that traditionally have been the main focus of song analysis. Whether singers change their use of frequency bands in response to increased anthropogenic noise, social interactions, or as themes evolve over time, is an important question for future research.

Physiological response of an isolated population of bottlenose dolphins (Tursiops truncatus) to anthropogenic stressors, Bocas del Toro, Panama.

The Archipelago of Bocas del Toro (BDT), on the Caribbean site of Panama, is the home of a small and genetically isolated population of bottlenose dolphins. In Dolphin Bay, dolphins are regularly exposed to intense dolphin-watching interactions. Previous research has found evidence that intense vessel traffic and its associated noise can generate stress on marine mammals. This is of major concern in coastal areas where dolphin habitat overlaps with various human activities. The objective of this project was to determine if boat traffic increases the concentration of cortisol hormone, a common biomarker of stress in marine mammals, and the reproductive hormones (progesterone and testosterone). These steroid hormones were used to evaluate the possible negative physiological effects to dolphin watching activities. During the last three years we collected 26 remote biopsies samples using a PAXAMRS rifle system during high and low tourist season. Preliminary data shown that mean cortisol concentration of this population tended to be significantly higher (0.52 ng/g $\pm$ 0.31; mean$\pm$SD) during the high tourist season compared with the low season (0.26 ng/g $\pm$ 0.14); t-test $t(13)=2.30$, $p=0.038$, no significance relationship between cortisol and reproductive hormones have been found yet. Understanding the physiological consequences of boat traffic, particularly dolphin watching activities, will significantly contribute to current management and conservation efforts. These efforts may include changing this population IUCN designation from vulnerable to threatened at local level. Ongoing research includes the collection of biopsy samples from a control population of dolphins that is not involved in dolphin-watching activities.

Marked phylogeographic differentiation of sei whale based on mitochondrial DNA analyses from Northern and Southern Hemisphere populations

The sei whale, Balaenoptera borealis, presents a disjointed geographic distribution, with populations that are separated either by continental landmass, as in the Northern Hemisphere, or by the Intertropical Convergence Zone between hemispheres. Such distribution, together with patterns of seasonal

migration, could result in a strong phylogeographic structure. Significant genetic divergence between sei whale from the North Atlantic and North Pacific Oceans has been reported, however, limited samples from the Southern Hemisphere precluded a global analysis. The largest whale mass mortality event ever recorded for this species occurred in southern Chile, with at least 340 dead rorquals. This has become the largest source of samples for the species in the SH. Here we evaluate the population structure between sei whale populations, comparing the North Pacific n = 18, the North Atlantic n = 86 and the South Pacific (n = 87, including 14 skins and 61 bones from the Chile mass mortality), and the South Atlantic (n = 2). At a local level, mitochondrial DNA control region analyses from South Pacific recovered 33 haplotypes, eighteen of which are shared by two or more individuals. High values of haplotype diversity (h = 0.97) and nucleotide diversity (π = 1.01%) were found. At a global scale, phylogeographic analyses showed a strong genetic differentiation between the Southern Hemisphere and both North Atlantic (FST = 0.69, p = 0.001) and North Pacific (FST = 0.32 p = 0.001), and a possible migration event from South Pacific to North Atlantic. Together with other recent studies, our results point to a marked phylogeographic differentiation between sei whale in the North Pacific, North Atlantic and Southern Hemisphere, which may reflect the existence of three major population units. These results need to be complemented by more samples from other locations within the Southern Hemisphere and the use of nuclear

Whale watching activity as a useful tool to monitorize the population of bottlenose dolphin (Tursiops truncatus) in the Strait of Gibraltar

The Strait of Gibraltar is a unique habitat where up to seven different cetacean species can be found in the area throughout the entire year or in distinct seasons. These consist in either high level predators taking advantage of the highly productive waters due to the particular oceanographic conditions, or transient migrators moving between the Mediterranean and the North Atlantic. Over the last 20 years, the area has become a hotspot for whale watching activities which, when performed responsibly, can serve as an additional tool for cetacean conservation through established data collection protocols for opportunistic platforms. One of the most sighted resident species in the Strait is the bottlenose dolphin (*Tursiops truncatus*), with an extensive dataset collected during whale watching activities.In this study we have analysed photosale of bottlenose dolphin dorsal fins taken during the period 2011-2018 using photo-ID methods, in order to create a catalogue of the individuals seen during whale watching trips along the Strait of Gibraltar. Our aim is the assessment of social group composition of this species and the identification of any changes in time. Long-term photo-identification studies can provide insight into habitat use, movements, and life history characteristics of individual cetaceans at individual and population levels, adding valuable information for conservation efforts.

Assessment of anthropogenic disturbances due to ecotourism on a grey seal (Halichoerus grypus) colony in the Blasket Islands, SW Ireland.

Pérez-Tadeo, María; Gammell, Martin; O'Brien, Joanne
Galway-Mayo Institute of Technology, Galway, Ireland

maria.pereztadeo@research.gmit.ie

Wildlife-oriented tourism has experienced a rapid growth in recent decades. While ecotourism aims to promote conservation, its actual impacts on wildlife and populations must be assessed, especially during critical stages of the life cycle. The grey seal (*Halichoerus grypus*) is a protected species in Ireland and therefore, its population is subject to monitoring programs. Consequences of anthropogenic disturbances due to ecotourism are being assessed on a grey seal colony over pre-breeding, breeding and mating seasons in the Blasket Islands Special Area of Conservation (SAC), SW Ireland. Here, the tourist season overlaps with part of the pupping period, and consequently the most sensitive time in terms of potential disturbances. Disturbance might adversely affect the fitness of this species by reducing resting and nursing times, forcing them into the sea and leading to abandonment of offspring. Impacts of ecotourism are being evaluated by investigating differences in the behaviour of grey seals hauled out on the beach between undisturbed and disturbed conditions due to approaching ferries, powerboats and walking tourists. Response distance of seals to approaching ferries is also taken into account. Preliminary results show a more frequent display of vigilance behavior (mean ± SD = 21.82 ± 11.46% of seals) and less proportion of

resting seals (62.34 ± 13.13%) under disturbed compared to undisturbed conditions (6.26 ± 3.10; 73.70 ± 15.79% of seals vigilant and resting respectively). The results of this study have identified the need for increased conservation efforts as well as a strict code of conduct for boat users in the area to reduce the effect of disturbance.

The one that got away? Evidence of failed predation events between a grey seal (Halichoerus grypus) and a harbour porpoise (Phocoena phocoena).

Corresponding Author: matthew.perkins@ioz.ac.uk

The relatively recently observed phenomenon of harbour porpoise (*Phocoena phocoena*) predation by grey seals (*Halichoerus grypus*) has been well documented in Europe over the last few years. These include numerous observer records, photos, videos, as well as multiple porpoise carcasses being recovered around the UK coastline with pathological evidence of grey seal interactions. Evidence obtained from these examinations include characteristic teeth and claw marks and the removal of large areas of blubber. However, as with all predator-prey interactions, the success rate is not 100%. The UK has conducted necropsies on four porpoises that suggest that the initial non-fatal interaction between the two species resulted in a bacterial infection with *Streptococcus phocae*. In all cases investigated the initial route of infection was suspected to be via penetrating cutaneous injuries found on the tail stock. The injuries found were consistent with bite marks from a set of canine teeth, the measurement of which indicated that these had most likely been made by adult male grey seals. The seal bite most likely led to the *S. phocae* infection, subsequent loss of condition and ultimately the death of the porpoises. In 3 out of 4 cases *S. phocae* was isolated from samples of the brain and in the fourth case from the liver. The tale stock lesion (bite wound) of one individual was also found to have severe infectious processes, with a large volume of purulent material present and highly reactive tissue around the puncture wounds. *S. phocae* was isolated directly from this site. The interval between the initial bite and eventual death is unknown, but the generally poor nutritional condition of the animals examined suggests this may have been a prolonged period.

Welfare in the wild: The status and future research needs of UK marine mammals.

Concerns regarding marine mammal welfare have grown significantly in the last century, often focussing attention on negligent practices by animal performance and aquaria. The welfare of wild marine mammals, however, receives less attention, despite the implications of poor welfare. Welfare in this context can be defined as meeting the environmental and biological needs of a marine mammal, e.g. food supply, habitat, physical health, thus diminished welfare is defined as failing to meet these needs. This can cause a wide range of adverse impacts such as reproductive failures and beaching. Fatal threats to marine mammals, such as whaling, have received significant public support, whereas researching and improving the welfare of marine wildlife through the lens of whether its needs are being met is as an overlooked theme. This is reflected in the lack of consideration of marine welfare in the planning and management of marine spaces.

We have undertaken a review that assesses how welfare has been examined compared to changes in behaviour and physiology in marine mammals. We considered research articles published in the UK from 1990-2016 and scored studies based on their interpretation of welfare. The results of this review indicate that welfare is both misrepresented and underrepresented in the current literature. Welfare is seldom explicitly examined, rather it is assumed or not appropriately investigated. We find there to be a distinct lack of studies examining chronic poor welfare, and identify this a key research need. To better inform management decisions relating to welfare, greater research focus should be given to the chronic implications of not meeting the environmental and biological needs of marine mammals, particularly from emerging and geographically underrepresented threats. Proportionate mitigation should be adopted by decision-makers using a precautionary approach where evidence is lacking

Temporal trend of intestinal ulcers in the Baltic grey seal (1977-2016).

Persson, Sara[1]; Roos, Anna[2]; Rigét, Frank[3]; Bäcklin, Britt-Marie

The Baltic grey seal *(Halichoerus grypus*) can be heavily infected by acanthocephalan parasites (*Corynosoma sp*) in the ileocaeco-colonic region and ulcers are often seen in the area at necropsy. To investigate temporal and spatial trends of these lesions, intestines from 2172 seals from 1977-2016 were examined.

The erosions and ulcers in the intestinal mucosa were evaluated on a 4 degree scale: < 4 mm erosions (0), 4-10 mm erosions (1), > 10 mm erosions or ulcers (2) and > 10 mm ulcers also affecting the muscular layer (3). Lesions of moderate (2) and severe (3) degree were considered to be pathological (and referred to as ulcers). The number of acanthocephalan parasites in colon was not counted as there can be thousands of them, but evaluated as no (0), slight (1), moderate (2) or severe (3). Generalized models assuming a binomial error structure were applied to test of the influence of age, year, area and parasites on the occurrence of ulcers.

An increase in prevalence of ulcers was observed in the early 1980s and up to mid/late 1990s, followed by a decrease until 2016. The overall frequency of ulcers was 43% in the Bothnian Sea, 38% in the Bothnian Sea and 23% in the Baltic Proper. Since about 2000 the temporal trend in the three areas have been similar (decreasing from about 50% to 20%).

Perforation of the colonic wall was the cause of death in 26 of the investigated Baltic grey seals. One of them was less than one year old and the others were 1-37 years old. As far as we know, only one case of intestinal ulcer in grey seals has been reported outside the Baltic Sea (Baker, 1980), so this adverse health situation seems unique to grey seals in the Baltic Sea.

Should I stay or should I go? Grey seal pups disperse widely in the southern North Sea.

Grey seal numbers in the southern North Sea have been increasing over the last 50 years, and thus their role in the ecosystem has become more and more important. However, little is known about their spatial utilisation of the southern North Sea, especially in relation to the dispersal of grey seal pups after weaning. We investigated these little-known aspects by recording the movements of 11 grey seal pups born at the largest German colony (Helgoland) between 2015 and 2017 for between one and nine months after leaving the colony. The individuals moved widely throughout the southern North Sea, some individuals moved long distances, along the Danish coast or to Dutch and UK waters. Based on a point process modelling approach we were able to show that pups strongly increased their distance to Helgoland already in the first weeks and also generally during the first 70 days at sea. We furthermore found that the foraging behaviour increased in frequency until week four which indicates that grey seal pups increasingly used their environment for foraging during these weeks after weaning. Our findings reflect the transition from naïve to more experienced pups which gradually increase their foraging effort and range to cover their increasing energy demand for survival and growth. This study contributes to our knowledge of the spatial utilisation of the southern North Sea by an increasingly important top predator, its behaviour as well as changes of these aspects with increasing age of the pups.

Feeding at depth: Insights into the feeding habits of an opportunistic delphinid revealed by stable isotope analysis.

As apex predators extensively influence of their environment, knowledge about their feeding strategies and trophic ecology is crucial for ecosystem management. Although short-beaked common dolphins (*Delphinus delphis*) are widely distributed and abundant, we know very little about their foraging ecology except for limited stomach content studies. Generally perceived as opportunistic predators that feed locally on abundant small pelagic schooling fish, common dolphins are frequently bycaught in related fisheries. Obtaining direct observations of feeding

habits of oceanic species is challenging. However, stable isotope analysis can provide useful insights into recently ingested and assimilated prey. This information can then be used to evaluate the short-beaked common dolphin's potential exposure to commercial fisheries bycatch.

We investigated the effect of age, sex, and season on the diet of short-beaked common dolphins in the Hauraki Gulf, New Zealand, using stable isotope analyses of carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$) on skin samples from stranded animals between 2004 and 2016. Tissue samples of potential prey species (previously identified from stomach content analyses) were sampled in 2018. Isotopic values of dolphin and prey tissues were then processed using MixSIAR models to determine the relative proportions of different prey assimilated.

Juvenile had higher $\delta^{15}N$ values than adults, suggesting ontogenetic dietary changes. Nitrogen isotope values were higher in austral autumn/winter compared to spring/summer, whilst $\delta^{13}C$ values decreased throughout the study period, suggesting temporal changes in primary productivity. Sex had only a minor effect on $\delta^{13}C$ values, with males and females isotopic niches overlapping by 55%. MixSIAR modelling revealed that 84.1% of the dolphins' diet consisted of species predominantly occurring in deep waters. These results highlight the importance of deep-water prey for Hauraki Gulf short-beaked common dolphins. This is surprising given the time they spend foraging in shallow waters of the gulf. Foraging in deeper offshore waters increases their susceptibility to fishery interactions and may explain current bycatch concerns for this population.

Mass stranding and unusual sightings of northern bottlenose whales (Hyperoodon ampullatus) in Skjálfandi Bay, Iceland

Beaked whales, such as the northern bottlenose whale (*Hyperoodon ampullatus*) are odontocetes characterised by their extreme, deep-diving behaviour and are therefore rarely seen in coastal and shallow waters. During summer and autumn 2018, unusually high numbers of northern bottlenose whale sightings, in addition to strandings of multiple beaked whale species, were reported around the coast of Iceland. These events coincided in time with the beaked whale Unusual Mortality Event (UME) around the British Isles. To determine the principal drivers behind these events, it is essential to collate the available information. Here, we describe a series of unusual sightings and strandings of northern bottlenose whales in Skjálfandi Bay, Iceland, between July and October 2018. We used opportunistic platforms, specifically whale-watching vessels and land-based observations, to record sightings and to collect photographs and behavioural data. Twenty-four individuals were identified through photographic analysis. Within the whole period, we observed a drastic change in the behaviour, diving patterns and sightings distribution of animals, together with a decrease in body condition and severe skin lesions. At least six individuals died in the bay during four separate events. A first adult female live stranded a month after the first sighting, soon followed by the live mass stranding of three sub-adult females. Finally, a dead stranded juvenile of unknown sex was found, as well as an adult female floating in the bay. To our knowledge, this is the first description of such extreme events for northern bottlenose whales. These findings will add to our current knowledge of the species and hopefully contribute to determining the drivers behind the UME of beaked whales across the North-east Atlantic during summer and autumn 2018.

The North Atlantic right whale consortium: A model for advancing science and conservation of marine mammals.

Research collaborations on all aspects of a species' biology throughout its geographic range are critical for effective marine mammal conservation. Challenges to such collaborations include sharing data and developing standardized data-collection protocols and frameworks to manage access to the data. The North Atlantic Right Whale Consortium (NARWC), formed in 1986 by five organizations independently studying the endangered North Atlantic right whale along the east coasts of the United States and Canada, is an example of a collaboration that successfully met these challenges. The NARWC's goal to coordinate research efforts and protocols and share data among these founding organizations facilitated a broader understanding of North Atlantic right whale biology and conservation needs, including critical information on distribution, reproduction, mortality, and anthropogenic impacts. Expanding on this success, the NARWC developed an open membership model that now includes research and conservation organizations, industry stakeholders, and municipal, state, and federal agencies in both the United States and Canada. Committed to the open exchange of information, the NARWC oversees multiple right whale databases, submissions to which are voluntary yet comprehensive. The NARWC database frameworks include well-defined QA/QC protocols, open access for management data requests, and peer review of access requests for research and publications. These approaches have resulted in many collaborations, multi-group publications, and a broad community understanding of detailed aspects of North Atlantic right whale biology. An annual meeting, a public website (narwc.org), and an annual "report card" are used to disseminate the latest information on right whale science and conservation progress and needs. The NARWC has served as the cornerstone for right whale research and conservation since its inception and its data sharing and collaborative framework is unparalleled in the marine mammal arena. Such an approach serves as a model for establishing other species related consortia, particularly for threatened and endangered populations.

Data deficient! A review of zoo record-keeping for captive bottlenose dolphins in Germany.

Pfender, David; Williamson, Cathy
Whale and Dolphin Conservation, Chippenham, United Kingdom
Corresponding Author: David.Pfender@whales.org

Data was obtained from the husbandry and veterinary records of 25 common bottlenose dolphins (*Tursiops truncatus*) held at the Tiergarten Nűrnberg (TgN) in Nuremberg, Germany between the years 1989 - 1991 and 2000 – 2014.

A systematic review of the data revealed that the records were neither standardized nor regularly recorded. Therefore, it was impossible to evaluate the behaviour and health of the dolphins in a scientific way.

A number of different drugs were administered to the dolphins, with Diazepam the most commonly administered. Aggressive behaviour and injury to both dolphins and staff were also recorded , as was calf mortality and the transfer of dolphins between facilities.

Under the requirements of the EU's Zoo Directive, EU member states must ensure all zoos implement a number of conservation measures, including "keeping of up-to-date records of the zoo's collection appropriate to the species recorded". This requirement is also mirrored in legislation implementing the Zoos Directive in Germany.

Open source, autonomous, camera system to facilitate the monitoring of Mediterranean monk seal caves

Pfyffer, Julien[1]; Gonzalvo, Joan[2]; Georges, Cédric[3]

Mediterranean monk seal *Monachus monachus* is the rarest seal species in the world and it is classified by IUCN conservation as Endangered. An Open Source, autonomous and connected time-lapse camera monitoring system was designed, assembled and installed in the Greek Ionian islands between May-November in 2018 and 2019 to test its feasibility as a possible affordable tool to assess the site-fidelity and distribution of the species. The first two prototypes were assembled using standard but sturdy electronic components in an attempt to keep the total price low (< 2000€) while being able to monitor simultaneously outside and inside a remote and partially flooded coastal cave, where monk seals rest and reproduce. Preliminary tests in 2018, monitoring two different caves found on the Northern tip of Kefalonia Island resulted in monk seals being recorded on two occasions and provided regular monitoring of human activity (e.g., boats, kayaks and divers) in the vicinities of the caves. Technically, both deployed systems

proved to be autonomous using solar energy from beginning of June to mid November, successfully recording pictures 85% and 92% of the time respectively. Cameras were set to trigger images every 15 minutes during day and night. These images were recorded locally on a USB key and remotely sent to a server in Switzerland using a 3G/4G router. This way researchers could not only have access to the generated data from anywhere, anytime (e.g., on their tablets or smartphones) but, most importantly, it provided immediate back up of the data stored locally in case it got accidentally damaged or even stolen. A third system will be installed on an inlet in the Inner Ionian Sea Archipelago, where monk seals are regularly observed and regular visits by tourists (i.e., disturbance) pose an important threat.

Microplastics in marine top predators - A pilot study from German waters.

Plastics build a high share of marine debris pollution in our oceans. Next to large debris objects detectable by the naked eye, the fractions beyond visible detection came into focus of modern research in recent years. The so-called microplastic particles (MPPs) operate as accumulators and circulators of toxins, chemicals, bacteria and viruses. Especially, marine mammals as top predators are susceptible of accumulating both. Besides, the physical impacts of MPPs are widely unknown. Before the impacts and effects of MPPs can be fully understood, the presence and extent within the gastrointestinal tract (GIT) have to be assessed. Therefore, the occurrence, amount and composition of MPPs in top predator species need to be investigated.

GIT samples of stranded marine mammals found on the coasts of Schleswig-Holstein (Germany) were collected during regularly conducted necropsies since 2014. The target species are the regularly occuring top predators in German waters: harbour porpoise [*Phocoena phocoena*], harbour seal [*Phoca vitulina*] and grey seal [*Halichoerus grypus*]. We investigate 10 stomachs, 60 intestine samples, and 30 faeces samples collected on a sandbank, to assess the occurrence of MPPs in the GIT of the target species since 2014.

Furthermore, the already established method by Bravo Rebolledo (2013) was improved and the utilisation decreased secondary pollution and conservable loss. Moreover, the found MPPs were successfully identified by Nile Red staining using a fluorescence microscope and were verified, a by Raman spectroscopic analysis for polymer identification.

With those valuable data collection, we were able to analyse the occurrence of MPPs in the GIT of marine mammals from German waters for the very first time.

The investigation on marine debris occurrence of all sizes and its impacts on marine biota and habitats are essential for implementing the European Marine Strategy Framework Directive (MSFD).

The relationship between polychlorinated biphenyls in blubber and levels of nematode infestations in harbour porpoises, Phocoena phocoena, using standings data from 1992-2012.

Post-mortem examinations of harbour porpoises, *Phocoena phocoena*, regularly reveal heavy parasitic worm burdens. These same post-mortem records show varying levels of polychlorinated biphenyls (PCBs) accumulating in the blubber of porpoises. Using a data set comprising harbour porpoises stranded in the UK between 1989 and 2002, previous research has shown a positive relationship between parasitic worm burdens and PCB accumulation in harbor porpoises. However, overall levels of PCBs declined sharply during that period and may be below proposed concentration thresholds for negative health effects. Here, we ask the question whether the relationship between parasitic worm burden and PCB accumulation still exists, using data gathered between 2002-2012. Overall, we find that there is still a positive relationship but this is more pronounced in parasite burdens recovered from the cardiac stomach than bronchi or pulmonary arteries. Suppression of the immune

system is the proposed mechanism for increased parasite susceptibility and our findings suggest that the legacy of PCB pollution continues to have adverse effects on harbor porpoise health in UK waters.

Studying the effects of ocean properties on the diving ecology of Weddell seals using hidden Markov models.

Corresponding Author: tp14@st-andrews.ac.uk

Weddell seals are a resident Antarctic species occurring on the fringe of the continent and are highly adapted to living in the sea ice year-round - a highly seasonal, highly dynamic environment. The Weddell Sea is unique compared with other parts of the Antarctic where Weddell seals occur. It has a wide continental shelf and is an important area for understanding how climate affects ocean circulation via dense seawater formation. There are early signs that Weddell Sea physical ocean dynamics are changing, making it important to characterise the relationship between seal behaviour and ocean properties in this area. To improve our understanding of longer term (e.g. weekly, monthly or seasonal) relationships between diving behaviour, oceanographic variables and bathymetric features, we model dive variables as time series, including haulout and surface behaviour to consider a more complete behavioural time series. We use a multivariate hidden Markov model (HMM) to estimate behavioural states along the time series of behaviour recorded for individual seals. Maximum dive depth, duration, and hunting time are used as state variables in the HMM. We specify haulout and surface behaviour as known states in the model, while estimating the parameters of the state variable distributions for four dive states. We use data collected from 19 adult seals tagged in the Weddell Sea in the austral summer of 2011. We use both classical and hierarchical HMMs to analyse tracking data collected using animal-borne sensors and compare the inferences. Our results suggest that seals spend more time hunting during deeper, longer dives. We show that these deep dives are associated with the seasonal inflow of modified Warm Deep Water onto the continental shelf in the southeastern Weddell Sea.

Distribution, density, and habitat use of harbor porpoises, Phocoena phocoena, in Frenchman Bay, Maine in relation to cruise ship presence
Pielmeier, Kate
College of the Atlantic, Allied Whale, Southwest Harbor, Maine
Corresponding Author: kpielmeier19@coa.edu

Bar Harbor, Maine is a popular cruise ship destination for several months of every year. In the last three years, the number of cruise ship visits to Bar Harbor has dramatically increased. Little is known about the effect of cruise ship presence on harbor porpoise distribution or density in general let alone in the Gulf of Maine. Although the primary threats to harbor porpoise are gill nets and entanglement, cruise ship noise pollution and presence may impact nearby harbor porpoise presence similarly to noise pollution from acoustic harassment devices or offshore wind turbine construction and operation in European waters. Six C-PODs (Chelonia Limited) were moored in Frenchman Bay at fixed depths but varied distances from cruise ship anchorages in the harbor. Acoustic data were collected from June to November in 2018. The variables interclick interval, clicks per second, and detection positive minutes were analyzed by cruise ship presence and absence. Interclick interval is significantly higher during cruise ship absence than presence. Clicks per second are significantly higher when cruise ships are present. Finally, harbor porpoise detection positive minutes decrease significantly in the presence of cruise ships. Data collection will continue for those months in 2019.

UAV derived photogrammetric assessment of Mediterranean monk seal Monachus monachus body-length and condition
Pierantonio, Nino; Gonzalvo, Joan
Tethys Research Institute, Milano, Italy
Corresponding Author: nino.pierantonio@protonmail.com

Measurements of body-size and mass can be used to understand several ecological and life-history traits of a species and are key towards the assessment of an organism's body condition, a proxy for its ecological fitness. We obtained body-length measurements and assessed body condition of Mediterranean monk seals *Monachus monachus* observed in the Inner Ionian Sea (Greece). Given the species' reclusive habits, direct manual morphometric information is difficult to gather. We obtained nadiral photographs using an unmanned aerial vehicle (UAV) and applied a photogrammetric approach to obtain standard body-length and width details. These were subsequently used to derive an index for body condition (BCI). UAV onboard camera and altitude sensors were previously calibrated to obtain a regression equation relating flight elevation and pixel distances measured on photographs. High-resolution images were extracted from videos

recorded during each flight and linked to flight data. During three flights, over 64 minutes of video were recorded and 311 images were extracted and later used for photogrammetric analyses. Average derived seal standard body-length and BCI were 148.8 cm (range= 103.1-189.6 cm) and 4.6 (range= 3.6-5.7), respectively. While repetitive measurements were obtained for each same individual seal, no interannual recaptures were obtained preventing the evaluation of annual growth and changes in BCI. This study is the first to apply UAV technology and photogrammetry methods to assess body-length and condition in Mediterranean monk seals. Although preliminary, our results show that this non-invasive approach provides a valuable tool to monitor this reclusive species. Using simple metrics such as body-length and condition, the influence of a variety of environmental and physiological factors can be evaluated. In this context, our results therefore pose the basis for further research with the potential to provide pivotal information to inform management and conservation of an Endangered charismatic species.

Patterns and trends in cetacean occurrence revealed by Shorewatch, a land-based citizen science programme in Scotland (UK)

Shorewatch is a citizen science project, organized by Whale and Dolphin Conservation, that records the occurrence of cetaceans during regular standardised watches (duration 10 minutes, spaced at least 1 hour apart) from a series of locations along the coast of Scotland (UK). Observer training and a clearly define protocol help deliver a valuable source of information about cetacean occurrence and activity along the coast. Since 2005, over 52000 watches have generated over 11000 sightings of at least 18 cetacean species, In addition to species, time and location of sightings, observers record group size, presence of calves, and sea state. Statistical models of sightings rate for the most commonly sighted species (bottlenose dolphin, harbour porpoise and minke whale) demonstrate seasonal, geographical and year-to-year differences in occurrence. Thus, bottlenose dolphin sightings show a clear seasonal cycle, highest in May and lowest in November. Harbour porpoise sightings declined from 2013 to 2014 but increased again until 2016. Minke whale sightings increased steadily from 2012 to 2017, peaking in May to July. While the bottlenose dolphin sightings rate was highest in Spey Bay (near Elgin in the Moray Firth), harbour porpoise and minke whale were most frequently sighted at Tiumpan Head (Isle of Lewis). The power to detect declines in local abundance (sightings rate) over a 6-year period (following European legislation) depends on the underlying sightings rate, the number of watches and the rate of decline. Based on the highest sightings rate (for bottlenose dolphins at Spey Bay in June) and assuming a binomial distribution of sightings per watch, around 500 watches (each year) are needed for an 80% likelihood of detection of a 10% per year annual decrease. Ongoing review and analysis of data from this successful citizen science programme will identify best practice and ensure usefulness to scientists and policy-makers.

Guiana dolphins increase group cohesion after playbacks of bottlenose dolphin sounds

Two cetacean species, Guiana dolphins (*Sotalia guianensis*) and bottlenose dolphins (*Tursiops truncatus gephyreus*) co-occur in a coastal area in southern Brazil, with an apparent habitat partition. This segregation can be motivated by ecological factors, such as habitat preference and competition. However, a local record of an agonistic interaction between these species suggests that Guiana dolphins might avoid bottlenose dolphins due to risk of aggression. In this work, we tested whether Guiana dolphin responds to the sounds of bottlenose dolphin through a controlled playback experiment. We used aerial images from a drone to detect surface behavior changes in Guiana dolphins by comparing periods before, during and after the exposure. Four exposure sessions were performed, with six minutes of videos per session, two minutes for each period/treatment. From these video footages, we extracted 281 frames with dolphins visible in the surface. Aerial videos were recorded

at standard altitude (~50 meters), and we use the number of individuals in each extracted frame as a proxy for group cohesion. Thus, our group cohesion proxy was used as response variable in a generalized linear mixed model (GLMM) to test if the response varied in function of period/treatment of the experiment and the number of previous exposures to playbacks during the day (from 0 to 2). We found that during and after the exposure, the Guiana dolphins group tended to be more cohesive. In addition, we found that there is a sensitization, as cohesion was higher whenever there were previous exposures to the playbacks in the same day. Although this is a preliminary result, this tendency of Guiana dolphins to be closer to each other seems to be a response to the presence of an imminent risk of aggression. Thus, fear of aggression appears to shape group behavior of Guiana dolphins in this population.

Diet ecology assessment of cetaceans and Mediterranean monk seals stranded between 2017 and 2019 on Samos Island, Eastern Aegean Sea, Greece.

An assessment of the digestive system content was performed for 19 dolphins (*S. coeruleoalba*, *T. truncatus* and *D. delphis*) and 5 *M. monachus* found stranded along the shores of Samos Island, Eastern Aegean Sea, Greece. According to the condition code of the carcasses, a complete or partial assessment of the digestive system content and morphometric measurements were performed. Prey and other items, such as marine litter, were isolated and categorised, a taxonomic classification was performed and conserved when possible. Percentage by number (%N), percentage frequency of occurrence (%FO), percentage by weight (%W) and Index of Relative Importance (IRI) were used to investigate the occurrence and relative importance of the prey. Despite some stomachs being found empty, the results of the study show a pelagic and demersal prey species composition for both cetaceans and *M. monachus*, indicating surface and benthic feeding habits. The local dietary assessment needs improved tools and efforts to investigate the distribution range and the role of these species within the marine environment, including the interaction with important ecosystem services such as fisheries. Further molecular analyses, diet-habitat associations, prey selection and foraging mechanisms studies are required on stranded and alive individuals to fully understand their ecology in the study area. Such research is crucial to empower efficient conservation strategies especially for those species like *M. monachus* and *D. delphis* which are facing a drastic decline caused by anthropogenic impacts.

Ultrasonographic blubber thickness changes and body condition determination during rehabilitation in harbor seal (Phoca vitulina) pups.

Pinnipeds, as most marine mammals, possess a specialized fat layer in the subcutaneous tissue called blubber that supports multiple functions (thermoregulation, reproduction, and buoyancy). The thickness of this fat layer is frequently used as an indicator of body condition, nutritional status, and health. In the current study, 34 harbor seal (*Phoca vitulina*) pups that were admitted for rehabilitation at the Sealcentre Pieterburen in June 2018, were subjected to ultrasonographical (US) investigations. A portable ultrasound scanner with a 3.5/5 MHz convex probe was placed in the pectoral region over the xiphoid process to assess the blubber thickness. The ultrasound image was comprised of fur, skin, subcutis, which contains the blubber, musculature, and thoracic cavity. The echogenicity of these anatomical structures increased with animal growth and its visualization was, therefore, better as the animals grew. The combined skin and blubber thickness were measured at arrival and repeatedly during the rehabilitation process. Later, they were correlated to several morphometric parameters (weight, length, and axillary girth); which showed a positive correlation between blubber thickness variation and all the morphological parameters, most significantly with the animal's weight (R2 = 0.8208). One of the aims of the project was to

assess if ultrasound was a reliable tool to measure blubber thickness; and it was demonstrated that the technique was useful, as the ultrasound measurements were consistent with manually-taken measurements performed during post-mortem examinations. Finally, ultrasonography-based body condition scoring (BCS) was compared with standard BCS classification (nine-point scale). Some differences were found between the two BCS systems; in particular the categorization of seal pups with BCS ranging from three to five was more challenging compared to the categorization at the extreme classes. In conclusion, ultrasonography has been proven to be an objective and useful instrument to assess the body condition of harbor seal pups admitted for rehabilitation.

Environmental DNA effective for cetacean research in all regions? A case study of seawater sampling in the presence of killer whales (Orcinus orca) in the Northeast Atlantic.

Whilst environmental DNA (eDNA) is becoming increasingly established in biodiversity monitoring of freshwater ecosystems, the use of eDNA surveys in the marine environment is still in its infancy. Here, targeted quantitative PCR (qPCR) and Whole Genome Enrichment Capture followed by shotgun sequencing was used in an effort to amplify killer whale DNA in seawater samples collected in close proximity to killer whales off south Iceland and from pelagic fishing vessels targeting Atlantic mackerel (*Scomber scombrus*) in Scottish and Irish waters. Samples were collected both inshore and offshore, in varying sea conditions and from the surface and subsurface but none returned strongly positive detections of killer whale DNA. Laboratory methodologies were validated by successfully amplifying a dilution series of a positive control of DNA extracted from killer whale blood from a captive individual. Furthermore, Atlantic mackerel DNA was successfully amplified from the same seawater samples. Positive eDNA detections of mackerel, which was present at all sites during sampling, were found for almost all samples. The various eDNA collection and amplification methodologies used are discussed, along with the abiotic and biotic factors that influence eDNA detection. Possible explanations for the lack of killer whale positive detections are provided along with consideration for potential pitfalls and the apparent limitations of eDNA for genetic research on cetaceans, particularly in offshore regions.

Mercury speciation and stable isotopic composition in marine mammals: New insights and perspectives.

Mercury (Hg) is a persistent toxic compound whose amount in the global biosphere has at least tripled since industrialization. Recently, the study of the seven Hg stable isotopes has emerged as a new promising technique affording to explore the Hg cycle both in situ and in laboratory. Mercury stable isotopes display both mass dependent fractionation (MDF, reported as δ^{202}Hg) and mass independent fractionation (MIF, reported as Δ^{199}Hg and Δ^{201}Hg). Our recent findings about Hg accumulation in the European seabass, *Dicentrarchus labrax*, showed how the combination of Hg isotopic values with Hg speciation allow tracing back Hg environmental sources as well as metabolic pathways within the organisms. However, such interpretation gets more complicated in more physiologically complex animals such as seals. With the aim of study basal Hg kinetic in an top predator without the influence of distribution and diet specialization, we measured T-Hg levels, speciation and isotopic composition in 6 captive pups of hooded seals, *Cystophora cristata,* and their diet the Norwegian herring *Clupea harengus*. The main objective was to select the tissue in which the information about Hg pathways would be conserved, leading to the optimal tracing of Hg sources along the food web. MMHg ranged between 84 to 98% in hair, 74 to

95% in muscle, 7 to 38% in liver and 4 to 27% in kidney. A significant ^{202}Hg enrichment resulted between seal hair and herring ($p = 0.011$), indicating important MDF between the ingested prey and these tissues. Instead, a significant MIF (Δ^{199}Hg and Δ^{201} values) was observed only between seals' kidney and herring ($p = 0.0003$). Our results showed that hair represents the best tissue for the analysis of Hg biomagnification along food webs; and that with the exception of kidney, MIF signal is conserved in all tissues during assimilation of prey items.

Monitoring marine mammals and floating marine litter in the Western Mediterranean's transect: The new Barcelona-Tangier trans-boundary transect.

The Mediterranean Sea is one of the most polluted seas in the world but at the same time it hosts a number of threatened species, including sea turtles and cetaceans. Several monitoring programs are active across the basin to estimate abundance, distribution and trends of these populations. On a long term basis, the Fixed Line Transect (FLT) Mediterranean network joints international research organizations (*e.g*. universities, NGOs) to systematically monitor using passengers ferries the presence of marine mega-fauna (*i.e*. cetaceans, sea turtles, seabirds) and its threats, specifically marine litter. We here present the results obtained from the new trans-boundary fixed transect implemented since November 2018 in the Western Mediterranean Sea along the route Barcelona-Tangier. This new transect, made possible through the collaboration with the Grimaldi Lines Company, covers approximately 1200 nautical miles from Barcelona (Spain) to Tangier (Morocco) and back. The whole transect is completed in 4 days and, thanks to the departure times from the two harbours, the portions of transect covered in daylight during the onward and the return routes are complementary. During each transect, one dedicated observer monitors marine mega-fauna from each side of the ferry, using the distance sampling method. A further observer monitors marine macro-litter using the strip-transect method according to the standardised protocol defined by the MEDSEALITTER project. A fourth volunteer records the information collected by the observers. Data obtained from this monitoring transect will fill the gap of information available on the presence of marine mega-fauna in this scarcely studied area. The route will also cover on a long-term basis the recently designed "Corredor de migración de cetáceos del Mediterráneo" protected area. Furthermore, data on marine litter would provide baseline information for future assessment of this threat in the area as well as the information necessary to plan prevention, mitigation and conservation measures.

Conservation status of the Mediterranean monk seal Monachus monachus population at Madeira archipelago

The small Mediterranean monk seal population of Madeira has been protected since 1988, when only 6-8 individuals were estimated to survive at uninhabited Desertas Islands. The conservation measures undertaken then resulted in a population growth and in an enlargement of the distribution area towards Madeira island. The overall current conservation status of this population was evaluated, based on a study developed from 2012 to 2018, using phototrap cameras to monitor the caves used by seals, GPS tracking to identify foraging areas, observers on board fishing and whale watching boats and a monk seal information network. In 2018, the population size is of 20 individuals older than 1 year, showing a slight recovery trend. Its recovery is limited by a low survival rate during the first year of age (0.38), and a low mean annual reproductive rate (0.51). The high first year mortality is related to breeding in marine caves, limited feeding resources and interactions with illegal fishing traps. The foraging habitat has been identified to be restricted to very coastal waters up to 200 m depth, and the poor conservation status of the marine environment in this area supports the idea of limitation of food resources as one of the main concerns for this population. A differential adult mortality by gender due to direct persecution is also suggested, since although sex-ratio at birth is 1:1, adult females are 3,3 times adult males. All the caves used by the

seals for hauling out and breeding are located inside protected areas.

With this new information, the conservation program that is being conducted in Madeira needs to be re-oriented and an updated Action Plan for the Conservation of the monk seal in Madeira is being developed to minimize detected threats and ensure the long-term survival of this population.

Modelling the functional link between movement, feeding activity and condition in a marine predator.

The ability to quantify animals' feeding activity and the resulting changes in their body condition as they move in the environment is fundamental to our understanding of a population's ecology. We use satellite tracking data from northern elephant seals (*Mirounga angustirostris*), paired with simultaneous diving information, to develop a Bayesian state-space model that concurrently estimates an individual's location, feeding activity, and changes in condition. The model identifies important foraging areas and times, the relative amount of feeding occurring therein and thus the different behavioral strategies in which the seals engage. The fitness implications of these strategies can be assessed by looking at the resulting variation in individuals' condition, which in turn affects the condition and survival of their offspring. Therefore, our results shed light on the processes affecting an individual's decision-making as it moves and feeds in the environment. In addition, we demonstrate how the model can be used to simulate realistic patterns of disturbance at different stages of the trip, and how the predicted accumulation of lipid reserves varies as a consequence. Particularly, disturbing an animal in periods of high feeding activity or shortly after leaving the colony was predicted to have the potential to lead to starvation. In contrast, an individual could compensate even for very severe disturbance if such disturbance occurred outside the main foraging grounds. Our modelling approach is applicable to marine mammal species that perform drift dives, and can be extended to other species where an individual's buoyancy can be inferred from its diving behavior.

Morphological plasticity of the respiratory system in cetaceans: Advances and its correlates to physiology.

Despite extensive research on the morphology of the cetacean respiratory system (reviewed in Piscitelli et al., 2013), there is still considerable mystery of how this system has mechanically adapted to a strictly aquatic environment and to withstand both rapid and extreme pressure changes associated with ventilation and diving. In this study, we shed light on new structural variations of the cetacean respiratory system that have direct mechanical and physiological consequences and give morphological evidence for ideas where there were only hypotheses before. We summarize detailed morphological adaptations across six families of cetaceans. This study revealed that all cetacean lungs have a monopodial branching pattern with morphometrics that create an overall low resistance to airflow. In addition, all species had discontinuous spiralling cartilage that extends through the terminal airways to the level of the alveolar duct, a smooth muscle/elastin network that creates sphincters in the terminal airways, and a double capillary network with one on each side of the alveolar septum. Cetacean lungs are exposed to changes in pressure both during breathing and during diving, and thus lungs of species that fill different ecological niches vary in degree of enhancement of these anatomical adaptations in order to meet the demands of that environment. For example, results showed that the terminal airway sphincters of the shallower diving, faster-ventilating species possessed a 2-fold decrease in elastin and collagen, a 2-fold increase of smooth

muscle and were 3.2-fold larger (more robust) with an 8-fold increase in abundance and more regular distribution compared to the deeper diving, slower-ventilating species. Based on morphology observed, the cetacean respiratory system can be classified into three general types of breathing-diving strategies with each strategy optimized for specific mechanics, physiology, and phylogenetic history.

Monitoring a critical population of the Bolivian river dolphin (Inia boliviensis) before and after closing the floodgates of a hydroelectric dam in the Amazon Basin, Brazil: A sample design issue.

Dam construction threatens aquatic fauna, degrading their habitat and causing population fragmentation. In this context, environmental impact studies were carried out from March 2010 to July 2015 as part of the licensing process concerning the Jirau Hydroelectric Dam construction, located on the Madeira River, Brazil, aiming to assess its impacts on the local fauna. The dam closed its gates in December 2012, creating a ~303 km^2 reservoir. *Inia boliviensis* presents a restricted distribution in Northern Bolivian and Brazilian rivers, which may be aggravated by dam interference. This study aimed to assess the presence of *I. boliviensis* before (BDC) and after dam construction (ADC), also evaluating if the sample design for this assessment was appropriate. Active dolphin searches were performed applying linear transects along the four sections of the river: Abunã, Mutum, Caiçara and Canteiro. About 986 hours of total effort were carried out during 40 days along 250 km of the river in falling, low, rising and high water levels. A total of 24 sightings were recorded BDC in the direct dam influence area (N = 49), while 42 sightings were documented ADC (N = 120). Abunã presented the highest number of records during both periods (BDC: N = 37; ADC: N = 107). A higher number of dolphins was detected during the falling and low seasons (BDC: N = 44; ADC: N = 92). This is expected, due to water level decreases and the highest concentration of dolphins in areas presenting higher food availability. An adequate statistical analysis was not possible, due to the unsatisfactory sample design and non-standardized data collection by different research groups. Implementing a standardized methodology, alongside experienced specialists during the entire survey period, is essential to provide adequate estimates for the monitoring of this population, assuring the best survival conditions for these dolphins.

Effects of coastal development on Indo-Pacific humpback dolphin habitat use in Hong Kong.

Corresponding Author: piwetz@hotmail.com

Hong Kong is one of the most densely urbanized coastal communities in the world, where ongoing development activities are a potential threat to Indo-Pacific humpback dolphins (*Sousa chinensis*). Several large-scale development projects in the waters north of and adjacent to Lantau Island, Hong Kong, contribute to anthropogenic noise and vessel activity in near-shore waters, with unknown consequences to dolphins. Although dolphins appear to be somewhat resilient to habitat alterations, abundance has significantly declined in the waters around Lantau Island over the past decade. We examined shifts in animal behavioral activity states and spatio-temporal presence near marine construction projects north of Lantau Island. Land-based observations and theodolite tracking were conducted discontinuously between 2012 and 2016 from seven locations historically used by dolphins. A total of 636 groups of dolphins were recorded totaling 151 hours of tracks. Data on eight proximate marine construction projects underway during sampling periods were obtained from the Government of the Hong Kong Special Administrative Region. Zero-inflated negative binomial hurdle models were plausible, indicating that season, time of day, and construction activity were important factors for predicting presence/absence of dolphins. Dolphin track duration was significantly lower during the spring and significantly lower in areas within 5km of chronic construction activity (θ=1.19, $p<0.001$). Dolphin presence off two locations that were relatively high in previous years, dropped to zero in 2016, concurrent with an increase in the number of nearby construction projects. Long term impacts of habitat displacement may depend on the duration of the disturbance, the quality and proximity of alternate available habitat, and the potential for historically used habitat to recover. One important management tool is designation and effective enforcement of suitable Marine Protected Areas (MPAs), particularly where site fidelity has been described, which may give refuge to dolphins displaced from highly-disturbed adjacent waters.

Individual strategies are determining factors to gain insight on harbour and grey seals' foraging ecology

Identifying the foraging behaviour of marine top predators with accuracy is essential to study their ecology. Individual strategies often have a critical influence on foraging ecology, and lacking to take them into account can bias the identification of feeding areas and behaviour at the colony scale. Our study aimed at identifying the foraging strategies of eight harbour seals (*Phoca vitulina*) and six grey seals (*Halichoerus grypus*) fitted with GPS/GSM tags by analysing their horizontal movements and dives, as well as stable isotopes ($\delta^{15}N$) in their whiskers. All harbour seal individuals exhibited foraging dives close to their haulout site (HL) (11±9.8km in average) in similar areas. $\delta^{15}N$ signatures were similar among individuals ($p>0.05$, 16.3±0.5‰) suggesting that they all foraged on prey of the same trophic level. Grey seals exhibited stronger inter-individual differences in foraging strategies, as shown by $\delta^{15}N$ signatures ($p<0.001$). Two main types of strategies were distinguished from a cluster analysis on stable isotopes. Two grey seal individuals presented foraging strategies similar to the harbour seals' one: their foraging areas were close to HL (17.9±10.4km) and they displayed a similar trophic position ($\delta^{15}N$ signature of 16.5±0.8‰). However, the four other grey seals foraged much further (foraging dives at 145.7±75.4km from HL) and displayed a higher trophic level ($\delta^{15}N$ signature of 17.9±0.5‰). This was supported by individual Minimum Cost of Transport Speed (MCTS, calculated from dive parameters) which was lower for individuals foraging closer to HL (1.6±0.1 $m.s^{-1}$ for harbour seals and 1.7±0.1 $m.s^{-1}$ for two grey seals) and higher for those foraging further (2±0.1 $m.s^{-1}$ for the four other grey seals). This study clearly identified intraspecific differences in individual grey seal foraging strategies. This suggests that identifying such differences in behaviour within a marine top predator species is essential to better interpret their foraging ecology at the colony scale.

Spatial distribution and connectivity of common bottlenose dolphin (Tursiops truncatus) communities along the eastern Adriatic coast

Long-term photo-identification studies on bottlenose dolphins (*Tursiops truncatus*) at two sites in the Croatian Adriatic Sea, corroborated with a genetic study, suggest that the population is structured into discrete local communities. However, the two study areas were far apart and did not encompass whole home ranges of the studied local communities. In 2013 field work expanded to include a new study area between the two existing ones. We used photo-identification data from the three contiguous study areas to determine social structure of bottlenose dolphins and to examine the spatial distribution and connectivity of the identified communities. The hierarchical cluster analysis, based on half-weight indices (HWI) of dolphin pairs, revealed three communities separated at HWI=0.011 threshold. We then used 95% Kernel Density Estimator (95% KDE) to estimate home ranges for individuals and calculated home range overlap ratios for each pair of individuals. The HWIs and 95% KDE overlap ratios were moderately correlated (r=0.58) and significantly higher for pairs within the same community than between communities, indicating both social and spatial segregation. The 95% KDE home ranges calculated for each community showed little to no overlap between them. The analysis of movements revealed that most individuals stay within their respective community's home range. The movements of individuals between community home ranges were low (3.8%) and sporadic. Based on results, at least three socially and spatially distinct, but not isolated communities inhabit the 300 km stretch along the Croatian Adriatic coast encompassed with this study. The future research and monitoring programs may profit from knowledge of their putative home range boundaries, as it can be accounted for in study design. Ultimately, the management of four Sites of Community Importance, which overlap with the three community home ranges, may use these results to

tailor conservation plans to specific needs of each community.

Spatial and temporal variation occurrence of Risso's dolphin (Grampus griseus) in southwestern coast of Portugal
Poças, Ana; Magalhães, Sara
Mar Ilimitado, Sagres, Portugal
Corresponding Author: pocas.ana@gmail.com

The presence of Risso's dolphin (*Grampus griseus*) has been documented in the Azores and Madeira archipelagos, but in mainland Portugal it has been very poorly studied. From 2005 to 2018, a total of 4342 opportunistic surveys were carried out by a qualified observer on board dolphin watching tours in Sagres, resulting in a total of 7375,79 h of search effort under Beaufort Sea state £3 and up to 12 Nm off the coast. Weather conditions, GPS position and survey track, depth, SST, group size and composition, and behaviour were collected.

Sighting Index (SI), Abundance Index (AI) and Kernel estimates were calculated in order to investigate the seasonality and habitat use. During the study, 83 Risso's dolphin sightings were registered, of which 72 during search effort. Sighting distance to shore ranged between 0.3 and 9.3 Nm (4.06 ± 0.27) and depth between 20 and 716 m (118.74 ± 13.18) (n=83). The occurrence of the species was not constant through time, being absent in two study years, and not recorded in the months of January, March or December, which can however be a result of a smaller effort during winter months. Spring (SI=0.016) and Autumn (SI=0.017) showed peaks in sightings (n=72), possibly related to seasonal migrations/movements due to changes in water temperature and prey availability.

Estimated group size varied between 1 and 100 (10,70 ± 1.48) with no significant variance between seasons. Calves were present all year round, which could indicate proximity to reproductive areas which are not well identified yet.

Although studies based on opportunistic surveys have limitations, they provide highly valuable information that otherwise would be unavailable. In this case, this opportunistic platform allowed the first insight into the coastal occurrence of this species in Southwest Portugal and during a relatively long period (14 years).

Recolonization of a grey seal /Halichoerus grypus/ in Polish Baltic coast

Together with the increase of the grey seal *Halichoerus grypus* number in the Baltic Sea the recolonization of its southern coast has been observed. First appearance of several individuals on the islets in the mouth of Vistula river has given an opportunity to record the settlement process of this unique haul-out. Year-round video monitoring station was established in 2010. The results collected so far allow to estimate the size of the seal group over the seasons but also provide the knowledge on their behavior in changing environment, inter-individual interactions, life cycle and human activity contributing to the disturbance in the area. These information is crucial for the development of a guidelines for touristic boats and enable direct reaction on disturbing human behavior. Moreover records of large groups of moulting seals in April and early May may contribute to re-consideration of the period of international census of grey seals in the Baltic Sea so far performed during the agreed moulting season at the turn of May and June.

Evidence of intestinal polycyclic aromatic hydrocarbon (PAH) DNA adduct formation links PAH exposure to gastrointestinal cancers in St. Lawrence Estuary Beluga.

Exposure to cancer-causing PAHs produces covalent PAH-DNA adducts. DNA adducts constitute biomarkers of exposure, which are also considered necessary for progression to cancer. In the Saguenay River of the St. Lawrence Estuary (SLE, Quebec, Canada) a unique population of beluga was exposed for 50 years (1926 to 1976) to large amounts of PAH waste dumped directly into the river from aluminum smelters using the Söderberg process. For many subsequent years high levels of PAHs were documented in the atmosphere, the river sediments and the beluga food supply. These exposures are considered etiologically related to gastrointestinal epithelial cancers observed in 7% of 156 mature (>19 yr old) adult beluga stranded between 1983 and 2012. Because PAH-DNA damage is chemically stable, we hypothesized that SLE beluga intestine would contain DNA with a measurable burden of PAH damage. To explore this possibility, we incubated sections of paraffin-embedded intestine with antiserum specific for DNA containing bases modified (damaged) with carcinogenic PAHs. We examined paraffin blocks of intestine taken from beluga in the contaminated areas SLE (n=51, 0-63 yr) and Cook Inlet (CI) Alaska (n=4, 0-26 yr), and beluga from relatively uncontaminated areas including Arctic regions (Eastern Beaufort Sea, Eastern Chukchi Sea, Point Lay Alaska) and aquaria (n=20, 0-46 yr). Nuclear light-to-dark pink color, indicating the presence of PAH-DNA damage, was found concentrated in intestinal crypt epithelial lining cells. The H-Scoring system, applied to coded photomicrographs, confirmed that SLE and CI beluga had levels of intestinal PAH-DNA damage significantly higher than the Arctic and aquarium beluga ($p = 0.003$ for SLE, and $p = 0.02$ for CI). In addition, intestinal epithelial cells from 4 SLE beluga with intestinal cancers contained particularly high levels of PAH-DNA damage, suggesting a link of causality between PAH exposure and intestinal cancer in SLE beluga.

Alternative of species distribution models using R and Python in the study of bottlenose dolphin in the Veracruz Reef System, Mexico.

The study of biotopes and the species distributions for communities have concerned the biogeography area to understand the existence, as well as the flow of life of the flora and fauna, considering climatic, biotic and environmental features for their aims. This refers that one of its tasks focuses on gestating predictive models for the activity of the specimens within a defined geographic space, through environmental data collected and under the basis of statistical and mathematical techniques. This research study was designed to present as an alternative the Python and R Project programming languages for the generation of species distribution models since they are free software and with accessibility to perform data analysis in various areas. The analysis was carried out from the information obtained about the bottlenose dolphin (*Tursiops truncatus*), a species which lives in the Veracruz Reef System located in the Gulf of Mexico, for the manifestation of the importance of this species and an identification of the distribution patterns within the residing biome. According to the data analyzed, three models were obtained, the first to locate the distribution of the dolphin, the second which predicts the presence of the species and finally the third model that calculates the absence of the dolphins. In conclusion, the programming languages used for this application had good efficiency and effectiveness to analyze this type of data. In addition, extensive results such as data cleaning, creation of vectors, models, predictions and visual representations (maps) were obtained using the different libraries and packages.

The times, they are a'changin: How longitudinal parturition dates of Scottish grey seals Halichoerus grypus affect colony birth curves.

Synchrony in breeding can structure sub-groups within a population. Timing of breeding at UK grey seal colonies follows a clockwise cline from

SW to SE. In Scotland, mean pupping date (derived from aerial survey, 1986-2016) at a colony with declining pup production, North Rona (NR, Outer Hebrides) varied from 06Oct-16Oct, at the Isle of May (IM, Firth of Forth) with recently stable pup production, it varied between 26Oct-05Nov.

Colony-specific mixed models were used to investigate how a mother's parturition date (PD) was affected by intrinsic variables (maternal identity, age, mass at parturition) and a Year effect in longitudinal data from known individuals, over nearly 4 decades (1978-2014). We asked if observed changes in colony average pupping dates were likely due to changes in the age/size composition of animals present or to common responses to large scale environmental (Year) effects.

Age and mass ranges of sampled mothers were similar but on average NR mothers were older and heavier: (mean±sd: NR 19.2±6.4yr, range 4-36yr, n=101: IM 16.6±6.3yr, range 5-40yr, n=135: NR 187±22kg, range 127-253kg : IM 176±24kg, range 109-264kg). At each colony, mean pupping dates of sampled mothers tracked colony means.

At NR, PD was highly variable between individuals, became earlier with maternal mass and became earlier with age . At IM, PD was also highly variable between individuals and became earlier with maternal mass, but varied as a quadratic function of age. Linear Year effects in mixed models indicated a mother's PD became later at NR (+0.26d/yr) but earlier at IM (-0.1d/yr), suggesting different regional influences.

Based on effect sizes, NR's gradual increase in mean birth date is likely from loss of older females and environmental effects, while IM mean birth dates vary more than expected in a numerically stable colony and could indicate intermittant breeding colony use by some mothers.

Navigating through people and systems to enable marine mammal science and conservation - a Malaysian/Southeast Asian Odyssey

The Indo-Pacific finless porpoise (*Neophocaena phocaenoides*) is one of 27 species of marine mammals found in Malaysian seas. Although an ubiquitous species throughout much of Southeast Asia, scientific information on finless porpoise distribution, habitat use, feeding habits and bycatch risk remains limited. Coupled with the species' apparent lack of charisma (i.e., small size, inconspicuous behaviour) when compared to delphinids and whales, it does not attract the same attention warranted to those other cetaceans, yet there are growing concerns over its conservation status. The Langkawi Archipelago, a UNESCO World Geopark, is a cluster of tropical islands off the north-western coast of Peninsular Malaysia. In 2018, the area was recognized as an Important Marine Mammal Area (IMMA), largely owing to the significant presence of finless porpoises, with Langkawi considered as one of the most ideal locations in the region to observe this elusive species. Systematic boat-based surveys in 2010 – 2013 totaling 117 survey days, 5498 km and 370 h of search effort found that the species was the most frequently encountered cetacean in Langkawi (n = 294 sightings), with an estimated abundance of 900 – 2000 individuals in an area measuring 1616 km^2. Boat-based surveys in 2016 – 2018 also found that the porpoises are still the most frequently encountered cetacean species in Langkawi (n = 148

sightings). Group sizes ranged 1 – 73 individuals, being some of the largest groups ever recorded in this region. However, 17 cases of dead porpoises recorded since 2010 (plus probably more unrecorded), with three occurring within the span of four days in 2018, puts the species' conservation status into concern. A Bycatch Risk Assessment will be presented highlighting the magnitude of risk the porpoises face in Langkawi. It is necessary that conservation attention be given to this highly overlooked porpoise both in Langkawi and the overall IMMA.

Strong impact of epizootics on long-finned pilot whales (Globicephala melas) in Strait of Gibraltar

The Strait of Gibraltar is one of the world's areas with more maritime activity, and cetaceans inhabiting this area, as is the long-finned pilot whale population, are threatened by noise and chemical pollution, overfishing and collisions by the many boats crossing the strait. One of the greatest threat identified until now for the species in the Mediterranean are epizootics that severely affect the most sensitive vital rate in long live species: adult survival. By multi-event analysis of a 16 years' database of photo-identification capture-recapture data, we analyse adult survival in the Strait of Gibraltar resident population and evaluate the effects of epizootics. We identify the severe effect of an epizootic morbillivirus episode occurred in 2006, but we also evidence a second collapse in survival in 2011, probably due to an another morbillivirus epizootic. These episodes seem to differently affect both sexes, with females being less affected than males. Interestingly, morbillivirus epizootic not only sharply decreased survival after the episode but the effect extended over time, probably showing a post-epizootic chronic effect. Epizootics seem to be dramatically frequent in the Gibraltar area. These lethal disease outbreaks are often the consequence of herd immunity decline that could be linked to anthropogenic threats like organochlorine contamination, thus the strong maritime activity and contamination at the area may put this population and the whole ecosystem at higher risks of epizootics. We warn about the conservation status of the long-finned pilot whale population and suggest revising their conservation classification at a local scale. We also advise to apply measures to reduce contamination on this nutrient-rich to improve conditions for many marine species inhabiting this area.

Prevalence of ulcers provoked by Anisakis spp. in cetaceans from the Northwest Atlantic: A signal of a long-term increase in anisakis populations?

Species of nematodes of genus *Anisakis* infect cetaceans worldwide. The life cycle includes crustaceans as intermediate hosts, fish and cephalopods as paratenic (transport) hosts, and cetaceans as definitive hosts, in which worms typically reproduce in the stomach. These nematodes are of significant health concern because they can infect humans, provoking anisakiasis, and/or eliciting allergic reactions. In cetaceans, individuals of *Anisakis* spp. often generate ulcers, which, in severe infections, can perforate the stomach wall causing peritonitis and, eventually, death. In this study, we report on ulcers provoked by *Anisakis* spp. in cetaceans stranded in the Northwest Atlantic along 2017-2018, and compare the frequency of occurrence and severity of these ulcers with data from a study carried out in cetaceans stranded in the same area during 1990-1996. Open ulcers were found in 32 of 43 short-beaked common dolphins, *Delphinus delphis*; 1 of 7 bottlenose dolphins, *Tursiops truncatus*; 3 of 5

striped dolphins, *Stenella coeruleoalb*a; 1 of 3 harbor porpoises, *Phocoena phocoena*, and 0 of 1 long-finned pilot whale, *Globicephala melas*. In the cetacean species with an acceptable sample size, i.e. common dolphin, the mean abundance of ulcers per dolphin was 1.1 ± 0.9, and their average diameter 24.9 ± 16.7 mm (range: 3-80 mm). Scars of old ulcers were found in 3 additional common dolphins. Areas with extensive fibrosis (maximum diameter ranging from 50 to 210 mm) occurred in 9 dolphins. Compared with common dolphins in the period 1990-1996, there has been a very significant increase of ulcer prevalence (74.4% vs. 15.0%) and abundance (1.1 vs. 0.22). Although we cannot rule out that common dolphins currently suffer from more environmental stress, thus being more susceptible to the pathological effects of *Anisakis*, these results support the possibility that *Anisakis* populations have increased in the area over the last decades.

Are lungworm infections in the striped dolphin, Stenella coeruleoalba, higher during DMV outbreaks?

Pool, Rachel[1]; Chandradeva, Nilani; Gkafas, Georgios; Raga, Juan Antonio[1]; Fernández Martínez, Mercedes[2]; Aznar Avendaño, Francisco Javier[2]

(2) Instituto Cavanilles de Biodiversidad y Biología Evolutiva (Universitat de València), Valencia, Spain
Corresponding Author: rachel.v.pool@gmail.com

Mediterranean striped dolphins, *Stenella coeruleoalba*, suffered two mortality outbreaks caused by the dolphin morbillivirus (DMV) in 1990-92 and 2007-08. In the first outbreak, at least two contributory factors have been linked to non-random mortality caused by the virus. In particular, high level of pollutants and inbreeding depression could have enhanced susceptibility of individual dolphins to DMV effects. An open, interesting question is whether dolphins killed by DMV also harboured unusually high parasite loads. This pattern could either reflect low immunocompetence and/or play a contributory role in generating mortality. In this study, we examined this hypothesis by focusing on lungworm infections in 92 striped dolphins that stranded along the Mediterranean coast of Spain in the summer and autumn between 1987 and 2018. Animals were grouped into three periods, i.e., dolphins that stranded in 1990-92 (first epizootic); dolphins that stranded in 2007-08 (second epizootic); and dolphins from other years (non-epizootic). Prevalence and intensity of lungworm infections were analysed using GLMMs with period, host body length and gender as fixed effects and year as a random effect. Although the intensity of lungworm infection in the first epizootic period (mean intensity: 42.41, 95% CI: 27.50-69.68) was higher than that from the second epizootic (mean intensity: 19.00, 95% CI: 8.50-29.50) and the non-epizootic period (mean intensity: 34.96, 95% CI: 19.09-62.09), only host body length (regardless of period) had a statistically significant effect on infection parameters. Accordingly, we found no evidence that dolphins affected by DMV had unusually high burdens of lungworms. However, we must bear in mind that the non-epizootic sample consisted of stranded dolphins, which do not necessarily represent the natural population and, therefore, the purported association between parasitism and DMV is open to further analysis.

The coastal acoustic buoy: A new tool for remote and real-time acoustic monitoring.

Porter, Lindsay[1]; Lee, Arthur[2]; Wood, Jason[3]; Turner, Jesse[3]

The Coastal Acoustic Buoy (CAB) represents a new generation of passive acoustic monitoring devices for marine species and underwater noise monitoring. There are currently two versions; a lightweight design housed in a floatation collar that can be deployed from a small boat and a robust cylindrical pack that can be installed on existing large buoys, therefore enabling deployment in more offshore areas. The lightweight version has a battery life of 14 days and the installation version has a battery life of 35 days. A choice of up to three channels and various sampling rates (maximum 500 kHz) provide multiple configurations and maximum flexibility. In conjunction with PAMGaurd software, marine mammal echolocation clicks, whistles and other tonal calls can be identified with existing detectors and classifiers designed for baleen whales, dolphins and porpoise. Modules can also be utilised measure ambient noise levels in rms, 0-peak, peak-peak and SEL across a customisable range of frequencies and time scales. Processed data can be sent real time using radio link to a base station or near real time via the cellular network and raw acoustic data is stored onboard. To date, CABs have been successfully deployed in Hong Kong, for Indo-Pacific humpback dolphins (*Sousa chinensis*) and the USA, to detect harbour porpoise (*Phocoena phocoena*) and orca (*Orcinus orca*). As with all PAM systems, the range of detection is dependent on species and site-specific conditions. Such a

flexible tool can provide large amounts of information in a relatively short period of time on marine mammal species that are elusive, rare or, most importantly, of conservation concern. Thus, conservation authorities are empowered to make meaningful management decisions in shorter time periods.

Are current European Environmental Impact Assessments (EIAs) sufficient for odontocete conservation during offshore wind farm development?

Potlock, Kelsey[1]; Bythell, John[2]; Berggren, Per[3]
(1) Newcastle University, Spring, Texas
(2) Newcastle University, Newcastle upon Tyne, United Kingdom
(3) Newcastle University, School of Natural and Environmental Sciences
Corresponding Author: whales4ever@gmail.com

Offshore wind farms (OWFs) are a growing strategy across Europe to meet renewable energy goals. Many OWFs are located in coastal environments where they overlap with the ranges of several cetacean species, creating a potential conflict between energy production and species habitat requirements. A key tool to support effective environmental stewardship in Europe is the Environmental Impact Assessment (EIA), as required by European Directive 85/337/EEC. As a measure of accountability and preparation, EIAs are used to gauge possible human impacts on the environment and allow for mitigation techniques to be applied as needed. However, current guidelines for EIAs are not a precise mechanism and are open to interpretation regarding implementation and Developer reporting requirements.

The goal of this study was to examine previously conducted EIAs focused around OWFs with regards to cetacean conservation within Europe and to propose revised procedures and improved accountability based on the outcome of the review. This study examined five OWFs within the North Sea and adjacent areas that have been granted consents over the last 18 years: three in the United Kingdom and two in Denmark. This included Nysted, Horns Rev II, Beatrice, Teesside, and the Blyth Offshore Demonstration Project. Several different issues were identified in the review, including inadequate baseline/post-construction monitoring, weak enforcement/penalties, incomparable EIA designs, incorrect species focuses, poor documentation, use of broad blanket statements, and a lack of language standardisation. These are all issues that may hinder efforts to review and improve OWF developments.

It is recommended that EIAs maintain strict levels of standarisation allowing for comparability, flexibility, and adaptability. Simultaneously, with well-funded and highly-structured monitoring schemes, EIAs can provide practical assessments of potential negative ecological effects from OWF developments. Coupled with appropriate legislation and policies, these recommendations will assist the sustainable development of OWFs for cetaceans in the UK and elsewhere.

Evidence for a fission-fusion society in a population of rough-toothed dolphins (Steno bredanensis) in Guerrero, SW Pacific Mexico.

Pouey-Santalou, Victoria[1]; Ramos, Eric Angel[2]; Weiss, Michael[3]; Audley, Katherina[1]

Toothed whale populations often exhibit complex association patterns and social structure that are important to understanding their biology. Studies of well-studied species, such as bottlenose dolphins, sperm whales, and killer whales demonstrate that sociality varies across different regions and between species. The lesser known rough-toothed dolphins typically inhabit deep oceanic waters in understudied regions. Because of this, and despite indications of complex sociality, the degree to which their populations are structured in most areas is unknown.

We evaluated the social structure of a population of rough-toothed dolphins in the Southwest Pacific Mexican state of Guerrero. Sighting (n = 82) and photo-identification data gathered during boat-based surveys from 2014 to 2018 (1688 hours of survey effort) were analyzed. Some individuals were observed interannually (up to 4 different years), suggesting site fidelity and residency. The half-weight index was used to quantify the strength of associations between all resighted individuals (76 individuals of 175 dolphins identified). Permutation tests showed strong evidence for non-random social structure, and estimation of social differentiation suggested a well-differentiated society (S = 0.73). Cluster analysis revealed 7 different clusters, with a modularity index indicating significant divisions in the population (Q = 0.34). These results suggest that rough toothed dolphins form a fission-fusion society where animals associate non-randomly to form groups of varying size and composition over time. Associations between individuals may be influenced by ecological factors and/or kinship. Our results suggest coastal rough toothed dolphin

social structure is comparable to other coastal delphinids such as bottlenose, Guiana or Hector's dolphins. Additional study would be required to further test this hypothesis. The relatively easy access to this particular coastal population and calm environmental conditions provide a rare opportunity to describe social structure and determine its importance to their lives.

The Commerson's dolphin *Cephalorhynchus commersonii* includes two recognized subspecies: *C. c. commersonii* from southern South America and the Falkland/Malvinas Islands, and *C. c. kerguelenensis*, restricted to the subantarctic Kerguelen Islands. Following the West to East model of dispersal/diversification proposed for the genus, the latter subspecies is thought to have originated from a long distance dispersal event from South America. In order to improve the evaluation of this biogeographic scenario, new samples from southern Chile (n=6) and the Kerguelen Islands (n=23) were added to previously published mtDNA control region sequences from South America (n=292) and the Kerguelen Islands (n=11). To complete the range-wide distribution, new samples were also added from the Falkland/Malvinas Islands (n=52), adding up to a total of n=384 samples. From the 28 haplotypes identified, four were private to the Falkland/Malvinas Islands and three to the Kerguelen Islands. Significant phylogeographic structure was found among the three areas, being much higher between Kerguelen Islands and South America together with Falkland/Malvinas Islands (Φst=0.44-0.51) than between South America and Falkland/Malvinas Islands (Φst=0.11-0.14). Using the frequencies and phylogenetic relationships of the haplotypes, the proposed historical biogeographic scenario of colonization was tested with Approximate Bayesian Calculations. Initial trials show that the dispersal event from South America and Falkland/Malvinas Islands to Kerguelen Island may have occurred in the early Holocene and was followed by a population expansion process in Kerguelen Islands. These results support the model of postglacial colonization of Kerguelen by South American *C. commersonii* followed by a still ongoing differentiation process.

Occurrence and distribution of False killer whales (Pseudorca crassidens) in Central America

False killer whales (*Pseudorca crassidens*) is a poorly known species with "near threatened" IUCN status. Knowledge is lacking on their movement

patterns and social structure. Little data is available on this species along coastlines as it is a pelagic species. and no data is specifically available in Central America. In order to get more insights on their general ecology and movement patterns we compared the photo-identification catalogue and investigated their occurrence in Nicaragua, Costa Rica and Panama. Data were gathered during boat based surveys on three sites in Central America between 1999 and 2017. A total of 36 sightings were made in the three countries (3 in Nicaragua, 27 in Costa Rica and 6 opportunistic sighting in Panama) covering a total of 465 hours over 3 years of effort in Nicaragua and 6100 hours from 2001 to 2015 in Costa Rica. Out of 36 sightings, only 16 sightings had photo-identification data. No recapture was made within and between sites and a total of 68 individuals were identified. Average group size was 10 in Nicaragua, 10 in Panama and 35 in Costa Rica. We recommend to include more data from adjacent countries to understand the distribution and occurrence of false killer whales in Central America. This is the first known attempt to characterize false killer whale population in Central America.

Clinical assessment of bone density in the common bottlenose dolphin, Tursiops truncatus

Common bottlenose dolphins, *Tursiops truncatus*, are utilized as indicators of ecosystem health in long-term research projects both through post-mortem evaluation of beach-cast individuals and capture-release health assessments. To establish bone density as a useful health and life history parameter for the bottlenose dolphin, a primary target skeletal site in the radius of the dolphin pectoral flipper was comprehensively defined and a normative reference dataset was developed for the species. Bone mineral density (BMD) was measured in radii from 280 dolphins using dual-energy X-ray absorptiometry (DXA). BMD throughout the radius was analyzed and a single region of interest (ROI) was selected that had a high correlation to the density of the overall bone (R^2=0.98). Traditional methods for bone density measurement, such as DXA, utilize radiographic (X-ray) scanners that have limited potential in open-water field settings due to inherent limitations of access, regulation, and the radiographic nature of the technology. Alternatively, quantitative ultrasound is portable, non-invasive, and does not expose patients or technicians to radiation, thus making it an ideal diagnostic tool for field applications. In laboratory measurements on disarticulated flippers collected from beach cast dolphins, a strong correlation was established between bone density as measured with X-ray and quantitative ultrasound (R^2=0.93). Differences in BMD values for male and female dolphins, left and right flippers, dolphins from different geographical regions, and dolphins with varying nutritional status were examined. Initial trials to develop clinical protocols and demonstrate the ultrasonic technique as truly non-invasive were conducted on managed care dolphins under veterinary supervision. Successful assessments were subsequently conducted to ultrasonically assess BMD in live, free-ranging dolphins during capture-release health assessments during 2014-2019. Development of this technology enables assessment of dolphin bone tissue to become part of the armamentarium of biologists and veterinarians and additionally broadens the understanding of dolphin and overall ecosystem health.

Defining residency: Can a standardized approach with photographic-identification data be used to classify site fidelity patterns for coastal and estuarine small cetaceans?

Corresponding Author: jessica.powell@noaa.gov

Residency is a qualitative term used heavily in peer-reviewed literature to classify marine mammals' recurring use of habitat or localized movements; however, there are few systematic criteria or quantitative metrics that have been used across studies and/or species to define residency. The ability to apply standardized metrics and classify residency is essential for the development and application of appropriate management strategies. The U.S. Marine Mammal Protection Act requires designation and management of individual populations, and estimates of anthropogenic serious injuries and mortalities (i.e., takes) to each respective population. If the estimated takes exceed a sustainability threshold, additional management and conservation measures may be required. In the

Southeastern U.S., common bottlenose dolphins (*Tursiops truncatus truncatus*) are particularly challenging with numerous coastal and estuarine populations that in some cases have overlapping ranging patterns. A standardized definition of residency for these populations is necessary to assign serious injuries and mortalities accurately, and assist with population delineations that are based primarily upon genetics with supplemental photo-identification and telemetry data. The goal of this study was to conduct a review of marine mammal literature from 1995-2018 that provide definitions or metrics for residency and/or site fidelity. "Residency metric scenarios" were then developed from compiled residency definitions to quantify the best descriptor of population movements using long-term photo-identification data. In Savannah, Georgia, the numbers of resident animals ranged from 39 to 125, highlighting the differences among various scenarios. These scenario outcomes were used to develop a universal residency definition recommendation with metrics that are best suited for coastal and estuarine common bottlenose dolphins in the Southeastern U.S., with the potential applicability to other small cetacean populations worldwide.

Genomic divergence of coastal bottlenose dolphins (Tursiops australis) in southern Australia is driven by strong environmental gradients.

Environmental features have long been thought to drive patterns of fine-scale genetic differentiation in coastal bottlenose dolphins. With the growing application of genomic methods for non-model species, associations between dolphin genetic variants and environmental features can now be empirically tested. We utilised a high-quality genomic dataset of over 8,000 single nucleotide polymorphisms (SNPs) to carry out the first genome-environment association (GEA) analysis in the recently proposed bottlenose dolphin species, the Burrunan dolphin, *Tursiops australis*. Strong sea surface temperature (SST) and salinity gradients along the southern Australian coast were revealed as the most influential variables in driving genomic divergence in these dolphins. We identified 241 loci putatively under selection and possibly involved in local adaptation to marine habitats across the region. In particular, differing conditions between and within South Australia's gulfs and embayments may be driving the adaptive divergence of the dolphins across geographical scales as small as a few hundred kilometres. Functional annotation of these loci has revealed potential selection on several genes related to sodium-induced ion transport, and with adipogenesis, which may relate to adaptations of the dolphin populations to salinity and SST heterogeneity, respectively. Since the classification of *T. australis* as a separate species is still controversial, it is important to improve knowledge about these dolphins, particularly in regard to drivers of genomic divergence and local adaptation. This study also allows a better understanding of the ability of bottlenose dolphins to adapt to changing environments, which is particularly crucial in the face of ongoing climate change.

Diving behaviour of migrating ringed seals crossing ferry line in Moonsund

There is a growing concern about the ship induced continuous anthropogenic noise that can negatively impact the sound sensitive species. Shipping noise has the potential for auditory masking of acoustically active marine mammals by reducing their communication space. West Estonian Archipelago and Gulf of Riga are inhabited by a below Good Environmental Status population of the Baltic ringed seals (*Pusa hispida botnica*). The seals travel regularly from the haul-out areas in the archipelago through a shallow and narrow (6 km wide) Moonsund to forage in the Southern part of the Gulf of Riga. A busy ferry line connecting the Muhu island to the mainland crosses the vital migrating route of the seals. The migration behaviour of several ringed seals were studied with telemetry data recorders. The locations of the ferries were obtained from the Automatic Identification System and their emitted sound levels were measured in situ to derive source level. Rate of co-occurrences of the animals and ferries was found from their spatial and temporal overlap. The seal telemetry data includes GPS resolution spatial data, dive depths, dive durations and times spent at sea surface. The measured movements and dive profiles allowed to assess the diving effort and

behavioral responses to the noise emitted by the ferries. This enabled the comparison of behavioral patterns in a natural and noise disturbed environments. Sound propagation modelling made it possible to assess sound exposure level of the diving animals in the water column. The result indicates to a possible avoidance behaviour and to an increase in energetic cost during migration and foraging. The habitat quality and integrity is the key contributor to the population status of this conservation-reliant species with a very limited distribution range in the Baltic Sea.

Pre-whaling population structuring and diversity of blue whales (Balaenoptera musculus) in the high latitudes of the North Atlantic

During the 20th century, blue whales (*Balaenoptera musculus*) were heavily exploited by the commercial whaling industry, reducing the population to less than 0.1% of its pre-exploitation abundance. Globally, blue whales are divided into four sub-species based on morphological and geographical distinctions. However, their sub-species and population divisions are poorly understood and the distinctions between them are vague beyond their presumed geographical separation. Assessments of population structure and genetic diversity only exist for North Pacific and Southern Hemisphere blue whales in the literature. Northern Indian Ocean blue whales have little available data and no such evidence is available for North Atlantic blue whales (*B. m. musculus*). To conduct this study, I identified and assembled a dataset of 23 North Atlantic blue whale samples dating from the early whaling period (1865-1953), available through museum collections, which I have sampled and analysed. The DNA analysis of these bone samples provides a rare opportunity to establish the genetic diversity and population structuring of blue whales across the North Atlantic at the start of modern whaling, to measure how genetically distinct this population is from other blue whale populations worldwide and to estimate how long ago the ancestors of this population colonised the North Atlantic Ocean. Here, I describe the mtDNA (control region) diversities of North Atlantic blue whales in order to measure pre-whaling diversity and population structuring within the North Atlantic as well as assessing population connectivity and timing the divergence of this population from other blue whale populations. No evidence of distinct blue whale populations within the North Atlantic before whaling has been found as there was no significant differentiation between Eastern and Western North Atlantic populations. North Atlantic and North Pacific blue whales should be considered as distinct sub-species given their high levels of inter-population differentiation, the levels of divergence seen between the North Atlantic and North Pacific.

AragoJ – A free, open-source software to aid single camera photogrammetry studies

Prieto, Rui[1]; Aleixo, Francisco[2]; O'Callaghan, Sean[3]

Single-camera photogrammetry (SCP) is a well-established procedure to retrieve quantitative information from objects using photography. It is often used in biological sciences when direct handling of individuals is unpractical, which is the case in many marine mammal studies. In fact, unprecedented access to aerial imagery from remotely operated aircrafts has boosted morphometry studies based on SCP. Studies using SCP can be of two types: 2D photogrammetry, where distance and angle measurements are used to quantitatively describe an object's attributes, and 3D photogrammetry, where object true shape is reconstructed from landmark coordinates. Paradoxically, software packages to deal with the complex calculations demanded by 3D photogrammetry are widely available, but software specifically designed to aid in 2D photogrammetry are scarce, and are often tailored for specific problems, narrowing their applicability. In 2D photogrammetry, workflow usually involves some

or all of the following steps: 1) calibration and correction of picture distortion when using non-metric cameras; 2) measuring the relevant structures in the photographs; 3) scaling measurements, either by using a scale in the image or based on camera parameters and distance to an object; 4) transcribing measurement and metadata to a database. Researchers often utilize diverse software to complete these tasks, increasing processing time and chances of transcription errors. Here we present a new cross-platform open-source software, AragoJ, that integrates and streamlines photogrammetry workflow. The software includes several measurement tools admitting both forms of scaling. Metadata inscribed in digital images EXIF information is easily selectable for export. It includes a module for self-camera calibration, and produces undistorted images. It also includes a module for storing mathematical expressions that can be called inside the software. Measurements, calculation results, and image metadata can be exported as a csv file. In tests, processing time using AragoJ was halved when compared with a competing methodology.

Estimating abundance trends of humpback whale population in Southeast Alaska from 2008 to 2019.

In 2008, Calambokidis et al published a collaborative, ocean-basin-wide study on the abundance and distribution of North Pacific humpback whales (SPLASH; Calambokidis et al 2008). This study created widespread enthusiasm among the scientific community showing that humpback whale numbers had risen in the North Pacific by an order of magnitude from ~1,200 individuals estimated shortly after the cessation of whaling (Rice & Wolman 1982) to ~20,000 four decades later. Similar increases in whale abundance elsewhere, lead to the removal of 10 of the world's 14 humpback whale stocks from the US Endangered Species List. However, recent observations in Southeast Alaska, a principal foraging ground for North Pacific humpbacks, have revealed declines in whale abundance, record-low calf sightings, and an increase in the number of whales in poor body condition which appear to be foregoing their migration to winter breeding grounds. Whether this trend is true, and further, whether it is linked to underlying changes in the marine ecosystem remains unclear. Resolving these issues is crucial to understanding the future trajectory of whale populations and establishing appropriate management strategies. Furthermore, as indicator species, changes in whale abundance can signal underlying changes in their ecosystem. Therefore, assessment of abundance of humpback whale population in Southeast Alaska can be a valuable tool for conservation and monitoring the health of our changing oceans.

In this study we compare abundance estimation of humpback whale population in 2008 versus 2018 and 2019 in Frederick Sound and lower Stephens Passage. In 2008, whales were surveyed from sets of stratified-random line transects across the summer, while in summer 2018 and 2019, systematic point transect surveys were repeated. Preliminary results show an estimated whale abundance of 228 (CV = 26.4%, 95% CI = 163-319) in 2008 and 155 (CV = 38.9%, 95% CI = 74-326) in 2018.

The impacts of ship noise in Eclipse Sound, Canada, on narwhal (Monodon monoceros) call rate.

Prieur, Crystal[1]; Frouin-Mouy, Heloise[2]; Rouget, Phillippe[3]; Terhune, John[4]
(1) University of New Brunswick

Corresponding Author: c.prieur@unb.ca

Cetaceans have the potential to be disturbed by anthropogenic noise. Little is known about how narwhal in the Eastern Canadian Arctic may respond to increased shipping in their summer calving grounds in August and September. In 2018, three passive acoustic monitoring (PAM) stations were deployed in Milne Inlet (two along the shipping lane and one 6 km away in Koluktoo Bay) over the open-water season to document narwhal vocal behaviour relative to ship traffic. A high-frequency cetacean (HF) auditory weighting function (Southall et al., 2019) was applied to calculate the broadband (10–31,500 Hz) noise levels. An automated call recognizer detected narwhal vocalizations; knocks (broadband pulses, produced singly or in a short series, <20 kHz), and low- and high-frequency whistles. Low- and high-frequency whistles and knocks were present in 1.2–8.0, 0.5–4.2 and 8.6–16.2 % of the recordings, respectively. Changes in the rates of these call types were analyzed in relation to ship location (automatic information system data, AIS). Along the shipping route, the knock rate increased when a ship was within 2 km of the recorder, and whistle call rates (high and low) decreased when a ship was

within 8-10 km of the recorder. These changes in vocal behaviour occurred when broadband levels exceeded 95–98 dB (HF) re 1 mPa. In Koluktoo Bay, knock rates increased slightly when a ship was within 12 km of the recorder. High and low whistle call rates decreased when a ship was within 9-10 km of the recorder. Broadband levels in Koluktoo Bay remained low regardless of shipping activity, never exceeding 10 dB above ambient levels. The insensitivity of narwhal hearing at low frequencies and the blocking of sound transmission by headlands along the inlet likely contribute to the absence of behavioural vocal changes until the ships were within 10 km.

Anticipatory and overnight whistling behaviour of bottlenose dolphins in human care

Probert, Rachel[1]; Bastian, Anna[1]; Elwen, Simon[2]; Gridley, Tess[3]

Bottlenose dolphins are highly social marine mammals and vocal communication is an important way in which they maintain contact. They are the most common cetacean found in human care, and are therefore one of the most studied of the cetacean species. Nevertheless, their overnight vocal activity is not very well understood. One method to analyse change in vocal behaviour is to look at change in whistle production over time. Whistles are a major component of their vocal repertoire and are primarily used to indicate heightened excitement, arousal or stress. The set routines of a dolphinarium can result in anticipatory behaviour in the dolphins and understanding the changes in whistle behaviour in response to this could be a valuable animal welfare tool for dolphin-keeping facilities. Continuous overnight recordings were collected over 24 nights in May, July and August 2018 from 17:00 to 7:00 at the uShaka Sea World dolphinarium, Durban, South Africa. A signature whistle catalogue of 10 known signatures was created, eight of which were confidently allocated to eight of the 10 individuals. Whistle production was measured using total signature whistle counts as well as counts of other non-signature whistle categories. Preliminary results indicate an obvious trend in whistle production during pre-feeding, feeding and post-feeding activities, which suggests an increase in whistle production in response to the anticipation of the morning feed. Further results will indicate whether this trend is statistically sound using generalised additive models, and give the first account of nocturnal vocal behaviour of the dolphins at uShaka Sea World.

Occurrence and pathologies associated with foreign body ingestion in stranded cetaceans, Canary Islands.

One of the major concerns in aquatic environment is the impact of marine litter. Plastic is the most prevalent item within marine litter and not only affects the chemical quality of the water but also impacts marine organisms. Currently, the presence of debris ingestion has been reported all over the world in different marine species, though little is known in cetaceans. In this research, we study the occurrence and pathologies associated with the presence of foreign bodies (FB) in stranded cetaceans in the Canary Islands during a sixteen years period (n = 465). Fifteen species were affected by FBs including eight out of the nine year-round species in the archipelago. A total of 36 individuals (7.74%; 36/465) presented at least one FB, being plastic the most common item found

(80.56%). Deep divers were the most affected group with *Grampus griseus* as the most affected species followed by *Physeter macrocephalus* and beaked whales. Two individuals of baleen whales were also affected (*Balaenoptera physalus* and *B. acutorostrata*). Ingestion of debris was lethal in 36.11% (13/36) of the cases presenting lesions such as stomatitis, bleeding ulcers, gastritis, perforations and impactions. As previous reports, no lesions were found in ten individuals which presented ingested FB. This is the first forensic study that, based on statistical analysis, define two risk factors for FB ingestion (poor body condition and deep diving behavior) and a protective factor (adult age).

Environmental factors affecting the Irrawaddy dolphin (Orcaella brevirostris) distribution in the Mahakam River, East Kalimantan.

The Mahakam River in East Kalimantan, Indonesia, is typical of other tropical rivers in Southeast Asia but is distinguished by a riverine population of the iconic Irrawaddy dolphins, known locally as *Pesut*. Like many other tropical rivers in Southeast Asia, the Mahakam River is also facing problems from rapid development in rural areas, characterised by a massive conversion of peatland forest to oil palm plantation, an increasing number of mining activities, and ongoing development of settlements. These developments are likely to have had both direct and indirect effects on Pesut.

Water quality parameters and land use type from sites in the upper, middle, and lower sections of the Mahakam River were used to quantify relationships with between broadscale catchment land-use changes and river habitat changes while anthropogenic factors such as fishing pressure and other forms of human disturbance were also assessed in relation to dolphin distribution. The objectives of this analysis were to (i) quantify changes in water quality in relation to land use, (ii) investigate the key environmental factors associated with Pesut distribution and abundance in the Mahakam River, and (iii) integrate these findings with other information on dolphin ecology to make recommendations that support dolphin conservation management.

Over 1996–2017, the land use in the sub-catchments of government water quality monitoring sites demonstrated changes that reflected increasing concentration on total disssolved solids (TDS), followed by nitrite (NO2-N) and sulphate (SO4). The middle reach of the Mahakam River was indicated as the primary habitat for Pesut. Several land-use related water quality parameters appeared to influence dolphin distribution through indirect effects on prey distribution. Accordingly, conservation management of Irrawaddy dolphins in the Mahakam River should focus on factors influencing prey species productivity in the river, such as the formation of fish reserves.

Evidence for factors that shift virus from endemic to outbreak in ongoing circulation of both IAV and PDV within pinnipeds of the Northwest Atlantic

The Northwest Atlantic has been a hotspot for pinniped viral infections for at least half a century. Of the 9 virus associated unusual mortality events that have been documented globally in pinnipeds, 6 have occurred in the Gulf of Maine. Each of the mortality events has been attributed to either Influenza A Virus (IAV) or Phocine Distemper Virus (PDV) and in both systems, it has generally been thought that unique seeding events initiated each outbreak. A

longitudinal analysis of stranded and rookery animals provides strong evidence that both IAV and PDV cocirculate endemically within the Northwest Atlantic. Both viruses are found within harbor (*Phoca Vitulina*), grey (*Halichoerus grypus)*, and harp (*Pagophilus groenlandicus*) seals, with no apparent species barrier to transmission. Both viruses have also been detected within the region during each year tested (2011-present). Serological evidence suggests high diversity in IAV throughout the years, with antibody recognition against nearly all hemagglutinin subtypes. In contrast, PDV shows a high degree of viral stability. Our recent genetic analyses suggest that PDV initially entered North America in 1988, underwent a split around 2002, and has since maintained two strains. The dominant strain has had no changes in the H protein since 2011 and does not appear to be under selective pressure in the ongoing UME. We hypothesize that the inherent pathogenicity of these viruses alone is not the sole determinant to initiate mortality events, but rather external factors that tip otherwise endemic virus toward mortality events.

First description of the cetacean community in French Guiana eez

In the context of oil exploration development off French Guiana, three boat campaigns were conducted to study the little-known cetacean community. From July 2011 to June 2012, for four days every two months, GEPOG NGO conducted a campaign; COHABYS consultancy led a campaign for five days per month from January to May 2018; OSL NGO conducted their campaign for 17 days in June-July 2018 and 19 days in September-October 2018. Surveys efforts in favorable weather conditions (Beaufort ≤ 4) took place over 1953 km, 1491 km and 3140 km respectively. Fifteen cetacean species were identified. The total number of group sightings and encounter rates (number of group sightings per 100 km effort) were: 52 groups and 3.2±2.6 groups/100km for GEPOG, 17 groups and 1.0±0.7 groups/100km for COHABYS, 64 groups and 2.0±0.4 groups/100km for OSL. We identified the dominant species for each habitat *i.e.* accounting for more than 20% of the encounter rate in the habitat under consideration at least for one campaign. These dominant species were: Sotalia (*Sotalia guianensis*) in the coastal area (0-20m); bottlenose dolphin (*Tursiops truncatus*), Atlantic spotted dolphin (*Stenella frontalis*) and common dolphin (*Delphinus delphis*) on the shelf (20m-100m); bottlenose dolphin, spinner dolphin (*Stenella longirostris*) and pantropical spotted dolphin (*Stenella attenuata*) on the upper slope (100m-1500m); pantropical spotted dolphin and sperm whale (*Physeter macrocephalus*) on the lower slope (1500m-3500m). These species were observed all year round and mother and calf pairs were sighted for all of them but the common dolphin. Two sightings of humpback whale (*Megaptera novaeangliae*) mother and calf pairs were also recorded. These results provide strong evidence of the importance of French Guiana EEZ to a diverse and abundant cetacean community. Data are now being processed to identify the areas and seasons that should be given priority consideration for their conservation.

More than metronomes: Variation in diving behaviour of Cuvier's Beaked whales (Ziphius cavirostris).

Cuvier's beaked whales are known for their extremely long and deep foraging dives, which are typically interspersed with a series of shorter, shallower non-foraging dives. To understand variation in this general pattern, we deployed satellite-linked depth-recording tags on 17 whales off Cape Hatteras, USA in 2017 and 2018 as part of the Atlantic Behavioral Response Study. Tags were optimised to record continuous data during any dive longer than 33 minutes and subsequent inter-dive intervals. We obtained 11,093 hours of diving data, including 4,635 dives. Twelve whales were exposed to sonar signals; we removed periods of the data records associated with this exposure from our analysis. Total dives per individual ranged from 71 to 524 (median 214, n=16). Generalised Estimating Equations, with Group ID as a blocking unit, showed significant variation ($p<0.001$) amongst individuals in dive depth, dive duration

and inter-dive interval, with multiple individuals demonstrating extreme outliers across variables. Dive shape, sex and season were also important predictors of dive depth with animals tagged in Spring diving on average deeper than those tagged in Autumn. Time budgets, based on time spent at depth, revealed that all whales spent more than half their time in a non-foraging state. Sequential dive durations were highly autocorrelated, and the proportion of long dives (greater than 59 minutes) varied considerably among individuals (0.16 to 0.82). Unlike some historical characterisations of diving behaviour in this species our results demonstrate considerable individual variation, which could be driven by a range of biological and environmental factors, including prey availability, sex and social behaviour. Our results are among the longest continuous diving records for Cuvier's beaked whales and suggest a level of behavioural plasticity that has important implications for defining baseline data for this species, particularly with respect to experimental exposure to anthropogenic noise.

Resighting and movement patterns of right whales (Eubalaena glacialis) sighted in an area designated for offshore wind energy development

North Atlantic right whales (*Eubalaena glacialis*) are exposed to numerous human activities during their migratory movements. We studied right whales at a 3,671 km^2 site designated for wind energy development south of Martha's Vineyard and Nantucket (MVN), off northeast U.S.A, to provide baseline information to developers. We examined the distribution, demographics, residency, and movements of identifiable right whales before and after they occurred at MVN using data collected from 232 aerial surveys and 42 days of opportunistic observations in 2011-2019. Sighting rates (animals/1000 km) were significantly higher in the spring than any other season ($p < 0.05$). Spatial sightings per unit effort analyses indicate that whales concentrate in different areas at different seasons. Preliminary photo-analysis indicates that at least 267 individuals have been identified, which represents >50% of the right whale population. Over the study period, 51% (137 whales) were sighted multiple times: 80 were resighted within a season (2-5 times) and 73 were sighted over multiple years (3-6 years). Adult males constituted the most common demographic group (40%), similar to the male-biased population sex ratio, and all age and sex classes were observed. In the winter and spring, examination of distance movements suggests that right whales were at northern [Gulf of Maine (GOM), Jeffreys Ledge, Cape Cod Bay (CCB)], and southern (Florida, Georgia) locations within months prior to visiting MVN. Several whales (4%) went back and forth between CCB and MVN, but most individuals were progressively spotted up north (GOM, Bay of Fundy, Gulf of Saint Lawrence) by summer. In the fall, they were first sighted at nearby locations (New York, Great South Channel, Jeffreys Ledge). These results coupled with observations of feeding, courtship, and calf presence, indicate that MVN is an important habitat. Our project outcomes will inform the spatial planning and construction of the offshore wind farm.

A cost-efficient standardised methodology for microplastics analysis: Case study of cetaceans and Mediterranean monk seals stranded on Samos Island coastline, Greece.

The real impact of plastic pollution on the marine ecosystem is an issue yet to be fully assessed due to the lack of data and logistic difficulties, especially in remote locations. This study proposes a cost-efficient field methodology to be adopted as a model for microplastics quantification in sentinel species of the marine ecosystem.

A preliminary analysis of the presence of microplastics was conducted on a total of 12 dolphins (7 *Stenella coeruleoalba*, 4 *Delphinus delphis*, 1 *Tursiops truncatus*) and 3 Mediterranean Monk seals (*Monachus monachus*) found stranded

on the shores of Samos Island, Greece, between 2017 and 2019. Necropsies were conducted *in situ* or in the laboratory when possible. The entire digestive system was isolated from the oesophagus to the last tract of the large intestine. All samples were sieved (mesh sizes: 500µm and 200µm), treated to dissolve the organic matter content and filtrated through glass fibre filters. The slides were observed under x40 magnification to quantify and categorise the microplastic items into type (fibre; fragment), colour and size. A "hot needle test" was conducted to distinguish between plastic pieces and organic matter. A test for airborne contamination was performed at random.

A high concentration and variety of microplastics were found throughout each tract of the digestive systems of all the animals analysed, confirming the wide scope of the plastic pollution affecting the top predators of the trophic chain. These results prove the efficiency of the proposed field methodology to fill the data deficiency and improve the crucial research on marine litter impact.

The top-down effects of cetaceans in the Gulf of Mexico: Who are the key players?

Due to their high historical and sometimes present-day abundances, capability for large-scale movements and high metabolic rates, cetaceans have the potential to affect the structure and function of ecosystems through a variety of mechanisms over both ecological and evolutionary time. Understanding top-down effects of cetaceans is important to assess their impact on communities and potential conflicts with fisheries. The Gulf of Mexico (GOM) is a large oligotrophic marine ecosystem with a high diversity of cetaceans (23 known species) that forage on a variety of commercially important species. An ecosystem model was constructed to evaluate the direct and indirect effect of cetaceans on GOM marine communities and fisheries. Seaward of the 1000 meters isobath, results suggest that top-down impacts are dependent upon the predator biomass, prey biomass, and importance of prey to the predator's diet. Due to their high abundance in the GOM and diet, cetaceans have a large, negative impact on juvenile stages of commercially important fishes (tunas and billfishes) through direct predation. Commercial fisheries target adult cohorts more than juveniles however there is competition for the small tunas (e.g., skipjack and Blackfin). We divided cetaceans present in the GOM, small (Delphininae) and large delphinids (Globicephalinae) and the deep-diving whales (e.g. beaked and sperm whales). Large delphinids have a negative impact on mesopelagic fishes, whereas small delphinids have an indirect, positive impact on mesopelagic zooplanktivores due to trophic cascade effects. Similar diets and the occasional predation of large delphinids on the small delphinids suggest that competition exists between these two groups. Comparatively, beaked and sperm whales do not have a significant impact on commercially important species but do negatively affect mesopelagic top predators like Dragonfishes. Ecosystem models will improve our understanding of each species ecological function and predict wider ecological consequences of potential declines or extinction of species.

Depredation mitigation device for pelagic longline fisheries: The PARADEP project.

Depredation is defined as the damage or removal of fish or bait from fishing gear by predators. The long term objective of the PARADEP project is to reduce toothed whale depredation impacting pelagic longline fisheries targeting swordfish and tuna. This objective comes in three main components.

The **scientific** objective of PARADEP includes two sub-objectives. The first one is to develop a physical depredation mitigation device. This innovative device will have three protective skills: physical (barrier between the fish and the predator), visual (hiding of the fish) and passive acoustic (modification of the fish acoustic signature). Device trials will be held in Reunion Island (Indian Ocean) onboard commercial pelagic longliners. The second objective is to acoustically monitor the depredation process. Hydrophones, cameras and accelerometers will be deployed on the fishing gear along with the devices. This will allow to detect toothed whale presence, identify the involved species and analyze their acoustic behavior when they interact (or not) with the devices.

The **economic** objective of PARADEP will assess : i) the direct and indirect loss due to toothed whale depredation impacting the Reunion Island pelagic longline fishery, ii) the device position in the market of fisheries equipment, based on its estimated price.

The **communication** objective of PARADEP is to share the knowledge resulting from this approach to the public, political managers, stakeholders, scientists and fishermen. This will be done by the use of several communication supports, including the construction of a dedicated website (https://paradep.com) and the participation to various workshops, conferences and meetings.

PARADEP is funded by the European Funds for Maritime Affairs and Fisheries (FEAMP), and is due to last 30 months (July 2018 – December 2020). It involves three partners: two research labs (IRD MARBEC and CEBC CNRS) and one pelagic longline fishing company (ENEZ DU, based in Reunion Island).

What can acceleration tell us about the movements of an animal? An in-depth analysis of dolphin behavior.

Obtaining detailed information about the behavior patterns of wild marine mammals has been a challenge over the years, and new techniques have been developed to automatically monitor movements. Accelerometry has shown serious potential in providing information about an animal's behavior; however, a validation of the behavior patterns is necessary. The goal of unsupervised classification is to be able to automatically identify the behavior performed by a dolphin without the requirement of video cameras. This validation is often impossible in the wild, so it is essential to do it in a controlled environment. For a data collection program involving two male adult captive dolphins (contexts: "alone" and "accompanied by other animal"), a total of 86 behaviors, grouped into 8 categories, were correctly classified by the algorithm: the Lateral Ascent, Lateral Swim, Lateral Dive, Inverted Dive, Glance Up, Dorsal Swim, Dorsal Dive and the Head Up. The most common behavior observed for both dolphins and contexts was Dorsal Swim. Sequence of behaviors were also analyzed and the results showed similar behavior sequences between both animals and both contexts, emphasizing that behavior patterns did not change because of this condition. An entropy analysis indicated that the dolphins' behavior contains a high-order structure that may allow the prediction, by a statistical model, of which behavior will follow a specific action. As far as we know, this is the first study building a behavioral map with the combination of the possible postures for a more complete behavior analysis. The unsupervised classification algorithm will make it possible to extract rare behavior patterns or those that researchers do not normally observe directly, including possibly anomalous behaviors. Even thought the algorithm is specific for bottlenose dolphins, it has the potential to be applied to other cetacean species and also other aquatic animals.

The evolution and diversification of delphinid skull shapes.

The family of oceanic dolphins (Delphinidae) consists of approximately 36 species that occur over a range of aquatic habitats from rivers to the open ocean and in climates ranging from the Arctic to the Tropics. They are the result of an explosive radiation, with a rich diversity of species originating over a short window of time. Within these species, there is a remarkable variation of skull shapes, which has been hypothesized to reflect adaptations to feeding strategy, preferred prey and habitat, as well as sound production. In this study, we investigate the radiation of skull morphology of the 18 delphinid species occurring in the North Atlantic. We used geometric morphometrics to construct species-specific 3D models consisting of 51 landmarks, based on at least 3 specimens per species. We then mapped these models on a phylogenetic tree based on full mitogenome data using squared-change parsimony. In the most parsimonious model of skull shape evolution, the most recent common ancestor had a skull similar to Lagenorhynchus, Lagenodelphis, Leucopleurus or Tursiops. Early morphological diversification occurred in 3 directions: 1) towards more specialized raptorial feeding of small prey

with longer, narrower beaks, exemplified by Stenella and Delphinus species. 2) towards wider skulls with shorter, downward-oriented rostra and smaller temporal fossae, exemplified by suction feeders such as Globicephala, Grampus and Peponocephala. 3) Towards shorter and wider skulls with larger temporal fossae and anterior displacement of the orbit, exemplified by Orcinus. Under this model, the current delphinid diversity was established early on and the only major later development has been a convergence of the globicephalines Pseudorca and Feresa with Orcinus, apparently related to the handling of large prey items.The family of oceanic dolphins (Delphinidae) consists of approximately 36 species that occur over a range of aquatic habitats from rivers to the open ocean and in climates

Humpback whale site fidelity, group composition types, behaviors and habitat use in Guerrero, Southwest Pacific Mexico.

In-depth marine mammal survey work has never been conducted before in Guerrero, SW Pacific Mexico and no official protection or monitoring measures are in place. We conjectured that humpback whales found off of Mainland Mexico include two distinct population segments, classified as threatened and endangered. In order to contribute to a clearer characterization of the North Pacific humpback whale population and generate conservation strategies, we conducted 1688 hours of boat-based surveys off of Guerrero (17.6417° N, 101.5517° W) between 2014–2018. We determined site fidelity and habitat use via photo identification, group type, location and acoustics and collected sloughed off skin samples for genetic analysis. Of 310 fluke IDs catalogued, 36 were resighted in Guerrero between 2014-2018. Intraannually, 21 individuals were seen more than once (2015(5), 2017(5) and 2018(11)) and interannually, 16 whales were resighted with encounters ranging from 345 to 1,103 days (mean:488d). There was an increasing number of sightings (n=638) along years, with effort time variation per encounter ranging from 6.86 and 1.38 h/sgt (mean:3.32). Solitary whales were the most frequent group type (LO:34.1%); followed by dyads (D:25.2%) and groups including calves (MC+:23.5%); the last two showed an inversely proportional relationship along years. Singing was detected 137/266 days (52%) that a hydrophone was deployed. Presence of competitive groups and singers, as well as mother/calf pair habitat use and behaviors suggests that this region is a calving and breeding ground.

In order to foster local stewardship, all data was collected in partnership with the fishing community and findings were publicly shared during weekly events and annual safe whale watch training programs. This approach resulted in the development of a successful community-led marine mammal monitoring and stranding network and effective coordination between tour guides. Federal recognition of the region as a whale watch zone is underway.

Decadal-scale changes in deep diving cetacean distribution in the central and North-East Atlantic.

Major changes in the distribution of some baleen whales have been observed coincident with changing oceanography of the North Atlantic in the last 30 years. This study aimed to improve understanding of the underlying ecological drivers of any changes in deep-diving cetacean distribution. We used data from two series of summer surveys (in Iceland-Faroes and Norway) to model density of sperm, long-finned pilot and northern bottlenose whales as a function of static (relief), physical and biological oceanographic covariates using GAMs. The best models, based on a robust model selection framework, were used to predict distribution. The study period was divided into two periods, 1987-1989 and 1998-2015, based on environmental changes in the area and data availability. The common covariates that best explained these three species' distributions (in both periods) were relief variables and SST. The selected dynamic temperature-related covariates for sperm and pilot whales were for spring, but for bottlenose whales were for summer. Summer relationships were also found for the three species for the other dynamic variables, except spring chlorophyll-*a* for bottlenose whales. The difference in seasonal relationships for bottlenose whales may

be related to a previously suggested north-south summer migration. As expected, the predicted high-use areas for all three species were deep waters, with some overlap among them in the central Norwegian Sea, and the Central North Atlantic, including the Irminger Sea. Differences in distribution likely reflect differences in prey. Changes in distribution between the two periods appear more as a range expansion than a shift, with generally higher predicted densities in northern waters in recent years, which could result from an increase in suitable habitat due to warming waters. This new knowledge will help improve understanding of how these species may respond over this wide area to a changing environment and inform their conservation.

Field observations and Google Earth detections reveal mud ring feeding behaviors by bottlenose dolphins in Corozal Bay, Belize and Chetumal Bay, Mexico.

Marine mammals sometimes evolve rare and complex feeding strategies involving learned behaviors adapted for targeting preferred prey in certain ecosystems. Rarely have the same complex tactics been detected in geographically distinct populations. Mud ring feeding is a behavior of bottlenose dolphins, reported only in Florida, USA, in which one dolphin kicks its flukes against the muddy bottom to create a circular mud plume to ensnare prey fish. Here we report evidence of mud ring feeding behaviors by coastal bottlenose dolphins in Corozal Bay, Belize and Chetumal Bay, Mexico documented from 2010–2019 during long-term monitoring of marine protected areas. Mud ring feeding events in Belize (n = 4) were directly observed from a small boat, plane, and drone, and inferred from aerial images of circular trails in the seafloor. Analysis of drone-based behavioral observations revealed that unlike dolphins in Florida, local dolphins created larger rings and spent more time hunting within and around the expanding mud plume. Visual searches for mud ring trails in satellite imagery covering both bays within Google Earth resulted in the detection of 94 trails and an instance of dolphins exiting mud plumes along the shores of Chetumal Bay in 2010. Size comparisons of mud rings and plumes imaged from the drone with remotely-sensed ring trails confirmed their similarity. The distance between our study site and Florida (ca. 1,100 km) and the millennia since these populations diverged suggests dolphins in these shallow muddy habitats independently innovated the creation of mud rings and converged on a similar feeding specialization. These findings illustrate dolphins are capable of converging upon the creation of complex objects to facilitate feeding, and stimulates the need for further study to investigate the prevalence of this tactic in the Caribbean Sea and its implications for the management of local dolphin populations.

Perception bias: How aerial imagery revealed underrated threat of entanglement in large rorquals.

Entanglement in fishing gear is a known threat to all cetaceans, pushing some species, like the vaquita and North Atlantic right whale, towards extinction. For large rorqual species, such as blue and fin whales, entanglement reports are relatively rare, leading to the presumption that entanglement is less common in these species. The known high proportion (60-80%) of previously entangled North Atlantic right and humpback whales is based on surviving animals bearing scars from fishing gear. The most prominent scarring is found around the tail and peduncle, visible when animals lift their tails before diving. Given that fin and blue whales are rarely fluking, entanglement rates have likely been underestimated. We used a drone equipped with a high-resolution camera to obtain aerial footage of individual blue and fin whales in the Gulf of St. Lawrence, allowing us to identify individuals and investigate the body for scars indicative of prior entanglements. We graded pictures based on angle, light, focus, resolution,

and body part. Three researchers independently examined the pictures and recorded scarring marks. We identified 91 individual fin whales based on pigmentation patterns. Of the individuals with good or excellent images (n=35), 42% had scars from previous entanglements, compared to 53% for individuals with excellent pictures only (n=17). The scarring occurred always around the peduncle, often the tail, rarely the dorsal and never around the flippers. Some images suggested that the focal entanglement point was the mouth, and scaring further along the body may have partly resulted from trailing gear. Thus, some scars may have gone undetected, and we regard our estimate as a minimum. The single sampled blue whale was matched to the existing catalogue and had a laceration on the peduncle. In conclusion, aerial imagery is the preferred method to quantify scarring rates in species which do not fluke frequently.

Beaker BANTER: A machine learning approach to acoustic classification of beaked whales.

Passive acoustic methods have proven to be effective for monitoring beaked whales; however, classifying beaked whale acoustic detections to species can be difficult for large datasets with multiple beaked whale species. Manual classification of acoustic data requires significant time investment by highly trained technicians and is difficult to reproduce. Here we develop and test a novel approach to beaked whale acoustic classification. BANTER is a newly developed machine learning approach to acoustic event classification that utilizes information from multiple rather than single call types (e.g. dolphin whistles, clicks and burst pulses). BANTER performs stably and yields a high rate of correct classification when applied to dolphins. Its conceptual framework easily lends itself to other species, study areas, and taxa. In an effort to apply this compound classification scheme to events consisting solely of click detections, we developed a series of alternative detectors, measurements and call classifiers to allow for BANTER acoustic classification of beaked whale species. Multiple click detectors were developed within Pamguard and applied to beaked whales detected on drifting recorders (US West Coast, Hawaii) and towed arrays (US Atlantic Coast and Gulf of Mexico). Measurement of spectral peaks/notches as well as measures derived from Wigner-Ville plots provide additional measurements for call classification. For overall event classification, BANTER considers results from these multiple call classification results. Correct classification scores for 917 beaked whale events detected in the US west coast (comprised of five putative beaked whale species) ranged from 89% to 100%. BANTER provides systematic and reproducible results in minutes. Also, BANTER's systematic approach combined with its tools to estimate model performance can be used to inform potential geographic variation. These results will be used to further develop a series of open-source software packages to facilitate BANTER event classification for data analyzed in Pamguard.

A calorific map of harbour porpoise prey in the North Sea

Ransijn, Janneke[1]; Booth, Cormac[2]; Smout, Sophie[3]

The distribution of harbour porpoises (*Phocoena phocoena*) is thought to be prey driven but our understanding of prey availability is currently limited. Harbour porpoises have restricted energy storage, and high foraging and metabolic rates. Energy balance is therefore crucial to our understanding of porpoise ecology, including caloric content of prey. This project provides a first attempt to describe the spatiotemporal variation in energy available from different prey species to porpoises in the North Sea.

Energy maps were produced for Atlantic cod, Atlantic herring, European sprat, sandeels and

whiting, for the most recent two years that North Sea-wide cetacean surveys were carried out (2005 and 2016). A cleaned dataset of the International Bottom Trawl Survey was used. Relative gear efficiency factors per prey species and size class were used to correct for catchability. Biomass values were converted to energetic content using published energy density values. These energetic content estimates were used to create density surface models using Generalised Additive Models with soap filters to avoid smoothing across boundary features.

Overall mean estimates of total energy available from the modelled species in the North Sea ranged between 21,610 (winter) megajoule (MJ) per km^2 in 2005 and 76,938 MJ per km^2 (summer) in 2016. Large amounts of prey energy were predicted with consistent high contributions from sandeels and whiting. Sprat and herring added considerably to the overall energy dependant on the season. Wild harbour porpoise daily energy requirements vary between 9-31 MJ. This suggests that even within "low" energy areas there would be sufficient energy to sustain porpoises if this energy was available to them. However, the energy predicted may not correspond to the actual available energy for porpoises given the role of other marine predators and the fishing industry present in the North Sea, prey patchiness, and 3D distribution of prey.

Humpback whale (Megaptera novaeangliae) spatial ecology and the risk of vessel strike in a Mexican breeding area facing extensive coastal modification

The mainland Mexico state of Nayarit is an important breeding/calving area for the 'Threatened' Mexican humpback whale population and acts as a migratory corridor to the 'Endangered' Central American humpback whale population. However, knowledge of the species' seasonal distribution and habitat use throughout the state is limited. Without a major container port, and it's geographic location sheltered by the Baja California peninsula, Nayarit was previously one of the only Mexican Pacific states not to receive heavy shipping. In the last five years, several large port developments have been proposed in the region, whilst maritime traffic is already increasing due to rapid tourism growth and coastal development. Vessel strike is the major modern global threat for large whales, particularly for small or endangered populations. Humpback whales are one of the most commonly hit species, and a significant proportion of the Mexican population bare propeller scarring, suggesting that vessel strike is already an issue. To characterize the distribution, composition and movement of whales, we conducted aerial and vessel surveys during two humpback whale breeding seasons (2018 and 2019) in coastal Nayarit. We identified high humpback whale site fidelity to Nayarit, long residency times within breeding seasons (over a month for some mother-calf dyads), and found strong migratory connections with Central American breeding areas. Humpback whale distribution models suggested differences in habitat use of migrating and breeding/calving activities, and identified critical areas of humpback whale habitat. Using the distribution models with AIS shipping data we quantified the risk of vessel strike in this region, identifying areas of current and projected risk based on planned developments. Our results allow for effective planning of port developments through the spatial assessment of the placement of shipping lanes to minimize vessel strike and the establishment of a Marine Protected Area to regulate commercial shipping and marine tourism.

Swimming dynamics of humpback whale (Megaptera novaeangliae) calves accompanied by their mother.

A study of the swimming dynamics of humpback whale (*Megaptera novaeangliae*) calves accompanied by their mother was conducted in the Sainte Marie channel (Madagascar). Our knowledge on such topic is quite limited and thus we aimed to prove the existence of specific swimming configuration offering energetic advantages for calf in mother-calf dyad, and to compare mother-calf swimming behavior. Through kinematic analysis, opportunistic underwater video clips of travelling mother-calf dyads were used to investigate the variation of calf's relative swimming effort (tailbeat frequency based parameter) according to the swimming configuration. Dive profiles collected using multi-sensor tags were used to compare the swimming control and stability. Analysis of 21 short video clips extracted from 4.5 hours of videotapes showed that calves swim mainly in echelon (close to its mother's mid-lateral flank) to save energy evidenced by a 23.5% reduction of swimming effort, and they also show a right-biased lateralized behavior. Analysis of 129 dive profiles from three tagged dyads showed that calves' active swimming behavior is much less elaborated compared to those of their mothers but the gliding is already fairly controlled. These findings highlight the importance of the proximity between mothers and their offspring and the necessity of strict regulations for their observations in order to minimize the risks of mother-young separation.

Pinniped entanglement response best practices.

Pinniped entanglement in marine debris and fishing gear is a global issue of increasing concern. With the growing number of entangled pinnipeds worldwide comes a greater need for protocols to safely respond to these animals. There are many different entanglement response methods employed to respond to entangled pinnipeds including physical restraint on land (herding boards, nets, etc.), physical restraint in the water (tangle nets, hoop nets, purse seine, etc.), non-remote (hand inject) sedation, and remote (i.e., dart projector) sedation. However, there are currently no standardized best practices for pinniped entanglement response. Therefore, the National Marine Fisheries Service sought to incorporate the most successful techniques used by responders in various geographic regions into one national Best Practices document. First, we developed a questionnaire asking marine mammal stranding network members and Pinniped Entanglement Group members for their own best practice documents, training manuals, and entanglement response forms and reports. We then summarized all existing protocols into one overarching National Pinniped Entanglement Response Best Practices document. This document covers best practices for preparing for an entanglement response, procedures, equipment, and drugs used during a response, assessing risk and mitigation, and identifying future research needs. Examples of best practices include: making human and animal safety a top priority; using a decision matrix and incident command system to assess and minimize risks to animals and responders; ensuring responders are well-qualified; clearly defining team roles and responsibilities; and continuing to adapt and search for better capture tools and techniques for maximizing safety. Once this Best Practices document is finalized, it will be available to pinniped entanglement responders worldwide to enable knowledge sharing and collaboration as we seek to continually improve our entanglement response techniques.

Protozoal agents infecting tissues from hunter harvested beluga (Delphinapterus leucas) in the Beaufort and Bering Seas

The extent to which protozoan parasites infect arctic populations of hunter harvested Beluga is unknown. These marine mammals are a source of nutrition for first nation peoples in the Western Canadian Arctic and Alaska, highlighting the importance of determining whether zoonotic protozoan parasites infect these populations. Two populations of Beluga from the Beaufort Sea

(n=48) or Bering Sea (n=28) sampled between 2008-2018 were assessed for protozoal infection using PCR-DNA sequencing. The genetic analyses identified two protozoal agents. A new species, *Sarcocystis monodontidis*, was detected in 36/76 (47%) animals. *S. monodontidis* was statistically more prevalent in Beaufort Sea Beluga than Bering Sea Beluga (65% vs. 18%; p=0.00011, two-sided Fisher's Exact test). *Toxoplasma gondii,* a prevalent zoonoses, infected 9/76 (12%) whales and was equally represented between the two whale stocks. Whales infected with *S. monodontidis* possessed light to heavy infections with individual sarcocysts noted within striated muscles of the tongue, esophagus, and diaphragm, as well as skeletal muscle fibers throughout the torso. No inflammation was associated with intact cysts. *Toxoplasma* parasites were detected in the heart and diaphragm of infected whales and immunohistochemical staining confirmed the presence of *Toxoplasma* cysts in the heart of one whale, establishing the presence of transmissible forms of the parasite. Multilocus genotyping of *T. gondii* infected whales identified two, previously uncharacterized, recombinant strains. This is the first study to genetically characterize chronic *T. gondii* infections in healthy, free-ranging Beluga with no associated histopathology of active toxoplasmosis. These whales are wide ranging and the source(s) of parasite exposure have not been identified. However, detection of novel, recombinant strains of *T. gondii* infecting Beluga may indicate the definitive felid host is expanding this parasite in the Arctic, since Beluga are not carnivorous, and were likely infected by ingestion of *T. gondii* oocysts, products of the parasite's sexual cycle.

Diversity and distribution of marine mammals over the submarine canyons off Otago, New Zealand.

Submarine canyons are hotspots of productivity in the deep sea, and important habitat for top predators. Canyons potentially concentrate mid-trophic level prey providing enhanced foraging opportunities for deep-diving marine mammals, but this relationship has rarely been tested. The continental shelf off Otago, New Zealand, is incised by a network of canyons which to date have been poorly studied. To investigate diversity and distribution of marine mammals, we conducted visual line-transect and passive acoustic surveys off the Otago coast between 2016 and 2019, in depths from 50 to 1300 m. For a subset of the surveys we recorded water-column acoustic backscatter (assumed to be a proxy for mid-trophic level biomass) with a 38 kHz scientific echosounder sampling concurrently with the visual survey. In all we completed 886 km of survey effort over 15 days, of which 272 km had associated backscatter data. We recorded 64 cetacean encounters representing nine species, and 217 sightings of New Zealand fur seals. The most frequently sighted cetaceans were dusky dolphin (n=27 encounters), sperm whale (n=10), and long-finned pilot whale (n=9). The poorly known Shepherd's beaked whale was seen on four separate occasions. Acoustic detections of sperm whales were made in every season, suggesting year-round presence of the species in deep water habitat in this region. Counts of fur seals per 1km survey segment were related to bathymetric and oceanographic variables and potential prey abundance via generalised additive models. The best model (32% deviance explained) indicated a negative relationship with distance to the coastline, and positive relationships with SST gradient and epipelagic and mesopelagic backscatter. Our results suggest that submarine canyons modify the availability of pelagic biomass and hence influence the distribution of marine mammals, reiterating the importance of these keystone features at a time when the human footprint on deep sea ecosystems is rapidly expanding.

The economics of extinction: The illegal totoaba fishery and the impending loss of the vaquita.

Read, Andy[1]; Littnan, Charles[2]; Reeves, Randall[3]

Corresponding Author: aread@duke.edu

The imminent extinction of the vaquita is being driven by bycatch in an illegal gillnet fishery for the totoaba, a large endangered drum. Dried totoaba swim bladders (*buches*) are smuggled to China where they can be sold on the black market for more than $20,000 USD per kg. We examine this case study in the context of general economic theories of rational choice, which posit that participation in an illegal activity (the totoaba fishery) will be favoured if: the revenue gained from illegal fishing outweighs that from legal fishing; the chance of being apprehended is small; and the cost of punishment is low. In this case, the

totoaba fishery is extremely lucrative (fishermen can sell *buches* for $5,000 USD per kg) and poachers face a low probability of being apprehended and prosecuted, so there are strong incentives to enter the fishery. An important factor contributing to the rapid development of the totoaba fishery was the existence of organized crime cartels, which adapted their existing trafficking networks to exploit the market for *buches*. In addition, a complete ban on gillnet fishing in the Upper Gulf may have exacerbated the crisis, as a government funding program designed to compensate fishing communities was poorly administered. Many fishermen received little or no compensation, further favouring their participation in the totoaba fishery. Finally, enforcement efforts were undermined by corruption, resulting in few arrests and fewer prosecutions. Thus, despite the investment of more than $100 million USD and political support from the highest levels of the Government of Mexico, the vaquita will go extinct. Seen through this economic lens, perhaps the demise of the vaquita was unavoidable. Nevertheless, there are important lessons to be learned for other endangered cetaceans, such as the Yangtze finless porpoise and Mekong dolphin, which are also threatened by illegal fisheries.

Depredation by coastal bottlenose dolphins (Tursiops truncatus) in the Southwestern Gulf of Mexico in relation to fishing techniques

Corresponding Author: me.rechimont@gmail.com

Cetacean–fishery interactions are a recurring problem. These interactions are conflict prone, especially between fishers and those seeking marine mammal conservation. In the southwestern Gulf of Mexico, a large fleet of artisanal fisheries operates using a range of different techniques. We recorded 90 fishing operations in two different fishing areas of Veracruz, Mexico, between 2009-2010 and 2014-2015, assessing whether dolphin interactions negatively affects fish catch and fish gear. These potential impacts were using three generalized linear models (GLMs) hypothesizing that (1) depredation decreases catch per unit effort (CPUE), (2) the predator presence modifies catch composition, and (3) prey species presence increases the likelihood of depredation. Of the gillnet hauls analyzed, 27 were subject to depredation by bottlenose dolphins, despite conditions and fishing methods varying among sites. Higher CPUE attracts larger pods, but a negative effect by depredation was not detected. We also found that depredation probability increased when there were higher capture volumes, when mackerels and jacks were present, and when operations were most southwesterly. Despite the short distance (< 80 km) between sites, we found that bottlenose dolphins on each site displayed different feeding behaviors towards fishing nets. Regarding conservation, bycatch caused by dolphins does not seem to be problematic. In fact, the increase in boat traffic and declining prey abundances due to overfishing could be the main causes of fishers' economic loss. Dolphin–fishery interactions may not represent an actual challenge for marine conservation managers, but stakeholders, fisheries, and governmental institutions should be aware that diminishing returns due to overfishing could exacerbate the apparently false notion of dolphins competing for the fish.

Developing minimally invasive diagnostic methods for monitoring lungworm infections and cortisol in harbour porpoises (Phocoena phocoena)

Harbour porpoises are the most abundant cetaceans in the North and Baltic Seas. Lungworm infections (Metastrongyloidea, Pseudaliidae) are the most health impacting parasitic infections of porpoises in those waters. They are regularly associated with secondary bacterial infections causing severe bronchopneumonia, often resulting in the animal's death. Additionally, effects of anthropogenic activities have the potential to cause chronic stress and may contribute to severe pulmonary infections.

Since exhaled breath (blow) sampling has been successfully established for hormone evaluations in large whales, the best tools to effectively collect blow samples and the necessary amount of exhales for an evaluable harbour porpoise sample were identified. Three different collection methods were tested and a simple Falcon 50mL Conical Centrifuge Tube was identified as most suited device. Since the amount of exhaled tissue is minimal (< 1 µl), the analyses had to be limited to one steroid hormone, and cortisol was chosen as first parameter. The next steps are to correlate blow cortisol levels with blood samples to evaluate if blow is a suitable matrix for non-invasive stress monitoring in porpoises.

For the detection of lung nematode antibodies in blood samples, serological tests were performed on blood from stranded carcasses and individuals in rehabilitation. The samples were grouped into positive (infection proven through necropsy or bronchoscopy) and negative (animals born in human care) clusters. Blood from animals in long-term human care was additionally evaluated for changes in antibody persistence over time. Since an ELISA with HRP-conjugated Protein A as secondary antibody was not able to discriminate between positive and negative samples, western blots are currently evaluated for their suitability as diagnostic tool.

These diagnostic tests can become important tools to monitor antibodies against lungworms as well as stress levels in free-living and rehabilitated harbour porpoises and help to further understand harbour porpoise population health.

Vocal imitation in a Grey seals pup

Vocal imitation is the ability to learn a previously unknown sound by imitating an acoustic model. This process allows individuals to rapidly acquire new communicative signals and comparative studies are useful to clarify the mechanism that enable plasticity in sound production and usage in different species. Pinnipeds share characteristics, such as the capability to produce a broad variety of vocalizations and a high degree of control over the supra-laryngeal part of the vocal tract, that support the ability to acquire new sounds. Specifically, grey seals (*Halychoerus grypus*) breed in high density colonies, where pups vocalise repeatedly to attract their mothers' attention. We studied Grey seals pups with an age-range of 5-30 days, during their rehabilitation period at the Sealcentre Pieterburen. We analysed the acoustic features of each animal and then selected a model call of an individual from the previous year that showed completely different acoustic characteristics. We presented a playback to a group of 5 grey seals pups and we recorded their vocal reaction. This 'novel' playback was played to the focal animals for 28 days, 30 minutes a day, while recording them. One individual of the group started to imitate the model and therefore to change its vocal features. We analysed the distribution of the acoustic frequencies based on temporal parameters for this animal before and after the experiment, the model and the other member of the group. Preliminary results show an increased acoustic similarity between this seal after the experiment and the model, compared to the same animal before the experiment and the other seals of the group. Overall, our study suggests that grey seals pups can spontaneously produce sounds outside their original repertoire through the imitation of a model and may therefore be capable of vocal production learning.

Productive harmony: Offshore wind and marine mammals.

At least 65 species of marine mammals occur in the offshore waters of the USA. Currently, twenty-nine US States, Washington, D.C. and three territories have adopted renewable portfolio standards to diversify their energy resources, promote domestic energy production and encourage economic development. As of April 2019, the Bureau of Ocean Energy Management (BOEM), under the Department of Interior, oversees 15 commercial wind energy leases in the Atlantic and industry interest in California and Hawai'i is increasing. BOEM's mission, in part, is to ensure that these activities are done in an environmentally responsible way. During the first two years of area identification (i.e. planning and analysis), BOEM's subject matter experts study potential offshore wind energy sites to identify areas of environmental sensitivity/importance, and develop lease areas appropriately. After a lease is issued, leaseholders

conduct surveys to characterize the site and assess the wind resource. BOEM works closely with lessees to ensure the necessary environmental data is provided, and/or collected, to support plan submissions. BOEM requires this data to assess the potential impacts to protected species from the proposed activities. BOEM's renewable energy authorization process includes approximately 8 years to assess and/or collect environmental and protected species data before any construction plan is reviewed. BOEM's Environmental Studies Program (ESP) solicits study ideas from the public on an annual basis. The ESP provides funding to other Federal agencies, academic institutions and researchers to design and execute studies to address these data gaps, including sound impacts to marine mammals, marine mammal distribution and habitat use, entanglement and vessel strike risks from all BOEM-related activities. In addition, BOEM uses the results of these studies to inform mitigation strategies, including protected species observers, monitoring and exclusion zones, vessel speed restrictions, sound source verification and noise reduction technology.

Population genomics of killer whales (Orcinus orca) in Australia.

Population genomic datasets have great power to detect cryptic and complex population structure and can generate information to address real-world issues in conservation and management of marine fauna. Killer whales (*Orcinus orca*) have highly complex population structure worldwide, and are currently assigned as data deficient by the IUCN. In Australia, there is limited information currently available about their population structure, but two regions with high seasonal use have been recently discovered: one located mostly inshore in Ningaloo Reef, north-western Australia (NWA), and the other offshore in the Bremer sub-basin, off south-western Australia (SWA). There is little knowledge about their feeding strategies in these regions, but observations suggest they prey upon multiple cetacean species, various fish species, including sharks, and cephalopods. Here, we present a population genomic assessment of killer whales from these two Australian regions. This was accomplished by using a genome-wide dataset of 9,035 high quality single nucleotide polymorphism (SNPs), and sequences of the mitochondrial DNA (mtDNA) control region. The results indicate that killer whales from these two regions represent genetically distinct populations, with low contemporary migration between them, and negligible levels of inbreeding within each population. Genomic estimates of effective population size using a linkage disequilibrium method resulted in 11 (95% CI 3-62.6) individuals for NWA, and 39 (95% CI 24.6-78.1) individuals for SWA. Analysis of mtDNA revealed only two haplotypes; one was predominantly found in SWA and the other in NWA. These results are consistent with studies of killer whale populations from other oceanic regions that showed low haplotypic diversity and high female philopatry. Additional SNP data to be generated from other Australian and New Zealand samples will be used to further clarify demographic parameters of relevance for conservation management of killer whales in the Australasian region.

Underwater hearing and communication in the endangered Hawaiian monk seal (Neomonachus schauinslandi)

Monk seals are among the most endangered marine mammals, and the most primitive phocid seals. We lack substantive bioacoustic information for monk seals, with no formal descriptions of underwater vocalizations and limited data concerning their ability to hear underwater sounds. The auditory biology of monk seals is compelling from behavioral, conservation, and evolutionary perspectives. These seals have been isolated for more than 10 million years, and have auditory structures that differ from those of other living species. Unlike other aquatically mating phocids, monk seals breed asynchronously and are not known to produce social calls in water. To address

knowledge gaps, we thoroughly evaluated a single captive individual. A mature male Hawaiian monk seal was trained to perform a psychophysical task while submerged. Sound detection thresholds were measured for narrowband tones across the frequency range of hearing. Additionally, an acoustic recorder was placed in the seal's living enclosure, enabling characterization of spontaneous vocalizations and seasonal trends in calling. We found this individual to have best hearing from 1 to 25 kHz, with reduced high-frequency hearing relative to other species. In contrast to an early report, this seal could readily detect low-frequency sounds, however hearing at all frequencies was less sensitive than in other true seals. Despite the absence of conspecifics, the seal regularly produced at least six different underwater calls with spectral energy below 1 kHz. Seasonal calling patterns reflected a period of reproductive activity lasting more than seven months, coincident with elevated testosterone levels and increased production of all call types. This study presents the first examination of underwater vocalizations in Hawaiian monk seals, provides insight into the perceptual abilities of this species and the evolution of underwater hearing within the phocid lineage, and enables improved assessments of noise effects on these vulnerable seals. [Supported by US Navy's LMR Program].

Four-flippered dolphin: A new interpretation of hind flipper evolution.

It is rare for hind flippers to develop in cetaceans, but their presence provides important insights into cetacean limb evolution from a tetrapod ancestor. An opportunity to study this occurred when a four-flippered, adult female, bottlenose dolphin (*Tursiops truncatus*) was discovered and captured off the coast of Japan. This study examines reconstructed images derived from her whole body CT scans.

The hind flippers are falcate-shaped, and supported by several bones. The right hind flipper is larger than the left. The most proximal bone lies adjacent to the pelvis and is identified as a femur in both flippers. The bones immediately distal are identified as the tibia (right only), and fibula (both flippers). The next set of distal bones determines the number of digital rays. The right flipper has three tarsals (calcaneus, tarsal, astragalus/talus) and three metatarsals (small, medium, large), while the left flipper has only two tarsals (calcaneus, tarsal) and two metatarsals (small, large). Four phalanges, gradually diminishing in size from proximal to distal, are aligned in one long digit extending to the caudal tip of each hind flipper. An additional single phalanx is found on the leading edge of the right hind flipper, immediately distal to the medium metatarsal.

Digit reduction in this dolphin is not surprising, as fossil whales had four (*Ambulocetus*, *Rodhocetus*) or three (*Dorudon*, *Basilosaurus*) hind digits. The common cetartiodactyl ancestor likely exhibited reduction from five digits, as modern descendants have four digits (hippopotami) or two digits (artiodactyls). Digit loss and limb shortening eventually led to hind limb disappearance during cetacean evolution. The re-appearance of hind extremities is an atavistic trait that harks back to tetrapod ancestry. The falcate-shape of this dolphin's hind extremities suggests an evolutionary path from archaeocete hind limbs, to an undiscovered recent ancestor with hind flippers, before hind appendages disappeared altogether in modern cetaceans.

Mapping prey fields of foraging humpback whales in British Columbia, Canada.

Effective conservation of whale and fish populations requires an understanding of trophic ecology that is difficult to obtain without concurrent acquisition of prey data and whale foraging observations. Developing a cost-effective sampling framework for obtaining time-series data on prey composition and spatiotemporal dynamics of baleen whale feeding remains a major challenge. We investigated a sampling method that measured a variety of surface and deep-water prey characteristics in North Pacific Humpback Whale feeding areas near northern and southern Vancouver Island, British Columbia (B.C.), Canada. The vertical distribution of prey was continuously recorded near feeding Humpback Whales from a small vessel using an Acoustic

Zooplankton and Fish Profiler (AZFP), following fine-scale transects to map three-dimensional prey fields. The surveys were conducted in daylight hours in regions with and without foraging Humpback Whales to describe prey in the areas used by the whales. Regional mid-water prey sampling informed the species composition of acoustic signal data, while humpback fecal sampling provided information about which prey species were actually consumed. Results showed consistent differences between feeding regions, with Humpback Whales targeting shallow Pacific Herring aggregations off northern Vancouver Island but deep layers of Walleye Pollock and euphausiids in southern Vancouver Island waters. Fecal samples from surveyed whales in southern waters comprised mainly bones from juvenile Walleye Pollock or Pacific Cod, while surface observations documented juvenile herring as the dominant humpback prey in northern waters, thus linking Humpback Whale foraging to concurrent measures of prey from the AZFP. Given the current lack of knowledge about Humpback Whale diet and the whales' impact on forage fish in B.C., this combined approach provides a framework for intensive baseline sampling that is needed for accurately estimating diet and regional prey requirements of Humpback Whales at the level required for making important fisheries decisions.

Applying novel methods to uncover the source rookery of Little Penguins predated by Long-Nosed Fur Seals

In South Australia, Long-Nosed Fur Seal (LNFS) *Arctocephalus forsteri* pup production has increased by more than 3.5 times since the 1980's. Little Penguins *Eudyptula minor* are a component of LNFS diet that is not well understood and LNFS breeding distribution is continuing to expand as the species recolonises their former range. Across southern Australia, a number of significant Little Penguin declines have been recorded and developing a better understanding of LNFS and Little Penguin predator-prey dynamics has been identified as a key priority. This research tests the use of Trace Element Analysis (TEA) and Stable Isotope Analysis (SIA) to identify the source rookery of Little Penguins predated by LNFSs. Feathers are the only consistent remain recovered from predated Little Penguins in LNFS scats. Once grown, feathers are metabolically inert and store stable isotope compositions and toxicological information that reflect the diet during the pre-moult phase. In this study moulted Little penguin feathers from 16 breeding sites (~22 burrows per site) were sampled to map feather 'fingerprints' for comparison with feathers recovered in scats from 15 LNFS sites (15-50 scats per site). The contribution of Little Penguins to LNFS diet varied between sites with feathers present in 0-40% of scats. This study found that nitrogen (δ15N) and carbon (δ13C) isotopes were effective at distinguishing sites at a regional scale, when combined with trace element signatures; Aluminium, Zinc and Iron, the highest site/regional resolution was achieved and in some instances site-specific signatures detected. Captive LNFS feeding trials confirmed that feather digestion did not compromise Stable Isotope and Trace Element signatures generated. Combined, SIA and TEA provide a novel approach to exploring complex marine predator-prey relationships, information on sites with high trace element loads and new insights into ecological shifts from top predator populations re-entering an anthropogenically altered marine environment

Data on the movements of marine predators are increasingly used in multispecies synthesis studies to identify ecologically important areas at sea. The rationale is that areas that are important for several predator species are places that support high abundance and diversity of lower trophic level species and thus have high ecological importance.

In the Retrospective Analysis of Antarctic Tracking Data project, we synthesized tracking data for 17 marine predator species of the extended Southern Ocean (circumpolar oceans south of 40˚S). The dataset includes >4000 tracks and nearly 3 million location estimates.

We fitted habitat selection models for each species and then combined their circumpolar predictions to identify regions of common importance. Regions with the highest mean habitat importance represent Areas of Ecological Significance. These were located around the Antarctic continental shelf and in two more northerly aggregations: one in the south-west Atlantic, encompassing much of the Scotia Sea and surrounding waters, and the second covering the chain of Subantarctic islands from the Prince Edward Islands through to Heard and McDonald Islands and parts of the Kerguelen Plateau.

The dataset includes tracking data for five marine mammal species: Antarctic fur seals, crabeater seals, southern elephant seals, Weddell seals and humpback whales. We present our circumpolar predictions of habitat importance for these species and discuss them with respect to predictions for the full suite of species.

Based on our predictions, we offer perspectives on spatial management and conservation.

Our synthesis had spatial and taxonomic data gaps that should be filled in the future. We are uncertain about the importance of ocean regions that are accessible to few land-based central-place foragers, such as the south Pacific Ocean, and we should collate available tracking data for more cetacean species. We encourage the marine mammal research community to fill these gaps through continued large-scale synthetic, collaborative research efforts.

A review of the current evidence on the classification of North Atlantic killer whales (Orcinus orca) as distinct ecotypes.

Killer whales are top predators known to feed on a wide range of prey species, including fish and marine mammals. In some regions, killer whale dietary specialization warrants, along with supporting movement, behavior, morphological and/or genetic differentiation, classification of subpopulations as separate ecotypes. Two ecotypes have been proposed in the North Atlantic based on limited and largely observational data, but remain unconfirmed. The existence of a North Atlantic generalist, which feeds on fish and occasionally on marine mammals, and a North Atlantic specialist, which feeds on marine mammals, have been proposed. The goal of this review is to evaluate existing evidence for the occurrence of North Atlantic ecotypes and to identify key data gaps required to clarify this question. Data acquisition is complicated because the observation of killer whales foraging in the wild is only occasional, often seasonal and may not accurately reflect the long-term diet of a population. Likewise, data on stomach contents is scarce and only available in necropsy cases. Thus, non-lethal, time-integrated chemical tracers have been applied to assess the diets of killer whales in the North Atlantic Ocean. Stable isotopes have shown that Norwegian and Icelandic whales rely on herring. However, the data resolution was low and could not clearly delineate groups. Therefore and to our knowledge, confirmation of specific ecotypes based on feeding differences remains elusive. Other dietary tracer approaches, some of which have been employed to

successfully identify North Pacific killer whale ecotypes, include comparisons of concentrations of biomagnifying pollutants, blubber fatty acid signatures, and compound-specific isotopes analysis. Ecotypes delineated based on feeding ecology could face differences in risks posed by climate-driven changes in prey availability and by exposures to environmental contaminants. Thus, improved conservation strategies should include renewed efforts to resolve the question of the existence of multiple North Atlantic killer whale ecotypes.

Inter-governmental framework for tackling cetacean bycatch

Accidental entanglement in fishing gear is generally considered the most serious threat to cetacean populations, as well as many other marine species. Addressing it requires effective collaboration between the environment and fishing sectors, a challenge that conservationists have been grappling with for decades. Using the example of the UN Agreement on the Conservation on Small Cetaceans in the Baltic, North East Atlantic, Irish and North Seas (ASCOBANS), the poster outlines the collaborative framework set up to combat bycatch and key aspects of the guidance given and work underway. In particular, this includes Resolutions for guiding member countries in how to address bycatch; action plans and regional groups to help stakeholders implement measures in a coordinated fashion; and workshops in order to understand issues better and to develop guidance. ASCOBANS and ACCOBAMS, the Mediterranean and Black Seas sister agreement to ASCOBANS, have established a joint working group on bycatch., which addresses their respective mandates. In providing its advice, the working group will liaise as necessary with other relevant bodies and fora, including working groups of the two Agreements, the ICES Working Group on Bycatch of Protected Species, the IWC bycatch initiative, Regional Seas Fishery Management bodies, RFMOs and NGOs active in the field. The Convention on Migratory Species (CMS), under which ASCOBANS was concluded, also gives bycatch a high priority. The Conference of the Parties has passed a number of resolutions on the subject. The CMS Scientific Council has an Appointed Councillor for Bycatch, who not only provides expert advice on the matter but also takes the lead in liaison with RFMOs and the monitoring of relevant research and technological developments. This poster will showcase the framework provided by the ASCOBANS and ACCOBAMS Secretariats for countries to combat bycatch in their waters and on the high seas.

Who's talking? The challenges of bioacoustics research in captive manatees in Mexico.

The vocal repertoire of Antillean manatees in Mexico and their association with different behaviors is largely unknown. We sought to identify and categorize the vocal repertoire of a captive population of manatees (7 females, 11 males) at the facilities of Dolphin Discovery in Quintana Roo, Mexico. The animals were held in groups of seven (Puerto Aventuras), three (Dreams), four (Cozumel) and four (Isla Mujeres) individuals per aquarium. We conducted 40 minute recordings per manatee, and 40 minutes per group when individual isolation was impossible. The recordings were collected in WAV format with an SQ26-08 hydrophone and Tascam DR05 digital recorder resulting in 408 minutes of acoustic recordings. Recordings were samples in 5-minute intervals and analyzed in spectrograms with Raven acoustical analysis software. We measured the maximum frequency, minimum frequency, and duration of calls. During the spectra analysis, the main challenge consisted in isolating manatee vocalizations, since dolphin vocalizations, anthropogenic sounds (boat propellers, aerial drone), and other environmental noise masked the sounds emitted by manatees. The noise frequency evidenced in the aquariums oscillated between 1600.0–8123.1 Hz, whereas the frequency of manatee vocalizations ranged between 3730.8–5561.8Hz, and 0.1 to 0.5 s. Vocal production rate was highest (3.53 vocalizations per 30 min) in groups of three or more manatees during socializing. We identified numerous recognized acoustic categories including tonal sounds with varying structures (e.g., increasing, decreasing, U-Shaped, complex modulation). To our knowledge, this is the first attempt to study the vocal behavior of Antillean manatees in the Mexican Caribbean.

Potential impacts of vessel noise on Commerson´s dolphins in Patagonia Argentina

Anthropogenic noise is a source of pollution in many coastal areas and can potentially affect marine species. Some of the impacts include reduction in range over which individuals can effectively receive acoustic signals, alteration of sound properties, among others. This study quantifies increases in ambient noise levels produced by individual vessels in two coastal areas of the Patagonia Argentina inhabited by Commerson´s dolphins, *Cephalorhynchus commersonii*. Acoustic data were collected using a dipping hydrophone from a drifted-boat. Third-octave band received levels were calculated empirically for three categories of vessels, and ambient noise. Two scenarios of sound propagation were considered: cylindrical and spherical, and compared to empirical measurements. Percentages of reduction in range for communication and echolocation were calculated for each vessel in comparison to ambient noise. Sounds were also obtained in presence of Commerson´s dolphins in order to examine possible changes in their acoustic repertoire that could be indicative of a noise impact. Single vessels produce median increases in received levels higher than 10 dB in the broad range of frequencies used by the species. Vessel noise potentially reduced up to 98% the range for communication of Commerson´s dolphins, within 100 meters of the noise source. Non-significant differences were found among commercial, recreational and ecotourism vessels. Variations in the acoustic repertoire of Commerson´s dolphins were registered in noiser environments compared to quieter environments, such as an increase in the proportion of clicks with higher peak frequencies. While these results incorporate several simplifying assumptions, this work contributes to establish a baseline for future assessment of impacts of vessel noise on the species, and proposes recommendations for the management of certain nautical activities, such as dolphin watching to strengthen conservation measures for the species in Patagonia Argentina.

Documenting sub-adults Blainville's beaked whales male-male agression: First underwater video ever recorded (El Hierro, Canary islands).
Reyes Suérez, Cristel[1]; Schiavi, Agustina[1]; Aguilar de Soto, Natacha[2]

Sexual dimorphism appears in Blainville's beaked whales. Adult males have a heavily arched lower jaw with a tusk-like tooth erupted at each side. The forehead and back is full of scars, presumably from male-male aggressions to gain access to females. Here we present the first known video that shows two sub-adults Blainville's males performing what seems to be a male-male aggression. The video was taking off El Hierro (Canary islands). The whole action took part between 1 and 10 meters deep. The individuals engaged in the behavior were i) MdHZ3, a 7 years-old sub-adult male (lower jaw slightly protuberant) known from juvenile and genetically sexed, and ii) MdHX50, a sub-adult male, based on the more arched lower jaw. Due to that, MdHX50 could be older than MdHZ3. During the behavior both individuals initially face at each other at a distance of approximately 20 m. Then they approached frontally at low speed until they were less than three meters apart. After that MdHZ3 rolled over his body and both met head to head and back to back slipping and spinning over each other. Then they separated, swam in circles and repeated the whole sequence. What followed was what seemed to be a chase-beating and retreating behavior: MdHX50 chased and beat MdHZ3 in the flank, while this one insistently retreated. This behavior was performed from MdHX50 over MdHZ3 a number of times, until both animals separated, with no signs of apparent wounds or scars. After that, they stayed in the area together swimming synchronously. Similar behavior has been documented in adult males of Northern bottlenose whales. No female seemed to be present in the near area. The purpose of the behavior described remains unclear; it might suggest training for "real" fighting once adults, playing behavior or maybe even hierarchical purposes.

Population features and threats to the Indo-Pacific bottlenose dolphins (Tursiops aduncus) in Iranian Dolphins' Bay Natural Heritage in the Strait of Hormuz, eastern Persian Gulf

Corresponding Author: mra@qeci.org

Background and aims: although small cetaceans in the Persian Gulf suffer from massive anthropogenic impacts, population biology and conservation status of their communities are unknown in most parts of this semi-enclosed shallow sea. A semi-resident community of Indo-Pacific bottlenose dolphins inhabits the Dolphin's Bay Natural Heritage, a nationally protected area (~97 Km^2) and the only Iranian dolphin-watching tourism site, located in the Strait of Hormuz. This study was undertaken to estimate for the first time size, structure, home range, and threats to this dolphin community.

Activities: data were collected during 16 small-boat surveys (~ 27 hours) in December 2017 and February 2018. The photo-identification technique was used to estimate the community size.

Findings and conservation implications: the size of the bottlenose dolphin community was estimated at 126 individuals. In addition, at least four neonates were observed during February, confirming the bay is a breeding habitat for this community. The group size ranged from eight to 100 individuals, observed in one to five subgroups, a mixture of adults, juveniles and calves. Based on previous observations, dolphins usually migrate to unknown areas seaward during late spring and summer months. Our surveys showed that during their presence, their home-range exceeds the easternmost limit of the bay, which calls for an immediate measure to expand the boundaries of the protected area. Fishing activities (e.g. purse-seines, fish hooks, cage-liked traps), which were recorded during 60 % of boat surveys, are the main putative threat for the dolphins. Further, while skippers are not trained for responsible dolphin-watching, tourism boat traffic is another threat for the dolphins. Therefore, the top priority is to cooperate with local communities aiming to promote responsible dolphin-watching, help develop alternative livelihood options for fishers and encourage fishing outside the protected area in order to reduce incidental bycatch and competition for fish resources.

Measurement of progesterone in the blubber of the Franciscana dolphin, Pontoporia blainvillei (Cetartiodactyla; Pontoporiidae), off the coast of São Paulo, Brazil.

The Franciscana dolphin (*Pontoporia blanvillei*) is a small odontocete endemic to the east coast of South America impacted by anthropic activities, mainly bycatch. The hormonal measurement in biological matrices (feces, urine, milk, etc) has been increasingly used in aquatic mammals for reproductive parameters. The present study validated the method of extraction and measurement of progesterone in blubber in this species besides correlating hormone concentration with gender, sexual maturity, age, stage of development and occurrence of pregnancy. The carcasses were collected from stranded and bycatch dolphins of the coast of São Paulo, Brazil. Stranded during the Santos Basin Beach Monitoring Project (PMP-BS), one of the monitoring programs required by Brazil's federal environmental agency, IBAMA, for the environmental licensing process of the oil production and transport by Petrobras at the Santos Basin pre-salt province. Blubber samples were collected and frozen at -20°C (n=96). After extraction, hormonal analyses were done by enzyme immunoassay and were performed on two units of hormone concentration (ng/g and ng/mg). The inter-assay coefficient of variation was 6.89%, the intra-assay coefficient of variation was 7.82%. The progesterone assay presented parallelism $F1.5=0.87$, $p= 0.45$, the mean extraction efficiency was 66%. No difference was found between measurement units. Progesterone levels were higher in females ($\bar{x}$=14.29±18.87 ng/g) than males ($\bar{x}$=6.25±9.60ng/g) ($Z=-2.15$; $p=0.03$), mature female ($\bar{x}$=32.93±23.39ng/g) than immature ($\bar{x}$=8.03±10.62ng/g) ($Z=2.57$; $p<0.01$), adult females ($\bar{x}$=26.35±25.75ng/g) than juveniles ($\bar{x}$=3.84±4.13ng/g) and calf ($\bar{x}$=14.05±13.65ng/g) ($H(2, N=46)=9.68$; $p<0,001$). Hormone levels of females had no correlation with age ($r=0.35$; $p=0.07$). Pregnant animals ($\bar{x}$=52.35±26.44ng/g) had higher levels of progesterone than the rest of the specimens ($\bar{x}$=8.79±11.79ng/g) ($Z=-3.03$; $p<0.001$), than mature ($\bar{x}$=23.78±21.3ng/g) and immature females ($\bar{x}$=8.65±10.78ng/g) ($df=2$; $F=16.39$; $p<0,001$), generating a biological validation of the use of blubber to estimate pregnancy in this species. These results showed all methods could be validated for *Pontoporia blanvillei.*

Quantifying individual manatee exposure to watercraft disturbance using GPS and long-term acoustic tags.

Estimates of population consequences of disturbance require information about how often, how long, and where individuals are exposed to the source of disturbance. Exposure data is also key to estimate the cumulative effects of multiple sources of disturbance. Florida manatees (T*richechus manatus latirostris*) are exposed to boat traffic throughout their habitat. Collision with watercraft is the primary anthropogenic cause of manatee mortality and passing boats are known to disturb manatee behavior. However, the cumulative effects of boat disturbance are currently unknown in part because limited information is available on the level of watercraft exposure experienced by individual manatees. Recreational watercraft are not required to carry the Automated Identification System (AIS). Therefore, it is particularly challenging to predict individual manatee exposure levels on biologically relevant scales using traditional co-occurrence methods. To quantify individual exposure to boat traffic, we deployed long-term sound and motion tags (DTAG-4) on three rehabilitated manatees. These individuals were considered naïve with limited exposure to watercraft disturbance before release. DTAGs were integrated into GPS tracking gear and were set to continuously record for up to 48 days at 32kHz sampling rate. GPS positions were collected every 15 minutes. Using the acoustic record from the tag to detect boat passes, we calculated hourly encounter rates and interpolated GPS positions to estimate the location of each encounter. Preliminary results indicate that boat encounters ranged from 0 to 14 passes/hour. Boat passages interrupted feeding and resting and manatees responded to some passes by engaging in travelling behavior, suggesting that there could an energetic cost to boat disturbance. Spatial and temporal exposure data were combined to produce individual-based exposure maps with estimates of disturbance and cumulative effects of watercraft traffic on Florida manatees.

Sperm whale and killer whale depredation on demersal longline fishery: A technological approach to understand animal behavior.

Toothed whales feeding on fish caught on longlines is a growing issue worldwide. This issue named depredation has a serious economic impact on the fishery economy, and raise questions about fish stock assessment and wildlife conservation. There is thus a critical need for mitigation solutions that requires a good understanding of the depredation behavior. However, depredation by odontocetes on demersal longlines is assessed nearly exclusively from surface observation performed from fishing vessel during hauling phases. Therefore, information on when, where and how odontocetes depredation on demersal longline occurs underwater is still limited.

In the present study, we investigated depredation by killer whales (*Orcinus orca*) and sperm whales (*Physeter macrocephalus*) on demersal longlines in the French Patagonian toothfish fishery (Southern Ocean). Using a combination of animal-borne behavioral and longline-attached data loggers, we revealed that both species are able to depredate longlines on the seafloor. This depredation behavior during the soaking phase raised question about the ability of the whales to detect the longlines. Therefore, using a passive acoustic monitoring we revealed that differences of acoustic signatures of boats between the setting and hauling phases. We hypothesize that this allows odontocetes recognizing the boat activity and therefore localize longline positions.

These results strongly suggest that depredation rates on demersal longlines by odontocetes are likely to be underestimated since interaction events at depth may be unrecorded. For the management of fisheries, these results also suggest an underestimation of the depredation rates which could impact stock assessments. Besides, the evidence that depredation can occur at any time during the whole fishing process should be considered in future developments of mitigation solutions.

Cohort variation in male lifetime mating success and the opportunity for sexual selection in a solitary carnivore, the polar bear

Despite the important role that population density plays in ecological and evolutionary processes, studies of solitary species that occur at low densities remain scarce. Within the context of mating systems, density is expected to influence the ability of males to find and monopolize mates, in turn influencing variance in lifetime mating success and the opportunity for selection. We investigate variance in male lifetime mating success (LMS) and the opportunity for sexual selection in a sexually dimorphic marine mammal, the polar bear (*Ursus maritimus*) using a multi-generational pedigree. Across 17 cohorts, born from 1975 to 1991, male LMS of 369 individuals ranged from 0-10 mates (mean = 1.43; variance = 3.41) with 40% of known-age males not known to have reproduced. The standardized variance in male LMS (i.e. the opportunity for sexual selection) (I_s = 1.66) was low but varied amongst cohorts (I_s range = 0.60-4.99). Non-breeders represented a significant variance component of LMS explaining between 13%-71% of the total variation in LMS among cohorts. In addition across all cohorts male bears had a positive Bateman gradient (β_{ss} = 0.99, r^2 = 0.93, $p < 0.001$), which indicated lifetime reproductive success was positively influenced by LMS. Our results support a growing body of evidence that suggests that male-biased size dimorphism and polygynous mating systems need not be associated with high variance in male mating and/or reproductive success.

Evaluating the utility of drone technology to survey the remote population of Pribilof Island harbor seals

Harbor seals are found throughout much of Alaska's coastal marine habitat and have long been significant subsistence and cultural resources of Alaska Native communities.The Pribilof Island stock is a very small, isolated, and under-surveyed population of harbor seals. Historic counts range from 150-300 seals but no effort was made to conduct surveys of all haul-out sites over the same time period. In the summer of 2018, the Aleut Community of St. Paul Island Tribal Government, the Duke University Marine Robotics and Remote Sensing Laboratory, and the NOAA Alaska Fisheries Science Center began a collaborative research project with the main objectives of obtaining a comprehensive survey of the Pribilof Island harbor seal stock and to evaluate the utility of drone survey technology on a remote seal population. Shore- and boat-based surveys were conducted with the use of multiple, small unmanned aircraft systems (sUAS). Two senseFly eBee Plus fixed-wing drones were used to map harbor seal haul-out habitats while collecting high resolution color and thermal IR imagery. A DJI Phantom 4 multirotor drone was also flown over targeted haul-out sites to collect color imagery. Counts from the 2018 surveys summed to 239 harbor seals ashore. Using an approximate correction for seals likely in the water, the current abundance estimate for the Pribilof Islands is 478 seals. This collaborative effort represents the first comprehensive survey of harbor seals conducted in the Pribilof Islands and initial steps towards developing a long-term monitoring and data collection program with the Aleut Community of St. Paul Island.

Partnering with lobster fishermen to reduce entanglement of North Atlantic right whales in the Gulf of Maine with ropeless lift bag fishing systems.

Riels, Richard
SMELTS, Sedro Woolley , WA
Corresponding Author: hayden2748@gmail.com

Sea Mammal Education Learning Technology Society (SMELTS) has created a patent pending Ropeless fishing system that uses compressed air with variable buoyancy lift bags to bring gear to the surface which completely eliminates the vertical line and buoy. The system is complemented by an acoustic modem used to track gear location and trigger lift bag inflation. This is a negatively buoyant fishing retrieval system that has the ability to lift heavy loads from the seafloor to the surface with ease.

WhaleFeast - Ecological, commercial and social implications of the recent extreme winter arrivals of herring and whales in Northern Norway

Corresponding Author: audun.rikardsen@uit.no

In the last nine winters, large aggregations of humpback (*Megaptera novaeangliae*) and killer whales (*Orcinus orca*), have been observed in fjords of Northern Norway as they exploit a newly established overwintering area for the Norwegian spring spawning herring (*Clupea harengus*). This abrupt change in herring distribution was likely caused by the occurrence of the very strong year classes starting to dominate the spawning population, firstly the 2004 age class overwintering in the area from Andfjord to Tromsø during 2010-2016, followed by the 2013 year class overwintering in the Kvænangen fjord further north from 2016 until today. Consequently, there have been major changes in the local ecosystems and a general increase in abundance of other predators in addition to whales, including different fish and bird species. The herring and whales also represent substantial economic opportunities for the local communities, with booming fishery and tourism industries. However, the associated increase in fishery and tourist boat activity have raised concerns about possible impacts on the marine ecosystem and whales in the region, for example related to depletion in dissolved oxygen, whale disturbances and life-threatening entanglements. The WhaleFeast project aims to facilitate planning, knowledge outreach and cooperation between regional research institutions and other stakeholders to generate knowledge exchange and best practices for a responsible co-development of vessel traffic, fisheries and tourism based on the whales and herring. For this we have used a combination of sampling methods, such as whale satellite tracking (including public online real-time tracking), ID-photos, environmental DNA, genetic and contaminant analysis (biopsies), herring abundance assessments, observational studies, interviews and workshops with stakeholders. Combining information from both biology and social science will deliver products to provide advice for optimal co-existence of whales, industry and humans, until the herring again move away from the coast and the feast is over.

Cultural heritage in animals: What is it and why does it matter?

Ring, Rebecca
York University
Corresponding Author: ringr@yorku.ca

Policy on biodiversity and species conservation is normally couched in terms of habitat or genetic preservation. I argue that where there exists culture, cultural features and cultural diversity need to be taken into account and valued in policy and management processes. My research focuses on the critically endangered Southern Resident Killer Whale (SRKW) population. These cultural beings are not reducible to their ecological or physiological features, so ensuring their continued existence goes beyond protecting their genetic heritage and habitat. For SRKWs to exist, their cultural heritage must be conserved. First, I argue that their social practices count as culture. Second, I argue that the reasons we have for valuing human cultural heritage apply to the SRKW case, and show how this can inform conservation policy and management.

What is culture? I argue that cultures are real social kinds, which are socially constructed ideas or objects that depend on social practices for their existence. Such phenomena can be grouped together according to their causal or constitutive properties or processes, allowing reliable predictions and explanatory power. The facts of the matter for social kinds are determined (in part) by social factors, rather than (only) physical, biological, or psychological factors. I draw on feminist and critical theory to make my case that culture is grounded in systems of social relationship, and that animal culture need not be precluded.

When it comes to cultural heritage value, conservation is widely considered an inherently values-based activity that can be understood as an expression of meaning and values that are attached to material objects. This can be extended to meaningful landscapes, plants and animals as 'natural heritage', and symbols, meanings, knowledge and know-how as 'intangible heritage'. The value of cultural heritage comes down to the significance that phenomena have for social groups, including the SRKW population.

Actual population size and growth trends of the Galapagos otariids

Currently, the Galapagos sea lion (GSL) (*Zalophus wollebaeki*) and Galapagos fur seal (GFS) (*Arctocephalus galapagoensis*) are within the most important endemic species for conservation in the Galapagos Archipelago. Both are classified as "Endangered" since their populations have undergone a drastically decline over the last decades. In this study we determined the population size of both otariids and their growth trends based on 5-years counts (2014 a 2018) of animals in all their rookeries, and the influence of environmental variability on pup abundance. The GSL population size in 2018 in the archipelago, after applying correction factors to the counts, is estimated at 17,000 to 24,000 individuals and has increased at an average annual rate (ʎ) of 5.8% over the last four years. The highest number of GSL counted in the archipelago was in 2014 followed by a population decline of 23.8% in 2015, which corresponded to a strong ENSO year. After that, the population increased mainly in northern, center and western rookeries. While GSL pup abundance showed a decreasing trend with the increasing in the intensity of ENSO event. The GFS population size in 2017, based on counts corrected, is estimated at 7,000 to 10,000 individuals and has increased at ʎ = 4.3 % from 2015 to 2017. The highest number of GFS counted was in 2014 followed by a population reduction of 38% in 2015 mainly in the western rookeries. After that, the GFS population experienced interannual fluctuations with different growth trends among regions of the archipelago. The GFS pup abundance has a strong decreasing tendency with the increasing in the sea surface temperature (SST). Our results show both species are highly vulnerable to changes in the SST associated to periodical oceanographic-atmospheric events in the Galapagos ecosystem which impact prey abundance and the flow of energy in the ecosystem.

High-frequency echo sounders produce lower frequency signals audible and with the potential to affect behaviour of marine mammals.

The use of active high-frequency echo sounders for commercial activities and marine research has been increasing in recent years. While these devices typically operate at centre frequencies outside the hearing range of most marine species, recent work has demonstrated that they may also emit unintended energy at lower frequencies. This may extend into the audible range for several species of marine mammals and have the potential to affect their behaviour. This study measured the full frequency spectrum of a SIMRAD EK60 echo sounder operating at target frequencies of 120 and 200 kHz. Results showed that the generation of both signal types produced broadband energy with frequencies also extending below the system's target frequencies, in the range of 70-100 kHz and 90-150 kHz for the 120 and 200 kHz signals, respectively. For harbour porpoises, the target frequency of the 120 kHz and subcomponents of the 200 kHz signal fall within the region of highest hearing sensitivity and are thus likely detectable. While less sensitive at higher frequencies, measured signal levels indicate that harbour seals will likely also be able to detect the lower frequencies (70-100 kHz) generated by both signal types. Detection of these signals will be dependent on source power, signal duration, repetition rate, signal directionality and the animal's proximity to the beam centre. In addition, detection will be dependent on water depth, local ambient noise and seabed and surface scattering, all affecting signal propagation characteristics. Given the theoretical detectability of these unintended lower frequencies by marine mammals, both signal types have the potential to elicit behavioural responses towards them. This potential conflict should be considered in environmental and behavioural studies using these devices and when planning marine mammal monitoring alongside ecosystem studies using active acoustic sonar systems. p { margin-bottom: 0.25cm; direction: ltr; color: rgb(0, 0, 0); line-height: 115%;

Strengthening the ecological toolbox: Analysis of alkenones in four cetacean species to estimate environmental water temperature.
Rita Espada, Diego[1]; Borrell, Asunción[2]; Aguilar, Alex[1]

(2) Universitat de Barcelona, Barcelona, Spain
Corresponding Author: diegorita@ub.edu

Alkenones are a group of molecules synthesised by cosmopolitan haptophyte organisms. These

molecules are extremely resistant to degradation and the unsaturation index ($U^{k'}_{37}$) of di- versus tri-unsaturated C37 alkenones ($C_{37:2} \cdot (C_{37:2}+C_{37:3})^{-1}$) can be used to estimate the temperature of the water in which the alkenone-producing organisms grew. Thus, alkenones can be found in thousands-of-years-old sediments and palaeoceanographers have used them to measure the water temperature in the past. However, this useful technique has received little attention in other fields. In this study, we developed a method to detect the alkenones in cetacean tissues and analysed them on one mysticete from the North Atlantic (*Balaenoptera physalus*) and three odontocetes from the Mediterranean (*Tursiops truncatus*, *Stenella coeruleoalba* and *Grampus griseus*). The results show the presence of alkenones in most samples of the blubber of *B. physalus* and the krill present in their stomach, as well as in the blubber of *S. coeruleoalba* and *G. griseus,* but they were present in only a few blubber samples of *T. truncatus*. The low prevalence of alkenones in *T. truncatus* may be caused by the coastal distribution of this species, in contrast with the oceanic distribution of the other three. The environmental temperature derived from the $U^{k'}_{37}$ in the samples from *B. physalus* and *S. coeruleoalba* was consistent with the average of their habitat while some of the *G. griseus* samples indicated values that were too low for the Mediterranean Sea (below 10 ºC). Our results confirm that alkenones are transmitted through the trophic web and can be detected in cetacean tissues. However, further research is required as some factors, e.g. the coastal habitat of *T. truncatus* or the mesopelagic prey preferences of *G. griseus*, appear to affect the abundance and $U^{k'}_{37}$ index of the alkenones in their tissues.

Variance in reproductive success among con-specificindividuals can potentially result in changes in haplotype (i.e. alleles) frequencies. A prior study found differential reproductive rates in two clades of humpback whales (*Megaptera novaeangliae*) sampled in the Gulf of Maine, and predicted an 11% decline in one clade versus a 30% increase in the other over a 75-year period. Here, we re-examined evidence for this finding after increasing the sample size by an order of magnitude and extending the period of observation by 21 years. The mt control region (mtCR) was sequenced for 1507 individual humpback whales sampled in the Gulf of Maine, including 318 mature females. Twenty-three haplotypes were identified among the mature females and used to build a Bayesian genealogy which confirmed two well-differentiated clades (BCD and IJK). Calving rates were estimated annually by clade for the same period as the prior study (1979-1995) and also extended through 2016. Whereas significant differences were found in reproductive rates over time in the prior study, larger sample sizes revealed comparable trends for both clades, both within the prior period and in subsequent decades. No statistically significant differences in reproductive rates were found at different levels of the maternal co-ancestry. Our study indicates that mt haplotypes and mt clades are not correlated with a differential reproductive rate in female humpback whales in the Gulf of Maine, and suggests against significant short-term mtCR-based selection.

Molecular identification of trematode parasites of West Indian manatees (Trichechus manatus), and their role as bio-indicators of their distribution and diet

Sirenians are hosts to a variety of parasites, which cause little or no pathology. In the Greater Caribbean, West Indian manatees (*Trichechus manatus*) harbor several major metazoan endoparasites, including a stomach nematode (*Heterocheilus tunicatus*), a nasal trematode (*Pulmonicola cochleotrema*) and five intestinal trematodes (*Nudacotyle undicola*, *Monoligerum blairi*, *Anaplocephala*sp., *Chiorchis fabaceus,* and *Chiorchis groschafti*). Parasitological studies have recommended the use of the latter two as bio-indicators of population distribution. Manatees live in varied habitats (marine, estuarine, fluvial, lake), but the relationship of these to their life history, and thus how it relates to their internal parasites, has not been studied. We sought to identify *Chiorchis* spp. through molecular analysis in different areas of the Caribbean. Ribosomal RNA gene of trematodes collected from 43 carcasses of manatees from Puerto Rico, Florida, Dominican Republic, and Colombia were amplified using the degenerate primers. For comparison purposes, intestinal trematodes were also collected from a dugong from Malaysia. Seventy-seven samples were sequenced and phylogenetic reconstruction was made with 313 bp of the 18S rRNA sequences using representative samples of each geographic location. The trees produced the same values of 100% of the posterior probability for Bayesian Inference and bootstrap values for Maximum Likelihood analysis for *Chiorchis* spp. and *S. travassosi*. We found that *C. groschafti* and *S. travassosi* infect only manatees and dugongs, respectively, in marine habitats in which they feed primarily on sea grasses. In contrast, *C. fabaceus* infects manatees living in fresh-water habitats in which they feed primarily on fresh water aquatic vegetation. Some manatees in Florida were infected with both species, indicative of their movement between marine and fresh-water habitat and their combined diet of sea grasses and other aquatic vegetation. This study documents how *Chiorchis* spp. serve as ecological bio-indicators of manatee habitat distribution and markers of their herbivorous diet.

Comparative morphology of the prostate of odontocete cetaceans: A histological, histochemical, immunohistochemical and ultraestructural study.

The prostate is the only male accessory gland described in cetacean. Only the anatomy and histology of the prostate of few species of these mammals has been described in the literature, and for most species this organ has not been studied. Pathologies of the cetacean's prostate has been reported and potentially can impair the reproduction, hence the importance of investigating the normal anatomy of this organ in such species. The aim of this work was to describe the morphological characteristics of the prostate of different odontocete cetaceans by histological, histochemical, immunohistochemical and ultraestructural techniques. The prostatic gland of 47 animals of nine different species was grossly and microscopically studied. Members of the family Delphinidae, Zhiphiidae y Physeteridae were included. In general, the prostate was a musculo-glandular organ with two distinct parts: The *Corpus prostatae* and the *Pars disseminata*. In the pygmy sperm whale (*Kogia breviceps*) and the Cuvier's beaked whale (*Ziphius cavirostris*), the prostate was a discrete gland with a small *Corpus prostatae*. Histologically the prostate consisted in acini and ducts, lined by a simple cuboidal epithelium, and organized in lobules. The prostates of mature and immature animals were compared. Immunohistochemical analysis was performed using low and high molecular weight cytokeratin, vimentin and prostatic specific antigen (PSA) commercial antibodies. Electron microscopy of the prostate of a bottlenose dolphin was performed and cytomorphological differences among major epithelial components of the prostatic epithelium were described. This work represents a comparative analysis of the morphology of the prostate of various cetaceans' species.

Drivers of distribution for the endangered Burrunan dolphin (Tursiops australis), anthropogenic or environmental influences?

The Gippsland Lakes, Victoria, Australia, supports a small resident maternal-based population of Burrunan dolphins (*Tursiops australis*). The Burrunan dolphin, recognised as vulnerable fauna within the Gippsland Lakes Ramsar site, is currently listed as Endangered under Victoria's Flora and Fauna Guarantee Act. There is now a high priority to protect this geographically and genetically isolated population. Seasonally, we see a dramatic and repeated shift in Burrunan dolphin distribution across the 75km long estuarine lake system. Potential drivers for this shift in distribution include habitat use, benthic structure (supporting lower trophic levels), prey availability and anthropogenic activities such as vessel use. The observed distribution shift coincides with a seasonal increase in vessels, with a high degree of non-compliance to approach Regulations observed. But is this the cause of the seasonal shift? To explore this further, seasonal boat-based surveys (2017-18) recording Burrunan dolphin sightings and behavioural observations were undertaken, and geospatially mapped to identify areas of significance for core-biological activity (i.e. feeding, resting/milling). In addition, habitat assessment and biotope mapping of key areas were undertaken via the Combined Biotope Classification Scheme (CBiCS). Methodologies included Autonomous Underwater Vehicle (transect and mosaicked images) and drop cameras (point location) collecting georeferenced seabed imaging for benthic flora and fauna composition and seabed features; and single-beam acoustic transects for seabed assessments. These assessments resulted in the classification of approximately 11 habitat biotopes, four of which were newly described for the Gippsland Lakes. Finally, to assess whether the benthic structure and habitat are key drivers in seasonal distribution of the dolphins, we used geospatial mapping to overlay the sightings and behaviour with the habitat biotopes.

Fin whale behaviours change during close-encounters with large ferries: Investigating ship strikes from platforms of opportunity.

An unknown number of vessels collide with whales ('ship strike'), causing mortality and injury. In addition to these direct impacts, indirect impacts are likely as ships may alter whale behaviour when a close encounter or near miss occurs. Fin whales (*Balaenoptera physalus*) are the most frequently hit whale species globally. The Bay of Biscay presents an ideal area to study ship strike risks due to high densities of fin whales in summer months, coupled with extensive shipping traffic. A partnership between a university, a marine conservation charity, and an industrial partner operating large ferries across the Bay of Biscay has enabled novel research into interactions between large whales and ships. Data on fin whale behaviour, breathing rates, and surface intervals were collected, alongside distance and bearing to the ship, from the bridge of a large ferry (185m length). The non-lethal effects of close-encounters between large vessels and fin whales were investigated and near-miss encounters quantified. During 4,828km of survey effort in the pilot study, 34% of fin whales sighted came within 500m of vessels, and on eight occasions the ship altered course to avoid collisions with animals. The breathing rates of animals increased significantly as the vessel approached, and dives were longer after close encounters with a vessel. This pilot study showed that large ferries provide an appropriate platform of opportunity for research into ship strikes and near-misses and can provide context of whale behaviours and drivers that may affect the likelihood of ship strikes. The continuation of this monitoring work is discussed, including the use of videogrammetry to measure accurate distances, bearings and to collect behavioural data at a finer scale. These findings will be used in models to highlight areas of risks and possible mitigation strategies.

Abundance, population growth and latent mortality of humpback whales in the Gulf of Maine in relation to human activities

Humpback whales (*Megaptera novaeangliae*) are exposed to a high level of human activity in the Gulf of Maine relative to other primary North Atlantic feeding grounds. Serious injury and mortality from observed entanglements and ship strikes have consistently exceeded management limits, but the population-level effects of these and unwitnessed events have yet not been evaluated. We used a mark-recapture data set from 2000 through 2016 to estimate abundance, survival, population growth rate and the impacts of human activities. Data were obtained through dedicated photo-identification surveys across the Gulf of Maine and high-intensity data collection at smaller scales throughout the region. Population parameters were estimated annually using a hierarchical, Bayesian state-space model that included sex, age, and a random time effect on survival while allowing sex, annual and individual whale effects on capture probability. Based on the posterior distributions of parameter estimates, median abundances ranged from a low of 893 individuals in 2001 to a high of 1,393 in 2016. Average annual population growth was estimated to be 2.8%. The annual number of reported entanglements was not correlated with population size, and there was no evidence that the *per capita* entanglement report frequency declined after Federally-mandated changes to fishing practices in U.S. waters in 2009 and 2015. Model results also did not suggest overall improvements in population survival rates after 2009. An estimated increase in survival from 2015 to 2016 may have been related to a required reduction in fixed gear buoy lines, but requires further investigation. Observed serious injuries and mortalities from all human sources in US waters accounted for at least one-quarter of the estimated number of deaths. This long-term study of individual humpback whales suggests a slowly growing population with on-going impacts from anthropogenic activities.

First record of a grey seal predating a shark in the UK: Combined evidence of a global trend for novel seal diet, or something we've missed all along?

French, Georgia[1]; Roberts, Andrew[2]; Edwards, David[1]

Corresponding Author: a.j.roberts@swansea.ac.uk

Predator-prey interactions have significant effects on food web stability, population dynamics and ecosystem linkage, and for threatened species in conflict with human food industry, a clear understanding of their trophic ecology is critical. Here we report the first record of a managed predator that is in conflict with commercial fisheries in the UK, the grey seal (*Halichoerus grypus*), killing and consuming a managed shark species, tope (*Galeorhinus galeus*). We present scenarios that may explain why this is the first recorded case, and discuss important ramifications. Competition with commercial fisheries and harbour seals (*Phoca vitulina*), plus climate-driven prey scarcity could be driving individual specialisation for feeding on tope and/or be responsible for a wider trophic shift in the diet of grey seals in the UK. Both paradigms could have serious implications for management of protected species and other threatened shark species that may be involved. The scenarios and evidence presented here could have important implications for our understanding of grey seal diet not only in the UK, but also across their range. Evidence indicates that seal species globally may be altering their diet, which could have significant effects on managed species, fisheries and food webs worldwide. Methodologies to improve our understanding of seal diet are also suggested.

Assessment of spatial distribution of industrial gillnet fishery fleet and its overlap with franciscanas (Pontoporia blainvillei) in southern Brazil.

The franciscana, *Pontoporia blainvillei*, is endemic and one of the most threatened small cetacean in the Southwest Atlantic Ocean. Due to its coastal habits (up to 50m) gillnet fisheries bycatch is the main conservation threat faced by the species. In southern Brazil (SBr)(Franciscana Management Area III–FMAIII), bycatch is considered unsustainable for franciscanas. Here, we used data from official logbooks to assess the spatial distribution of the industrial gillnet fishery fleet off SBr in 2017. Additionally, franciscana's sightings recorded during aerial surveys conducted off SBr in the summer of 2014, up to 50m deep, were used to evaluate the existence of an overlap between franciscana occurrence and net sets locations. Density (sets/km²) and encounter rate (ER) of franciscana's group/km were calculated between 0-10m,11-20m, 21-30m and 31-50m isobaths for the whole period and for the summer. The FMAIII was divided in FMAIII-N (27°S to 30°S) and FMAIII-S (30°S to 33°S). A total of 4,081 sets was analyzed (FMAIII-N: n=133, 0.014/km²; FMAIII-S: n=3,948, 0.144/km²). Density and ER varied as followed: FMAIII-N i) 0-10m: annual=0.001/km², summer=0/km², ER=0/km; ii)11-20m: annual=0.007/km², summer=0/km², ER= 0.181/km; iii)21-30m: annual=0.017/km², summer=0.001/km², ER=0.041/km; iv) 31-50m: annual= 0.013/km²; summer=0.0003/km², ER=0.056/km and FMAIII-S i)0-10m: annual=0.067/km², summer=0.013/km², ER=0/km; ii)11-20m: annual=0.194/km², summer=0.039/km², ER=0.053/km; iii)21-30m: annual=0.195/km², summer=0.052/km², ER=0.030/km, iv)31-50m: annual=0.059/km²; summer=0.025/km², ER=0.013/km. Our findings shown that sets/km² and ER are mostly concentrated at the same interval of depth (11-30m), revealing a large overlap between the franciscanas and fishing nets. These results could explain the high level of franciscanas´s bycatch in FMAIII. Due to the lowest sets/km² and higher ER in FMAIII-N, we suggest the withdrawal of the industrial gillnet fleet beyond 50m (~27km from the coast) in this area. Seasonal variation on the franciscana´s occurrence and the spatial distribution of the artisanal fleet should be also considered to build an effective conservation plan for the species.

Moving towards a sustainable cetacean-based tourism industry – case study in Mozambique.

Cetacean Based Tourism (CBT) is often confused with sustainable tourism. However, not every CBT operator has an environmental education component. In reality, tourism activities have proven to have many negative impacts to the animals and management is required to mitigate potentially-harmful effects. This study analysed the attitudes and perceptions of the marine operators and tourists that partake in dolphin-swim activities in the Ponta do Ouro Partial Marine Reserve (PPMR) in Mozambique. In this reserve, a resident population of Tursiops aduncushas been exposed to constant CBT since 1994. Boat traffic in the area (tourism and recreational) has suffered an increase of over 50% during the quiet months. The number of operators offering dolphin-swims has also increased from one to four. Observations were madeduring dolphin-swim activities onboard a CBT boat to quantify changes in dolphin distribution and behaviour. Attitudes and perceptions were studied using a hand-out questionnaire survey with close-ended and Likert scale type questions. Finally, assessment of the biological interpretation provided by operators were assessed via observation of pre-, during, and post-activity communications. Results show that the tours are an effective method to promote a pro-environmental behaviour and consequently increase compliance to the dolphin, whale and whale shark Code of Conduct (CoC). Nonetheless, both tourists and operators displayed only basic knowledge of the regulations of the reserve and of the CoC, indicating a need for improvement. There were short-term negative impacts on the dolphin population: the quality of human-dolphin interactions decreased as well as number of sightings in areas of high vessel traffics. A series of

recommendations were developed to create an effective interpretation programme for all operators, support the revision of the management plan, and to assist in devising guidelines for CBT at both national and international levels.

Ship strike management in priority regions of the U.S. West Coast: Effectiveness of past efforts and potential for new strategies.

Ship strikes are a major source of death for endangered blue, humpback and fin whales on the U.S. West Coast. Quantifying and mitigating ship strikes is an important step to ensure the recovery and resilience of whale populations. We used an encounter rate model based on ship data from AIS and whale habitat models to examine ship strikes in two high-risk areas: waters off Los Angeles/Long Beach and San Francisco Bay. We estimated ship strike deaths and their spatial patterns over five years for each location. In addition, we modeled and compared the effect of past voluntary and incentivized programs on whale mortality. Next, we simulated scenarios in which greater proportions of vessels complied with speed limits to examine the potential impact of increased participation in current speed programs or instatement of mandatory regulations. Finally, we identified additional areas outside the current extent of speed management that show the greatest additional mitigation potential and evaluated the hypothetical reduction in mortality from adding speed limits in those areas. Cooperation with voluntary speed limits increased moderately with management efforts and maximum reduction of modeled mortality in the managed areas was about 13% compared to before speed limit were implemented. Some of that reduction was from management efforts, but some stemmed from a long-term decline in ship speeds as companies employ 'slow steaming' to decrease costs and lower emissions. Off San Francisco, high compliance (80-90%) similar to that achieved with mandatory regulations on the U.S. East Coast could result in approximately twice the decline in deaths as has been achieved. The implementation of additional speed management areas would further decrease strike deaths. To effectively address one of the top human threats to whales, managers need to consider pursuing greater cooperation with speed limits and expanding those limits to key areas of risk.

Genetic study using mitochondrial ADN of sperm whales (Physether macrocephalus) of the Macaronesia.

The sperm whale is a cetacean with a cosmopolitan distribution and a complex matriarchal social structure. It is common in the Canary Islands throughout the year, suggesting that the archipelago holds a resident population. However, there is scarce knowledge about the biology and population structure of the sperm whale in the archipelago and overall Macaronesian region. This species is considered vulnerable and suffers a high ship-strike mortality in the Canary Islands, affecting mainly females and young, and it has been proposed that the archipelago could be an attractive sink habitat for Macaronesian sperm whales. Here we investigate this possibility by assessing genetic connectivity among the Canary, Madeira and Azores archipelagos. The results confirm the known low variability of mitochondrial DNA in sperm whales and shows an apparent lack of female connectivity between i) Azores, and ii) the Canary Islands and Madeira archipelagos, while there is some genetic flux of both sexes between the Canary Islands and Madeira. These results are consistent with previous findings in other places of site-fidelity in females and long ranging males. Observed photoID recaptures of female sperm whales among archipelagos can be reconciled with our results if there are subpopulations with different degree of site fidelity in Macaronesia. Results are applicable for conservation management of the species, as they suggest that the genetic replacement of female sperm whales dead by ship strike will be geographically limited. This increases the potential for a population level impact of ship strikes on sperm whales in the Canary Islands. The results also underline the need to increase sample size in the archipelago and surrounding region to base conservation measures for the species in the Macaronesia.

Use of SNPs to investigate the molecular epidemiology of M. pinnipedii infections.

Wen, Fengqin[1]; Price-Carter, Marian[1]; Subharat,

Tuberculosis (TB) due to *M. pinnipedii* has been diagnosed in 31 New Zealand (NZ) marine mammals, including an endangered Hector's dolphin. It has also been identified in tuberculous lymph nodes in NZ cattle. Genotyping by VNTR-DR showed that isolates from NZ sea lions, fur seals and cattle were distinct from each other and from Australian isolates. The Hector's dolphin isolate was the same type as found previously in 3 NZ cattle. Similarities between genotypes identified by VNTR-DR can sometimes to be due to homoplasy, however, where the same copy number at certain loci develops independently in epidemiologically distinct isolates. Therefore, to further investigate the epidemiology of *M. pinnipedii*, we used whole genome sequencing (WGS) and single nucleotide polymorphism (SNP) analysis. To date, 11 NZ and Australian *M. pinnipedii* isolates have been characterised by WGS and their relationship to other TB complex and *M. pinnipedii* isolates established via comparisons of SNP content. These isolates cluster separately from other TB complex organisms and appear more closely related to *M. microti* than other members of the TB complex. NZ isolates also cluster separately from ancient Peruvian human strains. SNP profiles suggest at least 3 major sub-clusters and a possible common source for the cattle and dolphin infections. We developed SNP assays based on WGS clustering and conducted these on 37 *M. pinnipedii* isolates, confirming the clustering patterns predicted by SNP phylogenetic analysis. In addition, these SNP assays were successfully conducted on 6 of 8 formalin-fixed paraffin-embedded (FFPE) tissues from animals with *M. pinnipedii*. SNP assays show promise for use in investigating the epidemiology of *M. pinnipedii*, including using archived FFPE samples.

The depths of winter: Seasonal distribution and abundance of deep diving cetaceans in the North-East Atlantic.

For wide ranging marine vertebrates with high locomotory capabilities, understanding relative abundance, distribution, habitat use and seasonal occurrence is of importance for conservation and management. Amongst the cetaceans, the susceptibility of deep diving species to anthropogenic noise, including seismic activity and military sonar has increased awareness around the timing and the extent of these activities. Ireland's offshore waters cover a large geographic area with complex bathymetry and oceanography, supporting a high cetacean diversity. Dedicated aerial line transect surveys conducted in summer and winter over two years, comprising 18,000 km of survey effort, in an area of 328,596km^2 resulted in 181 sightings of at least five deep diving species, comprising 568 individuals. Long-finned pilot whales were the most frequently recorded, comprising 52% of the sightings. Beaked whales (Ziphiidae) comprised 40% of the sightings, with some differences in sightings rate/species. Pilot whales were seen in all seasons, with the seasonal point estimates for the whole area varying between 3,080 and 9,036 individuals (with associated CVs between 0.31 and 0.41), showing no strong summer/winter pattern. At least three species of beaked whales were confirmed, with Cuvier's beaked whale most frequently sighted, in waters greater than 1000m depth and in winter, while Sowerby's beaked whales were seen in waters between 500 and 1000m. Seasonal densities of all beaked whales varied across the survey area between 0.005 and 0.015 individuals/km^2, and highlights the waters overlying the continental shelf margin west of Ireland as being particularly important for these deep diving cetaceans. The lack of strong seasonal differences in the abundance and distribution of all these species suggests that these offshore Atlantic habitats are suitable, at least during summer and winter, for most of the identified species, providing a baseline for future management and conservation efforts.

Singing in the deep: A description of sounds and repeated whistle types recorded from melon-headed whales (Peponocephala electra) in the Bohol Sea, Philippines.

Melon-headed whales (Peponocephala electra) are widespread throughout tropical and warm-temperate waters, but data on their acoustic behaviour remains scarce. While generally pelagic, melon-headed whales are known to frequent inshore areas near islands in the Pacific Ocean, such as the Northern Bohol Sea, Philippines. Between 2010 and 2012, we conducted 59 boat surveys from two locations in Bohol. Melon-headed whales represented 34% of the total sightings, corresponding to almost one sighting per survey-day. We record acoustics on five occasions in 2011 and 2012 during single species encounters of melon-headed whales, which allowed us to characterize their vocalizations. To describe whistle characteristics, we analysed a total of 84 minutes of acoustic recording using Avisoft (Avisoft Bioacoustics). We compared acoustic recordings from the Caribbean and Hawaii to provide insight into inter-population variability. Out of 611 whistles identified, 594 were categorized. Whistles fell into six whistle contour categories, predominantly upsweeps (33.2%), sinusoidal (17%) and constant frequency (16.5%). Frequencies ranged from 3.7 kHz to 25.1 kHz, and varied in duration, (mean= 0.572s, range=0.04-2.84s). Although parameters were similar to other geographical regions, whistles from the Philippines had an emphasis on higher start and minimum frequencies, and vocalisations fell into a wider frequency range. We visually grouped all whistles into categories of repeated whistle types, with 73 identified subcategories. We used the Signature Identification method (SIGID) to identify whether these vocalizations were signatures whistles, and 21 repeated whistles types fit the expected structure. While the underlying reason behind regional variation in melon-headed whale whistles warrants further investigation, this study represents the first dedicated work on the acoustics of melon-headed whales in South East Asia and sets the baseline for further reasearch.

Foraging strategies in wild harbour porpoises: Physiological vs. ecological drivers of diving behaviour.

Optimal foraging theory predicts that breath-hold divers should maximize the proportion of time spent foraging by consistently diving close to their aerobic dive limit (ADL). This framework has mainly been developed for deep-diving endotherms with relatively long transit times between food at depth and oxygen at the surface that may prioritize physiological over ecological drivers of dive time. This suggests the hypothesis that ecological drivers of dive times are more important for shallow divers, with short transit times to prey. We tested that hypothesis by studying harbour porpoises that forage almost continuously in shallow Danish waters to fuel their high metabolic rates. We quantified the cost of different behaviours using high-resolution sound and movement recording tags (DTAGs) that record depth, breathing, foraging and relative activity. Tagged porpoises (n=19) performed shallow (95-percentile=23m), short (95-percentile=125s) dives that were grouped using Hidden-Markov models into three behavioural states: non-foraging, pelagic-feeding and bottom-feeding dives. Almost all dives were less than half of each individual's estimated ADL. The drivers of dive duration appeared to change with foraging mode: bottom-feeding dives showed a negative relationship between transit and foraging time suggesting termination due to oxygen depletion, while dive duration increased with transit time in pelagic-feeding dives, suggesting an effect of patch quality on dive termination. Pelagic-feeding dives were more energetically expensive than benthic dives judging from post-dive respiration rates and proxies for activity. We suggest that porpoises adjust their foraging behaviour to prey distribution and quality, using more energetically expensive pelagic feeding in high-payoff prey patches and a more economical, but potentially less rewarding, bottom-feeding mode when prey are scarce. This prey-dependent foraging strategy allows porpoises to capitalize on

proximate prey while diving below their ADL, which may enable them to reduce their dive response while digesting and foraging concurrently to support their high metabolic rates.

Learning the hard way: the vaquita case.

What can the case of the vaquita tell us about ex-situ conservation?

This is a potentially valuable but complex tool for marine mammal recovery. Building capacities takes years and needs to be started long before ex-situ conservation is urgently needed. It's important to start considering the careful planning of phased conservation interventions as human-caused mortality drives populations from abundant to vulnerable to critically endangered.

Fecal thyroid hormone as a biomarker of nutritional status in North Atlantic right whales (Eubalaena glacialis).

The western North Atlantic right whale (*Eubalaena glacialis*; NARW) population has recently experienced declining calving rates and deteriorating health. Nutritional insufficiency, due to shifts in the zooplankton prey resource, has been hypothesized as a factor contributing to these trends. In this study, we investigated fecal thyroid hormone (fT3) as a biomarker of nutritional status in NARWs. Thyroid hormones regulate metabolism, and are especially responsive to thermal and nutritional stressors, decreasing during chronic food shortages to conserve energy. The study objectives were to: 1) validate a fT3 immunoassay; 2) investigate fT3 by sex, life history stage, and season; 3) compare fT3 in whales killed by vessel strike or fishing gear entanglement to healthy whales; 4) explore fT3 trends over two decades and, 5) examine the relationship of fT3 to stress-related adrenal hormones, corticosterone (fGC) and aldosterone (fALD). From 1999-2018, 397 fecal samples were collected and assayed for fT3, fALD, and fGC. A subset of samples (n = 110) were linked to identified whales with associated life history data. General linear models were used to examine fT3 concentrations by sex, reproductive state, and season, and to compare fT3 in whales killed by human activities vs. healthy whales. Results showed fT3 was highest in calves nursing on energy-dense milk and lowest in females recovering from lactation. There was significant seasonal variation, with lower fT3 in spring, and increasing levels throughout summer and autumn as whales gained energetic reserves. Fecal T3 was significantly lower post-2012 coinciding with declining health and decreased calving rates. Fecal T3 was positively correlated with fALD and fGC, and did not differ in human-related mortalities.This study shows that fT3 levels reflect nutritional state in right whales, and recently lower fT3 levels support the hypothesis that insufficient prey resources are contributing to deteriorating population health and depressed reproduction.

Novel non-invasive techniques for health monitoring and investigating the physiological response to stressors in cetaceans

There is a critical need for the ability to assess health and monitor the physiological impact to stressors (e.g. sound, shipping traffic, etc.) in cetaceans, particularly for conservation and management purposes. Blood has always been the "gold standard". However, blood sampling requires capture and restraint, and can be time consuming. Mystic Aquarium is developing and validating novel non-invasive techniques for assessing health and the physiological response to stressors in cetaceans. While these techniques are being ground-truthed under controlled conditions on Aquarium belugas, they will be transitioned to free-ranging whales and/or used during controlled experimental paradigms (e.g. sound exposure studies to investigate the physiological impact of sound). Two females and one male beluga were trained behaviorally for blood, blow, saliva and fecal collection. Sample collection occurred on a routine basis at the same time of day to collect enough material for assay validations (i.e. parallelism, accuracy, recovery, assay variability) and to measure cortisol and/or fecal glucocorticoid metabolites. For biological validation, whales were

sampled for all tissue matrices before, during and after an out-of-water event (OWE) for veterinary examinations. All three whales exhibited increased average plasma (pre=1.6 µg/dl, 30 min=8.4 µg/dl, post=1.9 µg/dl), blow (pre=0.13 µg/dl, 30 min=0.38 µg/dl, post=0.15 µg/dl), and salivary (pre=0.01 µg/dl, 30 min= 0.051 µg/dl, post=0.011 µg/dl) cortisol from baseline to 30 min OWE with the exception of the male who showed a lag time in peak cortisol. Fecal glucocorticoid metabolites increased 2- and 4-fold from baseline to 6.5 hrs post exam in the male and one female. This study is the first to show the time course of cortisol and its metabolites simultaneously in blood, blow, saliva and feces. All tissue matrices show promise for monitoring health and the physiological impact to stressors in wild and managed care cetaceans and will be useful in controlled experimental studies.

Are acoustic devices with low sampling rates effective in ecological studies of coastal bottlenose dolphins?

Echolocation is used by odontocetes for navigation and foraging. Passive acoustic monitoring efforts use detection of echolocation clicks to study distribution, habitat use, and behavior of many species. In general, however, acoustic devices with a sampling rate of up to 500 kHz are expensive. Thus, the use of recorders with a lower sampling rate and lower-cost, such as 48 and 96 kHz, may be an alternative for monitoring programs. Although the clicks produced by bottlenose dolphins are broadband, in general ranging from 0.01 to 150 kHz, the proportion of clicks emitted at lower frequencies are still unknown. Here, we investigated the proportion of clicks that can be detected below 24 and 48 kHz, in recordings up to 96 kHz. We used a Sony PCM-D100 digital audio recorder with a sampling rate of 192 kHz, connected to a Reason TC 4032 hydrophone (frequency range: 0.005 to 120 kHz) to record coastal bottlenose dolphins (*Tursiops truncatus gephyreus*) from a resident population in southern Brazil. We conducted the recordings in a lagoon system (mean depth of two meters, muddy bottom). We analyzed 1h15min of recordings of six different groups of dolphins. We used Raven Pro 1.5 to create spectrograms and analyze the clicks. We counted a total of 27,108 clicks recorded up to 96 kHz. Approximately 99.6% of the total clicks were detected below 48 kHz and 94.6% at frequency below 24 kHz. The proportion of clicks detected below 48 kHz is significantly higher than the proportion of clicks detected below 24 kHz (χ^2=1198.7, df=1, p<0.001). However, less than 6% of the total clicks are undetected below 24 kHz. We conclude that, at least for coastal bottlenose dolphins, ecological studies can use lower-cost acoustic devices with sampling rates of 48 or 96 kHz with no substantial loss in detection rates of clicks.

CeNoBS – a step closer in completing a generation dream: Basin-wide survey of cetaceans in ACCOBAMS area.

The European Marine Strategy Framework Directive (MSFD) aims at implementing a precautionary and holistic ecosystem-based approach for managing European marine waters, towards achieving their Good Environmental Status (GES). Eleven high level qualitative descriptors (D1-11) aim to describe what the environment will look like after GES has been achieved. The CeNoBS project was designed to "Support MSFD implementation in the Black Sea through establishing a regional monitoring system of cetaceans (D1 - Biodiversity) and noise monitoring (D11-Energy) for achieving GES". The Black Sea is a semi-enclosed sea with a narrow connection to the Mediterranean, containing the largest anoxic

water mass on the planet. Three Black Sea cetacean subspecies (*Tursiops truncatus, Delphinus delphis, Phocoena phocoena*) are already under much anthropogenic stress such as bycatch, pollution, underwater noise, prey depletion due to overfishing and human-mediated biological invasions. It has been impossible, however, to evaluate the level of such impacts as there have been only scarce baseline data available on the population abundance and distribution of these cetaceans in recent times. By implementing a dedicated aerial survey using the line transect distance sampling method in summer 2019, CeNoBS will strongly contribute to provide these baseline data, which has been anticipated in the Black Sea for over a generation. Moreover, CeNoBS will aim to elucidate the bycatch pressure and enhance the methodology of bycatch assessment, as well as to reinforce national expertise to implement effective noise monitoring. A great number of partners from the Black Sea riparian countries (Ukraine, Bulgaria, Romania, Turkey, Georgia) collaborate to implement the largest cetacean survey ever conducted in their region, which will complement the macro regional approach undertaken by the ACCOBAMS Survey Initiative (ASI) for improving the conservation of cetaceans and their habitats in the agreement area. **Keywords:** Black Sea; CeNoBS; MSFD; GES; Harbour porpoise; Bottlenose dolphin; Common dolphin; European Union

Mobilizing Hawaiian monk seal data accessibility for the 21st century.

Ronco, Hope[1]; Johanos, Thea[2]; Khurana, Vikram[2]; Robinson, Stacie[3]

Hawaiian monk seal (*Neomonachus shauinslandi*) research has generated one of the world's most comprehensive marine mammal population data sets. In its current form, much of the data are not accessible in real time, particularly in remote field settings where the majority of monk seals reside. The goals of this study are to identify and evaluate new technologies to streamline data collection, and put valuable data at the fingertips of biologists in the field where access to critical life history information like molt status or previous handling sensitivity can radically alter the immediate course of action for both research and response activities for a given individual. Electronic tablets were deployed during the 2018 field season to determine the feasibility of live data entry into a master database. Seal population assessment data were collected using two methods: on paper forms with data entry following the survey and on tablets where data were entered directly into the master database. Little difference was observed in time expenditure between the methods, and field personnel found tablet use in the field challenging. To address limitations identified in this pilot season, focus has shifted to using smaller mobile devices as reference resources rather than data entry tools. During the 2019 field season, we will evaluate paper reference resources updated manually against mobile reference databases updated electronically through the master database. We hypothesize this will save time by minimizing manual updates to paper forms, and increase both accuracy and consistency within the data by minimizing user error. The development of an accessible mobile database will contribute to monk seal population assessment and conservation activities by increasing efficiency, aiding decision-making, and enhancing animal safety. Mobile data management systems have the potential to aid research for numerous marine mammal species which typically inhabit remote regions far from the office computer.

Life at the edge: The limits on underwater behavior of air breathing Southern Ocean predators.

Marine mammals and seabirds undertake a form of central-place foraging because they must obtain their food at depth yet are obliged to return to the surface to breathe. Prey are not evenly distributed in space and time requiring predators to balance their metabolic needs. Over the last four decades, advances in data-logger technology have greatly increased our ability to study the diving of free-ranging marine animals, to quantify extreme behaviours – such as the deepest and longest dives – and how marine predators regulate their dive cycle. In our study, we aim to identify the underlying processes that characterize marine predators' diving capacity using historical and contemporary time-depth recorder data of three species of seals and three species of penguins

inhabiting the East Antarctic sector of the Southern Ocean. By performing a comparative analysis of relationships between basic dive parameters (e.g. dive duration, dive depth, post-dive interval) and between dive parameters and body mass across species we investigate marine predators diving limits. Through application of the first hunting time method, we examine how different species adjust their diving behaviour whilst foraging, and particularly how the diving response adjusts during high foraging effort (e.g. in response to changed prey distribution). Marine predators have been monitored as indicators of ecosystem change in the Southern Ocean. Understanding what determines the ability for an animal to dive is essential to elucidating its feeding ecology and important for answering broader ecological questions regarding ecosystem energy flow.

Metals in cetaceans in Greenlandic waters

Roos, Anna[1]; Boye, Tenna[2]; Simon, Malene
(1) Greenland Institute of Natural Resources
(2) Greenland Climate Research Centre, Greenland Institute of Natural Resources, nuuk, Greenland
Corresponding Author: anro@natur.gl

Pilot, killer and humpback whales and white-beaked dolphins have become increasingly more common in Greenlandic waters in recent years. All species, except killer whales, constitute part of the human diet in Greenland. We have analyzed metals in muscle from 12 humpback whales and four minke whales from west Greenland and nine pilot whales, 10 white beaked dolphins (WBD) and two killer whales from east Greenland. Eleven metals were analyzed including arsenic, cadmium, mercury, lead and selenium.

As expected, concentrations of mercury were highest in pilot and killer whales (up to 15,9 mg/kg wet weight (ww)). A maximum limit of methyl mercury in whale meat for human consumption is set to 0,3 mg/kg ww in Japan. All pilot and killer whales and 70% of the WBD had concentrations above 0,3 mg/kg ww.

Methylmercury can be detoxified by forming mercury selenide together with selenium in the liver. The ratio of Hg:Se on a molar basis can play an important role in an individual's health and a 1:1 relationship indicates an excess of mercury. In the present study, this ratio was between 0,012-1,70 (mean 0,46), indicating that there most often was an excess of selenium in relation to mercury. However, ten individuals had a ratio above 1 (all pilot whales and one killer whale).

Concentrations of arsenic were low and similar within the different species (0,11-0,68 mg/kg ww), with humpback whale showing the largest range and minke whale and killer whales had some of the lowest concentrations. Lead was below level of detection (<0,03 mg/kg ww) in all but two samples (WBD). Concentrations of cadmium were very low in all species except the pilot whales, where two had concentrations above 0,5 mg/kg ww, which is the EU recommended maximum level for cadmium in fish muscle for human consumption.

Predictors of breathing in migrating humpback whales (Megaptera novaeangliae)

Roos, Marjoleine[1]; Noad, Michael[2]; Dunlop, Rebecca
(1) University of Queensland, The Hague, Netherlands
(2) University of Queensland, GAtton, Australia
Corresponding Author: marjoleineroos@gmail.com

After diving, cetaceans must surface and breathe to replenish their oxygen reserves while offloading carbon dioxide. Changes in breathing behavior have been used as indicators of stress due to anthropogenic disturbance, however such changes could also be caused by natural factors. Humpback whales (*Megaptera novaeangliae*) have a breathing pattern typical of cetaceans. Their breathing behavior can be divided into two main aspects: 1) long dives with extended breath-hold, and 2) surface breathing bouts involving a series of relatively rapid breaths and shallow dives. The aim of this study was to determine the most important predictor variables for both breathing behavior components to better understand how a whale's breathing behavior can fluctuate according to its social and environmental context. A total of 40 migrating, adult humpback whales were tagged using digital recording tags (DTAGs) and focally followed from a land-based station and/or a small research vessel. Predictor variables measured included dive depth, swim speed, social context (e.g., number of males in the group), windspeed and water depth. Long breath-hold durations (>75 s), number of breaths in a breathing bout, and timing of breaths during a breathing bout were also measured. Two different modelling analyses were performed: one to explain the long breath-hold durations according to the predictor variables, the other to explain the breathing bout behavior. Preliminary results found that an increase in the number of males in the group (which was correlated with swim speed) shortened long breath-hold duration. This could be explained by increased energetic expenditure. This, in turn, influenced the breathing bout behavior: breath interval decreased with increasing preceding long breath-hold duration. This baseline information is necessary to

determine whether observed changes in humpback whale breathing behavior occur because of changes in a whale's natural context or anthropogenic disturbance.

Is the effect of noise mitigation during pile driving for offshore wind farms on the protection of harbour porpoises (Phocoena phocoena) overrated?

Rose, Armin[1]; Vilela, Raul[2]; Brandt, Miriam; Volkenandt, Mareike[3]; Wahl, Veronika[3]; Michalik, Andreas[3]; Wendeln, Helmut[3]; Diederichs, Ansgar[4]

All offshore wind farms (OWFs) built in German waters were accompanied by extensive passive-acoustic (CPODs) and aerial-survey-based monitoring programmes to assess potential adverse effects on harbour porpoises. Data collected during piling events of the period 2014-2016, when noise mitigation systems (NMS) reduced average broadband noise levels in 750 m distance to pilings to below 160 dB re 1 µPa²s (SEL_{05}), were compared with data of the period 2009-2013, when NMS were still under development and broadband noise levels in 750 m distance were on average 9 dB (SEL_{05}) higher. The aim of the study was to compare the efficiency of NMS during both periods regarding the effects of pile driving on harbor porpoises. CPOD and aerial-survey data revealed that porpoise density and detection rates were on average reduced in up to 15-17 km distance from pile driving, regardless of the period. Hence, no further reduction of the effect distance was found during the period 2014-2016 when compared with 2009-2013.

We a.o. hypothesise the following reasons which might have interacted to some degree: a) the seal scarer effect was stronger than expected and cannot be distinguished from the piling effect; b) porpoises exhibit a stereotypical initial response to pile driving and accompanied construction-related noise (e.g. vessel activities), so that a farther-reaching effect became visible only at very high piling-noise levels; c) stronger cumulative effects occurred during the period 2014-2016 due to tighter piling sequences; d) small-scale habitat differences among OWF areas led to heterogeneous response patterns.

Even though the results of this study still confirm a positive effect of NMS on harbour porpoises, the improvement of these systems seems to reach limits under the current construction procedures regarding the reduction of effect ranges of pile driving on harbour porpoises.

Clinical diagnostic advancements to better inform disposition decisions for live stranded small cetaceans

Cape Cod, Massachusetts, USA is a global hotspot for live dolphin strandings, especially *Delphinus delphis* and *Lagenorhynchus acutus*. Faced with a lack of rehabilitation or short-term holding facilities, local stranding responders have relied primarily on physical examinations and point of care blood work to rapidly assess dolphin health and make appropriate disposition decisions within just a few hours. Starting in 2018, an enhanced clinical diagnostics project was undertaken in an effort to identify additional diagnostic tools to better inform disposition and treatment decisions for stranded small cetaceans. Additional diagnostic modalities included ultrasonography (n=32), capnography (n=50), electrocardiography (N=51), pulse oximetry (n=2) and blowhole cytology (n=22). An expanded reference laboratory clinical chemistry panel including fibrinogen and serum iron concentration as well as erythrocyte sedimentation rates were performed (n=45). Pulse oximetry and blowhole cytology were not found to be useful point of care diagnostics due to challenges of dolphin anatomy and field infeasibility, respectively. The most common ultrasound findings were mild pleural lesions, gas in the renal capsule and gas within the hepatic vasculature. End tidal carbon dioxide partial pressures ($ETCO_2$) tended to be inversely correlated with respiratory rate (increased $ETCO_2$ with decreased RR). Electrocardiograms showed sinus arrhythmias in most cases, although some animals lacked this normal respiratory-driven cardiac pattern. Animals that did not survive the stranding event or post-release commonly had thinner body condition and decreased alkaline phosphatase, a documented marker of inflammation

in managed care cetaceans, and were often stranded for a longer period of time than those that survived. The combination of case history, physical examination, point of care blood analyses, ultrasonography, capnography and electrocardiography was shown to be most useful for rapid in-field assessment to determine appropriate dispositions for live stranded small cetaceans.

The harmful effects of captivity and chronic stress on the well-being of orcas (Orcinus orca).

Orcas are large, deep-diving cetaceans who are known for their global distribution, wide-ranging behavior, intelligence, and social complexity. They possess one of the largest and most complex brains in the mammalian kingdom. They are also the third most common species of cetaceans kept in aquariums and marine theme parks. Most spend many years, and sometimes decades, in captivity. At the time of writing, 63 individuals are held in concrete tanks globally.

The scientific data on how both wild-caught and captive-born orcas fare in captivity is increasingly robust in demonstrating that they cannot thrive under artificial circumstances in concrete tanks. In captivity, orcas exhibit a wide range of abnormal behaviors and often die at an early age from infections and other health conditions that are uncommon in a wild setting. Though numerous papers and reports describe these adverse effects, they do not offer a clear and systematic explanation for why captive orcas suffer chronic stress and how it affects their well-being.

We describe likely mechanisms for the high levels of morbidity and mortality in captive orcas, including the impact of chronic stress on the immune system, physiology and illness. We conclude that orcas are poor candidates for maintenance in captivity and suggest that a radical shift is required in their treatment, in order to meet their complex needs.

'Water, water, everywhere': Comparing marine mammal detections from eDNA with acoustic and visual data in the New York Bight.

Environmental DNA (eDNA) analysis is an increasingly popular approach for surveying species occupancy, wherein DNA shed by organisms is recovered and identified from environmental sources such as samples of water or soil. While several studies have demonstrated that marine mammal eDNA can be detected, few studies have focused efforts in open ocean environments and incorporating multiple species assemblages. Here, we assess the efficacy of eDNA metabarcoding as a means for detecting marine mammals and their prey species in the New York Bight (NYB), an area that extends 16,000 square miles from Cape May, NJ, to Montauk, NY. Beginning in 2018, >200 water samples were collected during dedicated marine mammal sighting surveys and in proximity to acoustic deployments. Samples were taken at the time of a cetacean sighting as the animal sounded, and then again at the same location at specified time intervals. Water samples were also obtained at various time and distance intervals in proximity to acoustic recording devices in order to contrast eDNA and acoustic detections. The eDNA results to date have yielded positive detections for target species observed (e.g., Fin, Minke, and Humpback whales) at the time of sighting and within 30 minutes after sighting, along with co-localized presumptive prey species (both observed and non-observed, including Atlantic menhaden, family Clupeidae, and sand lance, family Ammodytidae). While the use of direct observation methods and passive acoustics for determining distribution and occurrence of marine mammals in the NYB remains essential, the development of complementary new approaches, such as eDNA assessments, also strengthens our understanding of habitat preference for endangered whales and dolphins and their prey. Integration of these approaches is increasingly important for establishing robust baselines on marine mammals and their prey amidst increasing anthropogenic activities in the vast NYB area, which includes

projected offshore wind development, shipping and exploitation of marine resources.

Singing in South Africa: Monitoring the occurrence of humpback whale (Megaptera novaeangliae) song near the Western Cape.

Humpback whales (*Megaptera novaeangliae*) are highly vocal cetaceans, producing a wide repertoire of sounds including song, which is prolific at breeding sites. However, song has been increasingly reported from migration routes and feeding sites, including along the west coast of South Africa (28° to 34°S), a known migration route and feeding site for this species. Here we examine the occurrence of humpback whale song within False Bay from September 2016 – January 2018. Passive acoustic recordings from four locations were scrutinized for humpback whale vocalisations using long term spectral averages. In total, 7205 hours were examined, with song identified in 3% (211 hours) and being more prevalent at the most westerly sites. A strong temporal pattern was found with song exclusively documented in September and October 2016. Song was recorded during all hours of the day, however, a strong diurnal pattern was discovered with singing most common in the evening hours (21:00 to 23:00 pm). On 15 occasions, two or more singers were detected with temporally overlapping song components. These results indicate prevalent, albeit seasonal, song production by humpback whales off the coast of South Africa and highlight the utility of passive acoustic monitoring to indicate their presence and behaviour.

Citizen science as a tool for cetacean monitoring and conservation in the Gulf of Urabá, Colombian Caribbean

Citizen science interconnects formal science - generated by academic institutions- and other stakeholders; promotes the knowledge and empowerment of local communities on the environment that surrounds them and allows them to obtain information in areas and times beyond the systematic monitoring of scientific programs. In the Gulf of Urabá, the Colombian Caribbean, the "Delfín Gris Project" characterizes the populations of dolphins that use the ecosystem, in terms of presence, abundance and habitat use to create conservation tools and face the environmental changes that are generated by the construction of three ports. One of the strategies to collect information and promote different social groups to familiarize with the dolphins is citizen science. In less than a year, the registration of 25 groups of five cetacean species has been made by fishermen, tour operators and the coastguard of the army. Through these records, the presence of three species that have not been reported before in the Gulf (*Stenella frontalis*, *Stenella attenuata* and *Delphinus delphis*) have been confirmed. I has also been possible to cover areas that do not include weekly monitoring of the project. These results-have a great importance considering that in project monitoring had only registered two species in the area (*Sotalia guianensis* and *Tursiops truncatus*), with a limited distribution only to the west region of the Gulf, and with a probability of sighting of less than 10% in the others areas within the Gulf. The success of this strategy of integrating the community, has generated that local organizations have joined efforts to learn about marine fauna, generate productive alternatives around them and to make new rules for anthropic activities that promote conservation.

Singing activity and song structure of breeding stock G wintering off the coast of Costa Rica and Panama

Male humpback whales produce songs at their breeding areas presumably to attract females and compete with other males for access to females. These songs are composed of elements structured hierarchically and are population specific. Recent research shows that humpback whale song emission continues at their feeding areas. Thus, feeding areas that are used by whales from different breeding areas represent an opportunity for cultural transmission. Southern humpbacks migrate from feeding grounds in Antarctica to breeding grounds in Central America. Here we describe the acoustic activity and song structure of southern humpbacks breeding in Caño Island in Costa Rica and Secas, Coiba, and Perla Islands in Panama. Data was collected using multiplerecording systems including autonomous underwater recorders and recordings from the boat. After accounting for differences in recording effort, our results indicate that whale singing activity is significantly higher in Caño Island than in all Panamanian sites. In all sites whale songs were detected throughout the day, but in Caño Island there was a slight decrease between from 7 a.m. to noon. Singing activity peaked up in October for Caño, Secas, and Coiba. The song structure consisted of 13 unique units in Caño Island, 52 for Secas, 11 for Coiba, and 13 for Perlas. Only 12% of the units were shared among all sites. Within Secas the pace of annual theme change was slow with a rapid change between 2015 and 2017. Our results find considerable song unit differentiation between breeding areas in Costa Rica and Panama suggesting that these sites are probably used by males (at least some) from different feeding areas within Antarctica. If this is the case our results have important management implications. Future research will involve standardization of long-term recording methods between sites and expansion to include northern humpback whales migrating from California which are speculated to

Marine mammals vital rate estimation through a new regression approach

Rouby, Etienne
, LA ROCHELLE, France
Corresponding Author: etienne.rouby@univ-lr.fr

Marine mammal populations are globally threatened but effective conservation requires detailed knowledge, especially on population vital rates such as survival and fecundity to assess the effects of pressures, both environmental and anthropogenic. Survival analysis can be undertaken either with (longitudinal) capture-recapture data or (cross-sectional) time-to-event (e.g. death) data. The latter design can used age data collected on stranded individuals to construct life-tables. We developed a flexible regression approach to estimate survival rates from stranding data, that allows for seamless incorporation and testing of covariates (e.g. sex effects). Our approach is parametric and models the hazard (i.e. instantaneous mortality rate) as a mixture of two components that may be interpreted as juvenile and adult hazards. The latter includes frailty (hidden heterogeneity). We implemented our approach in a Bayesian framework, using Hamiltonian Monte Carlo with software Stan. We carried out a simulation study to assess the performance of our proposed model, and to determine adequate sample size for estimating survival rates. This exercise revealed that sample size of 500 individuals were adequate and realistic for accurate estimation of survival rates. Our approach is promising for species where capture-recapture design are not feasible. Low data requirement and estimation effectiveness make our approach parsimonious and relevant in informing conservation policies. We illustrate it on harbour porpoise population (*Phocoena phocoena*) in the Bay of Biscay and Channel.

Incidences of netmarks on two dolphin species caught in bather protection nets along the KwaZulu-Natal coastline, South Africa (2010-2017)

The Indo-Pacific bottlenose dolphin (*Tursiops aduncus*) and the Indian Ocean humpback dolphin (*Sousa plumbea*) are commonly found along the east coast of South Africa. Since 2009, detailed health investigations of the animals incidentally caught in bather protection nets along the KwaZulu-Natal coast have yielded a valuable dataset which allows for the assessment of netmarks, and evaluation if these can be used as reliable indicators of entanglement in stranded dolphins. Marine mammal dissection and necropsy reports as well as photographs of 125 animals known to have been caught in bather protection nets between 2010 and 2017 were investigated to determine prevalence of netmarks as well as any correlations with species, sex, age, and season. Our results showed that only 23.2% of the investigated

125 dolphins known to have died in nets presented signs of netmarks on the skin. There were clear differences between the two species, with only 13.8% of *Sousa* showing signs of netmarks, while 86.2% of *Tursiops* had netmarks. Furthermore, females were more likely to exhibit netmarks on the skin when compared to males (58.6% vs 41.4%). Adults were least likely to exhibit netmarks (31.0%), with the majority of dolphins being juveniles (69.0%; juveniles included calves, neonates and subadults). Seasonal differences were also observed, with more netmarks recorded in winter (37.9%), while summer appeared to have the least number of dolphins with netmarks (10.3%). This result was of particular interest as it contrasted with the assumption that increased temperature attributed to decay of dolphin carcasses and thus affected netmark occurrence. Netmarks and other injuries are considered to be a clear indication of entanglement. However, our study found that only a small percentage of bycaught animals actually present these signs of entanglement. Thus, other methods, in addition to netmark presence, are required to reliably identify entanglement cases in strandings.

Pollutants in polar bears from the Barents Sea – key drivers for spatial and temporal variation.

Barents Sea polar bears are among the highest contaminated polar bear subpopulations within the Arctic. Polar bears from the Barents Sea have two distinct movement patterns to cope with seasonal variation of declining sea ice: "offshore bears" take long migrations to follow the ice towards the eastern Barents Sea, whereas "coastal" bears stay close to Svalbard yearlong. We investigated lipophilic persistent organic pollutants (POPs) in relation to space-use strategy in female polar bears from the Barents Sea. Offshore bears (n=92) had similar levels of POPs than the coastal bears, but they were fatter than the coastal bears. As POPs are more concentrated in thin bears, the effect of habitat use may be masked by body condition. A follow-up study selecting individuals with similar body condition from both groups (n=38) indicated that POP concentrations were higher in offshore bears. Analyses of compound-specific and bulk stable isotopes (δ15N and δ13C), home range location and field metabolic rate based on telemetry studies and contaminants in harp seals from different locations indicated that higher POP concentrations in offshore bears were related to higher proportion of marine and high-trophic level food items in their diet, higher energy requirements, their distribution in marginal ice zones and higher concentrations of pollutants in they prey. Furthermore, we assessed temporal variation of POPs in relation to changes in feeding habits and body condition in female polar bears (n=306) from the Barents Sea in 1997-2017. Analyses of δ15N and δ13C indicated a decreasing intake of marine and high trophic level prey items over time, whereas body condition had a non-significant decreasing tendency between 1997 and 2005, and increased significantly from 2005 to 2017. However, temporal trends of POPs in polar bears were largely controlled by primary and/or secondary emissions of POPs, and not changes in body condition and diet.Barents Sea

Comparative morphology of the spinal cord and associated vasculature in shallow vs. deep diving cetaceans.

In cetaceans, the spinal cord and vascular supply for the entire central nervous system (CNS) lie within the vertebral canal. Unlike most terrestrial mammals, the cetacean brain is not directly supplied by carotid or discrete vertebral arteries, but instead by multiple intricate *retia mirabilia*. Thoracic and cervical *retia mirabilia* supply the epidural *rete mirabile*, which lies within the vertebral canal and feeds both the spinal cord and brain. The vertebral canal also contains the venous

components of the epidural *rete* and the veins that drain the CNS. Thus, the cetacean spinal cord lies within a highly derived, vascularized space within the vertebral canal. Our goal is to examine the relative sizes of these structures across cetacean species that display differences in diving ability. We ask whether (1) the size of the spinal cord, a metabolically expensive tissue, will be relatively smaller in deep *vs.* shallow diving cetaceans, and (2) vascular structures within the vertebral canal of deep divers will occupy a greater relative cross-sectional area than in shallow divers, because of their larger blood volumes. We section whole frozen vertebral columns at each intervertebral disc, take scaled photographs of the vertebral canal contents, and digitally measure areas of all structures in Image-Pro Plus. We are investigating the shallow diving *Tursiops truncatus*, intermediate diving *Delphinus delphis*, and deep diving *Kogia breviceps*, *Mesoplodon europaeus*, and *Ziphius cavirostris*. Preliminary analyses at a mid-thoracic vertebra (T5) demonstrate that in *Z. cavirostris*, the vascular tissues represent 97%, and the spinal cord 2%, of the vertebral canal cross-sectional area. In *T. truncatus*, these values are 86% and 10%, respectively. Thus, in both shallow and deep divers, the thoracic vertebral canal is predominantly a vascularized space. We will describe how these structures vary, both absolutely and relativey, along the length of the vertebral column and across species.

Health parameters of common bottlenose dolphins (Tursiops truncatus) in various salinity environments within the Barataria Basin, Louisiana

As part of a study to establish baselines of common bottlenose dolphin movements in various salinity gradients within the Barataria Basin, Louisiana, veterinarians conducted dolphin health assessments that included physical examination and skin assessment. Sample collection included blood for hematology and serum chemistry, tissue biopsies for histology, and serum/plasma/urine for osmolality. Pulmonary and reproductive ultrasound were also performed to provide further insight into individual animal health. Dolphins were sampled in two time periods in which salinity differed: June 2017 (salinity ranges at the site of capture = 0.7-10.2 ppt) (N = 13) and September 2017 (salinity ranges at capture = 17.7-20.3 ppt) (N = 22). Hematology and serum chemistry data were organized into panels representing organ systems or pathologic processes, and abnormalities were identified by comparing panel parameters with established reference ranges. Nonetheless, a high prevalence of skin lesions was identified, as well as abnormalities in serum biochemical markers and urine:serum osmolality ratios for dolphins sampled in the more northern (and lower salinity) portions of the basin. Unfortunately, this study was not designed to assess the dolphins' health after prolonged exposure to low salinity. Evidence from peer-reviewed literature and field studies suggest that continued exposure to low salinities may lead to adverse health effects. A synthesis and analysis of records using a standardized approach for assessments will be valuable in determining the long-term impacts of low salinity exposure in both natural events (e.g. extreme weather) and anthropogenic events (e.g. trapped behind levee construction). This project was funded through the Gulf Environmental Benefit Fund, National Fish and Wildlife Foundation.

A variable policy landscape for protecting marine species during offshore wind development

Roy, Kathryn[1]; McConnell, Martha[2]; Fortuna, Sarah[2]

Corresponding Author: kathrynr@aisobservers.com

The offshore wind energy sector in the United States is growing rapidly. The existing leases and planning areas for offshore wind development on the Atlantic Outer Continental Shelf (OCS) also coincide with important areas for marine protected species. While U.S. federal laws, the Marine Mammal Protection Act and the Endangered Species Act, are designed to ensure that offshore wind development does not negatively affect marine protected species, regulators and stakeholders are oftentimes not always approving developer plans prior to survey operations. As a result, wind energy companies can hold multiple permits and communications in relation to marine species monitoring and mitigation, which can ultimately lead to conflicting information between documents. From a Protected Species Observer (PSO) perspective, this can lead to confusion among vessel personnel during on-water operations, and lack of protection for marine

mammals. Our research suggests that on- water operations would benefit from a mitigation hierarchy, directed by Federal agencies, that allows for adaptability while ensuring environmental responsibility is upheld by all personnel from management to deckhands. In addition, our research demonstrates that the lack of standardized monitoring procedures, methods for recording data, and sharing of data continues to be inefficient for PSO operations. The transparency of data collected during offshore activities is essential for better understanding the impacts of activities on marine species, and to fill in data gaps on species distribution and behavior. This poster will present our findings in support of the following recommendations: 1) a single, industry wide PSO datasheet that is easily transferrable, 2) A "Notice to Leases" for the Atlantic OCS similar to that of the Gulf of Mexico, 3) a public data repository that would benefit scientists, policy makers, and marine protected species research, and 4) a requirement for comprehensive training opportunities for PSO professionals.

Effect of rehabilitation on the distal gut microbiome of stranded harbour seals (Phoca vitulina)

The Sealcentre Pieterburen, the Netherlands, rehabilitates stranded harbour (*Phoca vitulina*) and grey seals (*Halichoerus grypus*). Most seals stranded on the Dutch coast are orphaned pups or young seals with parasitic pneumonia that are admitted to the Sealcentre with critical health status. Different aspects during the rehabilitation process such as feeding, water and environment may affect the gut microbiome of the seals. Therefore, we investigated the distal gut microbiome of the seals before and during rehabilitation using 16S amplicon next generation sequencing.

During summer 2015 and winter 2015-2016, rectal swabs were collected from 200 harbour seals that were admitted for rehabilitation to the Sealcentre. Samples were collected at admission, during rehabilitation (days 8 and 15) and just before release. Seals that died were sampled during postmortem examination. Here we present the changes observed in the microbiome of seals that did not receive antibiotic treatment during their rehabilitation.

From all swabs collected, DNA was isolated and amplicon sequencing was performed using Illumina Miseq 2x300bp sequencing of 460 bp of the 16S V3–V4 region. Reads were analyzed using DADA2. Alpha and beta diversity were determined using Phyloseq and tested for significant differences between sample groups adjusting for confounders using Linear Mixed-Effects Models and PERMANOVA.

The distal gut microbiome of harbor seals at the rehabilitation center was primarily composed of bacteria of the phyla Firmicutes, Fusobacteria, Bacteroidetes, Proteobacteria and Gracilibacteria. We observed that age, duration of stay in rehabilitation, change from milk to salmon feeding and the individual itself had a large effect on alpha diversity. In addition, rehabilitation did not result in a lower alpha diversity. However, beta-diversity differences were observed between the microbiome of wild animals and rehabilitated animals.

Cetacean morbillivirus in Spanish Mediterranean Sea: Update.

Cetacean morbillivirus (CeMV) has caused thousands of deaths in cetaceans worldwide. The first known outbreak happened in 1988 on the USA's Atlantic coast. Since then, different outbreaks have affected cetacean populations in the northern hemisphere, especially in the Mediterranean and on the Atlantic coast of the USA. In Mediterranean Sea, two important outbreaks affected to striped dolphin population, first one was in 1990 and second in 2007. Both of them started at the same location, in Valencian Community coast (Spanish Mediterranean Sea).

Therefore, this zone has been transformed in an important place for better understanding of CeMV epidemiology. Since 2010 all cetaceans that have stranded in Valencian Community coasts have been analyzed for CeMV. In 2011, we identified a third outbreak of CeMV in western Mediterranean Sea that affected to 50 striped dolphins in only two months. Sequence that was found in all positive animals were phylogenetically close to 2007 CeMV outbreak sequence. Additionally, since 2012 to present we have detected that a novel sequence of CeMV is circulating in Mediterranean striped dolphin population and has an Atlantic origin. We have identified this novel sequence in 5 striped dolphins and one common dolphin from Western Mediterranean coast. In this work we review the current state of knowledge on CeMV in western Mediterranean Sea and epidemiology of the disease.

Blue whales off the Southern coast of Sri Lanka during the Southwest Monsoon Season.

Russell, Grace[1]; Bridge, Marcus[2]; Nimak-Wood, Maja[2]
(1) Gardline Limited, Norwich, United Kingdom
(2) Gardline Limited, Great Yarmouth, United Kingdom
Corresponding Author: grussell924@gmail.com

Observations of 37 individual blue whales (*Balaenoptera musculus*) were recorded off the southern coast of Sri Lanka during the Southwest Monsoon Season (SWM). Sightings were made during a scientific geophysical survey campaign conducted in July and August 2017. Whilst blue whales are regularly recorded on the continental slope of southern Sri Lanka during the Northeast Monsoon Season (NEM) (December - March) and during the two inter-monsoonal periods (March - April and September - October), limited data is available for the SWM (May - September) mostly due to unfavourable weather conditions and very little survey effort. In the northern hemisphere, blue whales undertake seasonal migrations from higher latitude feeding grounds to lower latitude breeding and wintering areas. However it has been suggested that a population of blue whales in the Northern India Ocean (NIO) remains in lower latitudes year round taking advantage of the rich upwelling areas off Somalia, southwest Arabia and western Sri Lanka. Data from this study nevertheless support a theory that a certain number of individuals remain off the southern coast off Sri Lanka during the SWM, suggesting that the productivity in this region is sufficient to support their year-round presence. This study therefore fills a knowledge gap regarding the presence and movement of blue whales in the NIO highlighting the importance of data obtained from platforms of opportunity.

Four decades of stranding response: Hotspots, coverage gaps, and shifting baselines in North central Gulf of Mexico.

Russell, Mackenzie[1]; Wingers, Noel L.[2]; Nelson Seely, Courtney[2]; Carmichael, Ruth H.[3]
(1) Dauphin Island Sea Lab/AL Marine Mammal Stranding Network, Dauphin Island, Alabama
(2) Dauphin Island Sea Lab, Dauphin Island, AL

Corresponding Author: mrussell@disl.org

Cetacean stranding data from Alabama (AL) in the northern Gulf of Mexico (nGOM) have been recorded since 1978, with dedicated stranding response beginning in 1987. Currently, no publications summarize historic and modern stranding trends in this state, which connects the eastern and western nGOM coastlines. To define long-term stranding patterns, we analyzed available Level A data collected in AL between 1978 and 2018, stratified by stranding response agency to account for variation in response effort through time. From 1978-2018, 788 stranding events were recorded involving at least 13 different cetacean species. Bottlenose dolphins (Tursiops truncatus) were the most commonly reported stranded cetacean in AL (n=683, 87.9%) followed by Stenella spp. (n=32, 4.1%). Most strandings recorded during this forty year study occurred on Dauphin Island, Fort Morgan, and Orange Beach, indicating specific stranding hotspots in AL. Three unusual mortality events (UMEs) occurred in the nGOM during this period: 1990, 1993, and 2010-2014 with increased strandings in AL (n=61, 48, 169, respectively). Mean annual stranding numbers during years of dedicated response from 1987-2006 were 20.1 strandings per year. In 2007 and 2008, there was a response agency coverage gap, reflected in low stranding numbers with an average of 4.5 strandings per year. During the 2010-2014 nGOM UME, there were 36.2 average annual strandings. Post-UME stranding values remained elevated from 2015-2018 with 39.1 average annual strandings. The elevated annual averages in years after the 2010-2014 UME compared to mean stranding numbers before 2010 indicate a possible shift in baseline stranding trends for AL, potentially due to a combination of increased strandings after the Deepwater Horizon Oil Spill in 2010 as well as increased awareness and effort by area responders. The examination of historical and modern stranding demographics will allow for more focused stranding response and evaluation of changing trends in the nGOM.

Photographic identification of beluga whales in Cumberland Sound, Canada.

Photographic identification is a valuable tool in the monitoring and management of at-risk marine mammal populations, providing insights into their movements, site fidelity, social structure, and reproductive history. The isolated beluga whale population in Cumberland Sound, Baffin Island, Nunavut, was commercially exploited for several decades until the 1960s. The population was reduced from over 8,000 whales to its current size of approximately 1,400 whales, and it is still harvested by the local Inuit community Pangnirtung at a rate of 41 whales landed per year. Consequently, it has been listed as threatened (COSEWIC and SARA). The objective of our study was to develop a catalog for future analyses, including a capture-mark-recapture technique to estimate population abundance. Photographs of belugas were taken in August 2017 and 2018 using a DJI Phantom 4 drone and supplemented with boat-based photographs in 2018. Whales were identified using scars from natural sources and from hunting wounds. Analyses of the 2017 images indicate that approximately 36% of the population is marked and at least 43 whales were photographed with markings that appeared to be unique and likely to persist over long periods of time. Four whales were photographed and identified in both 2017 and 2018. Group sizes ranged from 1-16 whales with an average group size of 3.7 whales. Approximately 70% of the population were classified as adults, 16% as juveniles, 7% as calves, and the remainder were unknown; these classifications were made based on color, size, and proximity to adults. Creating a photographic identification catalog for this population will allow us to infer life-history characteristics (e.g. calving rate and survival) which is needed for understanding population growth and for monitoring the population. Gaining a better understanding of the Cumberland Sound beluga whale population demography will allow for the development of more effective conservation and management strategies.

Florida manatee behavioral response to boats

The Florida manatee (*Trichechus manatus latirostris*) is a threatened species which suffers substantial mortality from collisions with boats. To better understand the causes of manatee-boat collisions, we combined advanced tag technologies with boat-based focal follows to document the behavior of manatees in response to opportunistic vessel approaches. Argos-linked GPS tags and digital acoustic tags (DTAGs) were deployed on 18 manatees in southwest Florida, providing high-resolution data on manatee location, depth, heading, fluking, and orientation. This permitted a multi-dimensional reconstruction of the manatee's movements and behavior in relation to the trajectories and sounds of passing boats. We built generalized linear mixed models to determine which boat, manatee, and habitat factors accounted for variation in the occurrence, type, and timing of manatee behavioral responses during boat passes. Manatees displayed significantly higher rates of change in roll, heading, depth, and fluking behavior during boat passes <50 m than during periods in which boat noise was absent. Manatees changed their behavior in 89% of cases in which the boat passed within 10 m, significantly higher than during more distant passes. Manatees were more likely to change depth if they were actively fluking or not on a seagrass bed. Boat speed did not affect the occurrence or intensity of manatee response. However, the timing of a manatee's change in behavior relative to an approaching boat was influenced by boat speed; slower boats allowed the manatee more time to respond and behavioral change occurred earlier relative to the time of the boat's closest point of approach. Our findings indicate that fast-moving boats likely pose a greater threat to manatees than slower boats.

Risso's dolphins (Grampus griseus) as an indicator species for the monitoring plan of the Cabrera Archipelago National Park, the largest marine National Park in the Mediterranean Sea

In February 2019, Spain upgraded Cabrera National park to a total extent of more than 90.000 hectares, mainly offshore from the original Park created in 1986. One of the main features protected by this extended MPA is the Emile Baudot Escarpment, which offer a unique foraging habitat for species feeding on deep sea cephalopods. The Risso's dolphin (*Grampus griseus*) is known to feed on mesopelagic squid over areas with steep bottom topography and is one of the most commonly observed predators in the region.

Monitoring a large offshore MPA poses a series of logistic and economic challenges. After being involved in collecting data that has contributed to the declaring of this National Park, the research organisation Alnitak is now focused on ensuring the long-term monitoring through EMS[1] and the use of indicator species such as the Risso's dolphin. In this study we present the results of the development of an "open source" photo identification catalogue for Grampus griseus hosted at the Organismo Autónomo de Parque Nacionales (OAPN), which is the managing body of the upgraded area.

In addition to a schedule of 4 dedicated surveys per year in all seasons, we present a citizen science APP that should allow the input of images by opportunistic observers, thus contributing to our database and supporting the determination of baseline information to provide recommendations on management and conservation.

Macro-litter in stranded cetaceans in North-eastern Portugal

Marine litter is presently recognised as a global anthropogenic threat to marine and costal environments impacting hundreds of marine species, through entanglement and ingestion. Entanglement or ingestion were already reported in 58% of all cetacean species, and consequences of these encounters include internal and external injuries, drowning and limited predator avoidance capabilities, impairment of feeding ability, blockage of the digestive tract, starvation and death.

We present macro-litter ingestion/entanglement frequency of occurrence (F.O.) rates in cetaceans found stranded in the north-central coast of Portugal, collected by the national marine mammal stranding network since the year 2000. For Mysticetes (n=76), only one case of ingestion was recorded (F.O.=1,3%), on a Minke whale (*Balaenoptera acutorostrata*). Considering Odontocetes (n=2232), marine litter including different plastics and derelict fishing gear was registered on 13 species, with variable frequencies of occurrence. Although the overall rate of ingestion/entanglement was equally 1,3%, when considering only animals with marine litter, Pygmy sperm whales (*Kogia breviceps*) showed the highest F.O. (33,3%), followed by Sperm whales (*Physeter macrocephalus*) with 28,6%. Rates of ingestion/entanglement in cetaceans could be influenced by each species' behavioural and feeding habits (deep diving, bottom or pelagic feeders) and by sample size. In terms of mortality rates, plastic ingestion or entanglement as cause of death was attributed to one Sperm whale, one Pygmy sperm whale and one Common dolphin, corresponding to 10% of all cetaceans registered in the present study that interacted with marine litter through ingestion/entanglement (n=30) and to 0,13% of all stranded cetaceans. It is important to note that marine litter reported from stranded animals represents only a portion of the overall affected marine animals, so the presented ingestion/entanglement rates are surely underestimated. Also, on-going studies on microplastic ingestion should disclose more severe impacts of marine litter on cetaceans stranded in Portugal.

Revealing former sperm whale distribution in Indonesian waters based on historical whaling data using habitat models

Knowledge on the presence and habitat preference of species are important for conservation purposes. However, in Indonesian water records of animal occurrence that cover vast areas are lacking. The most abundant available record concerns historical whaling data for sperm whale. In 1935, Charles Haskins Townsend recorded sperm whale captures from 1761-1930, a species that is ubiquitous around equatorial Indonesia. However, since Townsend only depicted the points where whaling occurred, the information on their distribution and seasonal movement pattern were never available. This study aims to assess the former sperm whale distribution and seasonal movement patterns by applying known sperm whale habitat preferences to the whaling historical data. This is done using a presence only habitat model Maximum Entropy (Maxent), and Generalized Additive Model (GAM) with nine submerged topographic variables. Maxent predicted a wider area of distribution than GAM, and its distributions agreed best with the whaling sighting data. We found that distance to coast, distance to -5000m depth contour, and submarine key features such as trough and trench are important variables that characterises sperm whale habitat. The results firstly show that in four areas in east part of Indonesia no seasonal differences occur in sperm whale distribution, while noticeable seasonal differences in distributions were observed in other areas. This historical distribution can be a baseline in assessing present sperm whale distribution. Our study demonstrates the benefits of incorporating unconventional datasets such as historical whaling data into species distribution models to inform conservation management of cetaceans.

Behavioral development of infant carrying behavior in captive Commerson's dolphins

Sakai, Mai[1]; Honda, Natsuno; Wakabayashi, Ikuo[2]

Corresponding Author: maimorisaka@gmail.com

Infant carrying behavior is vital for cetacean mother and calf dyads as it provides protection from predators when foraging with an undeveloped neonate. We investigated the development of infant carrying behavior for Commerson's dolphin (*Cephalorhynchus commersonii*) in Toba aquarium, Japan. We recorded the dyad's position (e.g., echelon, infant, other position during pair swimming or solo swimming), and defined infant carrying as the mother engaging in stroking behavior more frequently than a calf during 3 second period. We also video-recorded and analyzed distance per stroke (DPS) during echelon position and solo swimming. A male neonate and its mother were observed from day of 5 to 199 after birth, for 16 days in total. About 30% of the observation time the dyad adopted the infant position throughout the study period. During day 5, the dyad adopted the echelon position most frequently (52%), with preference for this position declining gradually over time. In contrast, solo swimming increased up to 50% by day 107. Infant carrying was observed 29% of the time on average during the first month, and declined during and after the second month (< 10%). Video analysis revealed that DPS of the mother during echelon position was 43% (1.2m) comparing to its solo swim (2.1m). On the other hand, DPS of the neonate was 1149% (7.4m) comparing to its solo swim (0.6m) in day 6. DPS of the neonate during echelon position decreased drastically in the second month (2.7m, 338% of solo swim (0.8m)) and the third month (2.0m, 154% of solo swim (1.3m)). These results suggest that infant carrying behavior occurred mainly in the first month. Quantity and quality of infant carrying behavior might change depending on a calf's swimming ability and physical development.

Putting passive acoustic data to work: Developing a standardized, open-source approach to automated analysis of passive acoustic data.

Passive acoustic monitoring has shown great potential for cetacean population assessment, including density estimation and habitat modeling. This requires competence in cetacean detection,

classification, and localization, but this potential has been impeded by unreliable species classification, manual data processing, and a lack of integration between acoustic data and other critical ancillary data. Additionally, a wide variety of tools are available and researchers have generally pursued different approaches to the processing and analysis of acoustic data, severely limiting the reproducibility and comparability of results. Here we present a series of Free Open-Source Software packages for Acoustics (FOSSA) that can be used to efficiently process and analyze passive acoustic data. Built in R, FOSSA currently consists of three packages: (1) functions to extract data from acoustic detections, integrate it with ancillary data (e.g. visual and environmental), generate summaries, and output data for downstream analyses (PAMr, in beta testing), (2) a powerful and systematic method for cetacean species classification using passive acoustics (BANTER, complete), and (3) a package for the coordination of acoustic cetacean population assessment tools (PAMde, in development). These are currently designed to work seamlessly with acoustic data collected and analyzed with Pamguard software, but their utility will apply broadly to a variety of acoustic data. A key goal of FOSSA is modularity and flexibility - technology is rapidly evolving, so these packages are designed to allow users to easily incorporate new techniques with minimal effort. Ultimately, the analytical advancements provided by PAMr, BANTER, and PAMde will allow for efficient, standardized results that can be quickly produced with minimal human intervention. FOSSA, as well as supporting data and training materials, will be made publicly available.

How U.S. laws work to protect and recover endangered marine mammals.

The United States has powerful marine mammal and endangered species laws that reduce threats and promote the recovery of marine mammals. We will provide a clear description of how the U.S. Marine Mammal Protection Act and Endangered Species Act work. We will also provide some comparisons to European laws.

We will discuss the recovery of endangered marine mammals in the United States. The Endangered Species Act is the most powerful wildlife law in the United States, and it has successfully prevented the extinction of 99% of species listed under the Act. Using U.S. marine mammal stock assessment reports, species recovery plans, five-year status reviews, and primary sources from peer-reviewed scientific journals, we quantitatively analyzed population trends for 37 marine mammal populations within U.S. jurisdiction since listing. We found that 18 marine mammal (78%) populations significantly increased after gaining legal protections.

We will describe how conservation measures triggered by Endangered Species Act, such as ending exploitation, tailored species management, and fishery regulations, and other national and international measures, appear to have been largely successful in promoting species recovery, leading to the delisting of some species and to increases in most populations.

Finally, presenters will illustrate the benefits and shortcomings of the U.S. marine mammal and endangered species laws to address threats to marine mammals. We will also describe the threats to these bedrock environmental laws, and what is being done to secure these important conservation tools.

Three-dimensional hierarchical prey search behavior of lactating northern fur seals

spottedseal7gomasio@eis.hokudai.ac.jp

Marine prey are often distributed hierarchically, wherein small, high-density patches are nested inside larger, lower-density aggregations three-dimensionally. Marine predators usually adjust their movements according to the hierarchical distribution of their prey, and their adjusted movement often appears as area restricted search (ARS). The foraging behavior of lactating northern fur seals (Callorhinus ursinus; NFS) can be defined on three time scales, a single dive, a succession of dives (a bout), and the foraging trip (one or more dive bouts). Previous studies examined bout- and trip-scale ARS in two dimensions. Here, we used spherical first passage time (SFPT) to detect volume-restricted search (VRS, term for 3D ARS). We aimed to examine VRS behavior in a single

dive-scale and bout-scale by using SFPT. In 2006, four lactating NFS were instrumented with GPS and 3D data loggers and recovered after 1-3 foraging trips. We reconstructed 3D dive paths by using depth, tri-axis acceleration, tri-axis magnetometry and swim speed. We identified the spatial-scale of VRS using SFPT analysis on 3D paths of the bottom phase in each dive and for dive bouts during each night. We used vertical turns considered as a prey encounter index to examine to foraging effort during each dive. VRS scale for individual dives (small VRS) was 4-5 m in diameter and VRS scale of dive bouts (large VRS) was 32.4±5.8 m. Of all dives for each seal, 22.1±6.0% were dives with small VRS. However, vertical turn rate did not differ between dives with and without VRS. Large VRS included both dives with and without small VRS. Therefore, it appears that searching on the dive bout scale is important in NFS foraging. In the future, we should pay attention to bout-scale behavior to examine foraging efficiency of NFS during foraging trips.

Plasticizers and flame retardants in dolphins from the Mediterranean Sea.

Sala, Berta[1]; Giménez, Joan[2]; de Stephanis, Renaud[3]; Barceló, Damià[1]; Eljarrat, Ethel[1]

The present study investigates the occurrence of halogenated and organophosphate flame retardants (HFRs and OPFRs) in blubber of 8 individuals of endangered common dolphins (*Delphinus delphis*) from the Alboran Sea (Mediterranean Sea). HFRs are applied to materials to increase their fire resistance. Polybromodiphenyl ethers (PBDEs) are the most used HFRs and can be found in plastics, furniture or electronic devices. OPFRs are a large class of FRs, which are also used as plasticizers. Both HFRs and OPFRs are endocrine disruptors affecting thyroid glands and some reproductive functions and can cause neurotoxic effects. OPFRs were also suspected carcinogens affecting liver, kidney and testes tissue. PBDEs were detected in all individuals at concentrations ranging from 93.3 to 2045 ng/g lipid weight (lw), with a mean value of 1050 ng/g lw. OPFRs were also detected in all the samples with total concentrations between 151 and 2159 ng/g lw, with a mean value of 1146 ng/g lw. If we take into account that OPFRs represent around 15% by volume of the FR total global production, whereas HFRs represent around 30% by volume, the environmental occurrence of HFRs should be something higher. Moreover, higher bioaccumulation potential of HFRs versus OPFRs has been previously described, as well as limited OPFR biomagnification through food web probably due to biotransformation processes. All these data suggested that HFR levels in dolphins, with a high trophic level, should be higher than those of OPFRs. Thus, the similarity on the range of concentrations for both groups of pollutants could indicate an additional OPFR source of pollution in addition to their use as FRs. Precisely, the OPFR use also as plasticizers, as well as the large amount of marine plastic debris could contribute to the OPFR levels found in dolphin tissues.

The ACCOBAMS certification for highly qualified Marine Mammals Observers.

SALIVAS, Maylis[1]; Lyne, Patrick[2]; David, Léa[3]
(1) ACCOBAMS Secretariat, Monaco, Monaco
(2) Irish Whale and Dolphin Group, Castletownbere, County Cork, Ireland
(3) EcoOcéan Institut, Montpellier, France
Corresponding Author: msalivas@accobams.net

During their Sixth Meeting in 2016, Countries member of the ACCOBAMS expressed the importance of providing a standardized training programme for Marine Mammals Observers (MMOs) and Passive Acoustic Monitoring (PAM) Operators operating during human activities generating noise. In this context, a Resolution was adopted in order to guarantee, throughout the Agreement area, a high-quality standardized training of MMOs/PAM.

The aim was to propose recognized and credible certification with standard training for the whole ACCOBAMS area. In this context, ACCOBAMS countries are encouraged to give permits, in priority, to industrial companies employing Highly Qualified MMOs/PAM operators.

In 2018, the ACCOBAMS Permanent Secretariat, with the assistance of the « ACCOBAMS MMO/PAM Courses Committee», finalized the standard high level course material. This material was provided to the three current accredited "ACCOBAMS highly qualified MMOs/PAM operator" trainer organizations, that will be responsible for running the training in the ACCOBAMS Area (to date: Blue world Institute, Oceanomare Delphis Onlus and DMAD).

Most of the measures proposed to be implemented in the ACCOBAMS area are standard, with some peculiarities including a more conservationist approach and an adaptability: *i.e.* the mitigation zone should be defined on site with in-situ measurements and take into account the level of noise that is known to be harmful to cetacean

species based on more recent knowledge, and should be expanded for behavioural impacts.

The first ACCOBAMS training for High Quality MMO/PAM Operator has been carried out by ACCOBAMS in Constanta, Romania (12 to 16 September 2018). Twelve trainees from five countries of the Black Sea undertook the training provided by four relevant experts and professional MMO/PAM operator. Subsequent trainings will be delivered by accredited "ACCOBAMS highly qualified MMOs/PAM operator" trainer organizations. For more information see the website "Netccobams.com".

Agonistic behaviour between breeding females of the northern elephant seal (Mirounga angustirostris) at Islas San Benito, Mexico.

Agonistic behaviour between individuals of the same sex is generally related to individual reproductive success. It has been studied widely in male pinnipeds, where it determines access to territories or females. Agonistic behaviour also occurs between females, for example to protect pups or defend space at the breeding site, but has been studied little, particularly in phocids. We investigated aggression between breeding females of the northern elephant seal (*Mirounga angustirostris*) to determine its characteristics and functions and to document the relationship between aggression and female characteristics (e.g. body size) and social environment (e.g. harem size). We studied seals at the southern breeding colony at Islas San Benito, Mexico, during the breeding seasons of 2006-2007 and 2007-2008. We observed >5500 interactions between females in >1100 hr of observation. We found that most directed agonistic behaviour was between nursing females, not pregnant ones, and that it varied in relation to body size but not to characteristics of the social unit, such as harem size or operational sex ratio.

Humpback whale calves' vocal repertoire in the Sainte Marie channel breeding ground.

Humpback whales use vocalizations during diverse social interactions or to organise activity such as foraging or mating. Unlike songs, which are confined to males, social calls are involved in social interactions, and have been reported to be produced by all types of individuals, adult males and females, juveniles and calves alike. Recent studies have described these social calls in different geographic areas; however, the context and biological functions of these social calls remains unknown. This study, aims to investigate the vocal repertoire of humpback whale calves during interactions with their mothers. We recorded mother-calf vocal activity during the breeding season in Madagascar by using Acousondes tags attached to mother-calf pairs (either mother or calf or both). Based on a previous description of the vocal repertoire of social sounds in the study area, we were able to identify 9 types of calls by calves, varying from low to mid-frequency, including one call presenting amplitude modulation. Two of the calves' vocalizations reported in this study were similar to calves' vocalizations described in the literature of other geographic areas, and four call types appeared to be group-specific. Though humpback whale calves' vocalizations are in general relatively simple in structure, we found that calves are also able to produce combined calls, composite calls and sequenced calls. Such diversity in call production may be part of the vocal ontogeny of humpback whales, and could lead to a more stable and complex vocal repertoire at adulthood.

The 'Glider and Whales' project: How to explore occurrence and distribution of whales in the Indian Ocean using acoustic glider.

Samaran, Flore[1]; BEESAU, Julie; Dreo, Richard[2]
(1) ENSTA Bretagne, Brest, France
(2) NATO STO Centre for Maritime Research and Experimentaion (CMRE), La Spezia, Italy
Corresponding Author: flore.samaran@ensta-bretagne.fr

In this project named 'Gilder and Whales' an autonomousglider SEAEXPLORER equipped with one hydrophone was used tostudy marine

mammals by listening to the sound they produce, through 3 missions in the Indian Ocean (IO). The glider's speed was close to 0.5 knots, which was slow enough to ensure a good listening quality. It embedded several equipment for positioning, communication and data transmission, and for oceanographic monitoring (pressure, temperature, light)to describe the oceanographic habitat in which the detected animals live. In May 2017, the glider made its first mission in the western part of the Indian Ocean to explore the south of Madagascar in the southeast of Walters Shoals. During 10 days, it traveled nearly 200 km and continuously collected acoustic data with a sample rate of 32 kHz as well as environmental data. In February – April 2018, the glider made two other missions of 17 days each, to explore the eastern part of the Indian Ocean and specially waters around Amsterdam and Saint Paul islands. Through these 3 missions, the glider collected more than 500 Go of acoustic data. Among them, calls, songs, echolocation clicks and whistles produced by different cetacean species including Antarctic blue whales, Madagascar pygmy blue whales, fin whales, sperm whales and dolphins had been manually detected. Detection of cetacean sounds were analyzed to assess the temporal distribution and mapping of species in the studied areas, the time of the days when detection occurred and the ocean depths where acoustic encounters were recorded. This project could attest the capability and the efficiency of the glider technology for cetacean study and highlights how the glider provides a useful alternative to fixed passive acoustic monitoring to explore remote areas.

Killer whale dietary preferences during a period of contrasting availability of prey resources.

Samarra, Filipa[1]; Eleman, Ayça[2]; Pinfield, Roisin[3]; Ólafsdóttir, Anna[1]; Óskarsson, Guðmundur[1]; Gunnlaugsson, Thorvaldur[1]; Víkingsson, Gísli[1]

(3) School of Biological, Earth & Environmental Sciences, University College Cork, Cork, Ireland
Corresponding Author: fipsamarra@gmail.com

In the North Atlantic, killer whale occurrence is generally related with the spatial distribution of lipid rich fish species. In Norway and Iceland, killer whales appear to specialise on herring although this dietary preference may be seasonal. Indeed, in the Norwegian Sea, killer whales associated with mackerel but not herring in the summer. In Icelandic waters, mackerel has been increasingly observed in the summer and currently greatly surpasses the estimated stock size of the Icelandic summer-spawning (ISS) herring, which has been declining. Whether herring-specialist killer whales switch from a preferred herring prey to mackerel in this context remains to be tested. Given the similar trophic position and diet of herring and mackerel, it is difficult to test dietary preferences for either prey using standard chemical tracer analyses of killer whale tissues. Thus, we investigated spatial associations with both fish species by conducting marine mammal observations onboard the International Ecosystem Summer Survey in the Nordic Seas taking place in offshore Icelandic waters in July 2015 and 2017. Simultaneously, we monitored killer whale occurrence and feeding behaviour in an inshore herring spawning ground, Vestmannaeyjar. Killer whale sightings in offshore regions (n_{2015} = 15 and n_{2017} = 2) suggested more likely associations with herring catches than mackerel. In inshore herring spawning grounds, killer whales occurred regularly (19 days with killer whale sightings in 2015 and 10 days in 2017) and were observed feeding on herring. These results suggest preferential feeding on herring, despite decreasing prey availability and increasing availability of an alternative resource. This may be because prey requirements are being met even under the current decreased stock levels or because strict prey specialisation, as seen in other populations, constraints diet switching but future work will be required to estimate the prey stock size required to sustain this population.

Dietary preferences of Tursiops truncatus and Globicephala macrorhynchus in Madeira Archipelago (NE Atlantic) inferred from fatty acids of biopsy samples.

The common bottlenose dolphin (*Tursiops truncatus*) and the short-finned pilot whale (*Globicephala macrorhynchus*) occur year-round in the waters off Madeira Archipelago, and present island-associated populations, yet no literature is found about their diet composition in this region. Bottlenose dolphins are usually opportunistic feeders inhabiting coastal waters, but oceanic groups also occur offshore. Pilot whales inhabit offshore deep waters, with a diet based almost exclusively on cephalopods, but encounters of inter-specific mixed groups are very frequent in Madeira and are likely explained as occasional foraging associations. Analysis of fatty acids (FAs) profiles has been revealed as a powerful technique for quantitative and qualitative assessments of cetaceans' diet. This method is based on the principle that FAs are transferred almost unmodified from the prey to the blubber of the predators. Following this approach, we analised 34 different FAs in order to obtain fine-scale profiles from blubber samples of free-ranging bottlenose dolphins (n=30) and short-finned pilot whales (n=30), and compared them with those from samples of the three most abundant small pelagic fish species in the region (*Scomber colias*, n=15; *Trachurus picturatus*, n=18; *Sardina pilchardus*, n=16), and squids (*Sthenoteuthis pteropus*, n=6; unidentified squid, n=5). Samples collection occurred year-round in 2017-2018, covering all seasons. This is the first study aiming to clarify diet composition and seasonal dietary preferences of these top-predator key species in Madeira Archipelago, using fatty acids analysis, and discussing trophic relationships among these two species. The results are showing us which are the predominant prey species and also if there is a shift in prey abundance in the study area. This knowledge is crucial when implementing conservation measures for these protected species of cetaceans and in the management of the fishery activity in the archipelago, given the commercial relevance of these prey species in the region.

Morbillivirus infection and fishing interaction affecting cetacean species in the Paraná state, southern Brazil.

Sampaio Santos, Vivian[1]; Brunaldi Marutani, Victor Hugo; Rorato Nascimentos de Matos, Andressa Maria; Parra Cesar Nogueira Carreira, Lucas[1]; Moreira, Jessica Regina; Farias de Nóbrega, Daniela; Domiciano Guarnier, Isabela; Domit, Camila[2]; Frederico Rodrigues Loureiro Bracarense, Ana Paula

Corresponding Author: vivianssamp@gmail.com

Cetacean morbillivirus (CeMV) causes epidemics fatalities worldwide. Three strains are characterized (DMV, PMV and PWMV) and a novel strain Sotalia guianensis-CeMV was described in Brazil. Interactions between fishing and morbillivirus might accumulate effects increasing population vulnerability. To investigate the occurrence of CeMV and identify possible fishing interaction in cetaceans off Paraná coast. Since September/16, 51 dead stranded cetaceans recorded by the Projeto de Monitoramento de Praia da Bacia de Santos* (PMP-BS) - a monitoring program required by Brazil's federal environmental agency, IBAMA, for the environmental licensing process of the oil production and transport by Petrobras at the Santos Basin pre-salt province (25°05'S 42°35'W to 25°55'S 43°34'W) - were necropsied. From 25, lungs and central nervous system (CNS) samples were collected to histological and immunohistochemical (anti-CeMV) evaluation. Species stranded included S. guianensis (SG) [60%], Pontoporia blainvillei (PB) [16%], Tursiops truncatus (TT) [12%], Steno bredanensis (SB) [4%], Stenella frontalis (SF) [4%] and Balaenoptera acutorostrata (BA) [4%]. Bycatch was suggested as causa mortis for 14 animals (9 SG, 4 PB, 1 SF). In lungs, pneumonia [44%], edema [16%], bronchopneumonia [16%], pleuropneumonia [8%], pleuritis [4%] and hemorrhage [4%] were observed. CNS findings included encephalitis [12%], meningoencephalitis [8%], spongiosis [4%], polioencephalomalacia [4%] and meningitis [4%]. Seven animals presented lesions suggestive of morbilliviruses. The IHC assay revealed immunolabeling in 11 CNS fragments (5 SG, 3 PB, 1 TT, 1 SF and 1 SB) and 8 lungs (6 SG, 1 TT and 1 SB), contrasting with previous studies where pneumotropism predominated in SG. This difference may be related to a higher neurovirulence strain. All the morbilliviruses transiently infect the CNS, but the development depends on the efficiency of the immune system response. This disease induces immunosuppression, survivals of sub-acute condition may progress to secondary infections. In conclusion, CeMV occurs on the Paraná coast, potentially facilitating the bycatch

Assessment of marine mammals bycatch rates in Chilean demersal fleets

Bycatch of marine mammals by fishing fleets has become an issue of global concern, mainly due to drastic declines in population abundances of several species and increasing evidence of such interactions from monitoring programs. As a response, many RFMOs and countries have taken actions to afford this issue. Consequently, as of 2013 Chile incorporated permanent monitoring programs to register bycatch and discards during fishing operations through observers on board. Considering records and operational information obtained during 2017, this work evaluates marine mammals bycatch rates in different industrial fleets that operated in demersal Chilean fisheries. The study included: one crustacean trawling fleet (CRTF, 29°S–38°S), two hake trawling fleets (SHTF, 33°S-34°S; LHTF, 34°S-40°S), two multi-specific trawling fleets (FRTF and FATF, 41°S-57°S), and two long line fleets (PALF and SHLF, 46°S-57°S). The bycatch rate estimators used were based by cluster sampling design. The results showed that two species of sea lions, *Otaria byronia* and *Arctophoca australis*, were caught incidentally by the fleets studied. Both, the FRTF and FATF fleets did not exhibited marine mammals bycatch. Contrarily, higher rates were observed in the SHTF fleet (0,262 animals/haul) and, to a lesser extent, in the LHTF (0,127 animals/haul). Bycatch rates of 0,054 animals/haul were observed in FRTF and FATF, while, lower rates were observed in the CRTF fleet (0,004 animals/haul). Regarding to mortality of specimens caught, it varied between 34% and 90% depending on the fleet. The differences observed may be explained by the proximity of the operations to sea lions' colonies. Thus, higher rates were observed in fleets that operated closer to the coast and during winter season when animals search for food. These results provide evidence of the impact of each fleet on marine mammals bycatch, allowing focusing and customizing the mitigation efforts according to the scale and features of the problem.

Estimation of bias in distribution and abundance of different cetacean species using data collected during seismic surveys.

Sanchez Cabanes, Alicia; Vilela, Raul[1]; García-Gómez, Jose Carlos[2]

Marine mammal data are often difficult and expensive to collect. Seismic surveys generate abundant data on marine mammals and may reach extensive offshore areas but is rarely used to assess species distributions and abundances due to the bias and uncertainty associated with the noise produced by the vessels. Cetaceans in the UK North Sea waters have been widely studied and seismic survey effort and sighting data systematically collected, thus constituting a perfect test area to account for the bias and assess the accuracy of the distribution and abundance of different cetacean species based on data collected in seismic surveys.

Data from 1467 seismic surveys between 1996 and 2018 were examined and compared to previous not biased works. To take into account detection bias and environmental conditions while specifically addressing the local-scale dependence structure of the data, we use a model-based inference approach, which assumes occurrences spatial locations as a point process using a spatial Log-Gaussian Cox process. The method adopts a flexible Stochastic Partial Differential Equation (SPDE) approach to model spatial structure in density and Integrated Nested Laplace Approximation (INLA) for Bayesian inference, simultaneously fitting detection and density models at fine scale.

Over 11,500 sightings and acoustic detections of cetacean species were identified, being white-beaked dolphins the most frequently encountered species, followed by Atlantic white-sided dolphins and minke whales. Sperm whales, harbour porpoises and long-finned pilot whales were also commonly found, while fin whales, killer whales and short-beaked common dolphins were moderately sighted.

Results are compared with previous abundance and habitat use studies in the area for the main species. Bias estimation opens the door to the use of this type of data to estimate the potential distribution and abundance of cetaceans in other regions where there is a lack of independent data but seismic surveys occur.

Conservation of the Amazonian Manatee Trichechus Inunguis (Sirenia: Trichechidae), in Loreto - Peru.

Corresponding Author: juan.babilonia@gmail.com

The Amazonian manatee *Trichechus inunguis* is a purely aquatic herbivorous mammal hunted for its meat and marketed as pets, regularly trapped in blackwater lakes and streams in and near the Pacaya-Samiria National Reserve in northeastern Perú. These are also accidentally caught in fishing gear by fishermen who also use the meat as bait to catch some species of Amazonian fish. If we do not reduce human impact, these species may disappear.

Since 2007 the Amazonian manatee has been conserved, with the "Rescue, rehabilitation and release" program of this species, it has managed to rescue 51 manatees that were living in captivity and in deplorable conditions, 23 individuals (45.10%) were released in areas protected natural, being monitored for 8 to 10 months by a radio telemetry system, 17 individuals (33.33%) died in the rehabilitation process, most of these were found in a cachexic state; currently there are 11 individuals (21.57%) among offspring, juveniles and adults, 08 of them ready for the next releases. It was reported the birth of 02 manatees in captivity, guaranteeing the survival of this species for future populations.

An educational program is also developed, with the purpose of generating environmental awareness and positive emotions in children and adults regarding the conservation of this species in rural communities and cities in our region, using different methodologies, such as: talks, workshops, leisure activities, guided tours and especially contact with nature and thus guarantee future generations of young people who can protect our resources. In the last 3 years the hunting of this species has been reduced and an increase of the populations in the conservation areas is observed. It is advisable to encourage the monitoring of threats, and the establishment of abundance index and basic information for decision making, including local people for the conservation of this species.

Using photo-ID for assessing bottlenose dolphin skin lesions

PhotoID studies have provided information about effects of natural and anthropogenic impact factors on different species of cetaceans. In this study we analysed photographs of the bottlenose dolphin *Tursiops truncatus* collected between the years 2012 and 2018 at El Hierro (Canary Islands, Spain) to identify signs of interactions or lesions on the skin of the dolphins. We found signs of viral, bacterial, mycotic and parasitic infections, neoplastic diseases, other non-infectious diseases, and intra/interspecific interactions, as well as human interactions. In addition, we found many cut dorsal fins, which could be due to on-going interactions of dolphins with deep water artisanal hook fisheries, or with debris. These results have implications for the conservation and management of this critical species in the Canary Islands and highlight the need to evaluate the interactions with fisheries and other human impacts within existing SACs designated in the archipelago to protect bottlenose dolphins.

Studies of Northern elephant seal (Mirounga angustirostris) population demographics and social structure at Piedras Blancas, California: A multi-faceted collaborative effort.

Piedras Blancas (PB), California is home to the largest mainland northern elephant seal (*Mirounga angustirostris*; NES) rookery (breeding site) in the world. It comprises 6 miles of unconnected beaches housing around 25,000 NES. Cal Poly has initiated the first formal study of this population. Here we report the results of our pilot efforts, during the 2018 and 2019 breeding seasons. Our current objectives are to: (1) record NES movement between breeding sites, (2) collect baseline population demographic data, (3) analyze mating success of males in relation to beach geography, and (4) measure basic morphometric data for weanlings. We tracked NES movement using dye marks, flipper tags, and re-sights. Citizen scientists assisted with re-sights, expanding our efforts. Demographic data and mating success were investigated through visual male-female aggregation (harem) counts via weekly visual surveys. Weaning weights and morphometrics were collected from pups within 5 days of weaning. In each breeding season, we conducted 26 surveys, marked and/or tagged 425 NES, and measured 50 weanlings. Across seasons, we have obtained over 500 re-sights of individuals, including approximately 50 re-sights contributed by citizen scientists. Preliminary analyses of 2019 NES

weanling data suggest an 8% higher average weaning mass for males compared to female weanlings (P = 0.022), indicating an earlier manifestation of sexual dimorphism than observed at other rookeries. We have also documented differences in overall weaning weights between beaches within the rookery, suggesting lower weaning weights at beaches subject to greater human disturbance. The PB population of NES is growing exponentially and migrating to new beaches to meet their spatial needs. We are working with California State Parks, which manages the land, to ensure the data we collect informs the management plan for this rookery as the NES population continues to grow and human-seal interactions become more common.

Modeling behavioral responses of fin whale (Balaenoptera physalus) to whale-watching tourism in the Marine Reserve Isla Chañaral, northern Chile.

Whale-watching (WW) has exponentially grown over the last few years, becoming not only an economic alternative for local communities, but also an important educational tool. However, several studies have shown that some cetaceans exhibit behavioral changes in response to WW boats, and thus there is concern that this activity may be detrimental to target species. In Chile, the Marine Reserve Isla Chañaral is an important place for whale-watching activities, due to a high diversity of cetaceans and the frequent occurrence of the fin whale (*Balaenoptera physalus*). During austral summers from 2014 to 2018 we analyzed short-term responses (travelling and resting behaviors) of fin whales to the WW tourism using the theodolite method. We modeled changes in the reorientation, linearity and speed as variable responses. The co-factors used were: tourism scenario (absence of boats, with boats and after boats), month, year, group size, number of boats and distance from land station. For resting behavior, the most significant co-factors for all the variable responses were month and tourism scenario, while for travelling month and year were the co-factors. At rest, the three variable responses changed during the post-boat scenario, with an increment in speed and linearity and a decrease in reorientation, which suggests that fin whales move from rest to travel. Also, for resting behavior, the speed increased during February, the month where WW intensifies. Similar results were observed in this month for travelling behavior, with an increment in speed. It is important to note that the speed of whales decreased during 2017-2018 years, which could be associated to an improvement in approaching techniques of tour operators after participating in a sustainable tourism workshop. Even when our results indicate that fin whales are being impacted by WW, an appropriate behavior of tour-operators seem to diminish impact the short-term responses by fin whales.

Assessing dolphin extinction risk in presence of hybridization

Hybridization has been documented in several marine mammal species. Human disturbance can increase hybridization rates by affecting species distribution and abundance. Depleted species, in particular, may face genomic extinction due to lack of conspecific mates and high introgression rates. Understanding how introgressive hybridization can lead to genomic extinction helps identify the management action needed to protect threatened species and populations. However, data on hybridization rates and fitness parameters (i.e., fertility and survival) of parental and admixed individuals are often missing. In such cases demographic models can be used to: 1) project population dynamics under possible hybrid and parental fitness hypotheses (i.e., hybrid vigour, outbreeding depression) and 2) identify the main demographic parameters affecting population extinction. Here, we present a new matrix population model to project hybridization dynamics, and we use it to evaluate the hybridization outcomes for two odontocete

populations interbreeding in the semi-enclosed Gulf of Corinth, Greece: the common dolphin *Delphinus delphis* and the 60-fold more abundant striped dolphin *Stenella coeruleoalba*. We projected hybridization dynamics for 100 years under different fitness scenarios for parental and admixed individuals. We performed a sensitivity analysis to identify the main demographic parameters affecting the probability of genomic extinction of the two populations. Common dolphins were predicted to go extinct in one generation time (16 years), regardless of the scenario. The growth rate of striped dolphins was affected by hybridization, and their population could eventually reach genomic extinction—except for scenarios where the fitness of admixed individuals was lower than that of parentals. The probability of extinction of both striped and common dolphins was most affected by the survival of mature and juvenile individuals. For common dolphins, the low initial abundance was also important. Our study shows that hybridization represents an additional and important threat that may contribute to the eradication of local populations.

Rorqual ingestion estimates based on direct measures of feeding rates and prey quality.

As ecosystem engineers, rorqual whales have oversized impacts on marine food webs by ingesting vast quantities of low-trophic level prey while also aiding in nutrient cycling. However, evaluating the biomass of prey consumed by rorqual whales is challenging in large part because prey densities are difficult to quantify, lunge-feeding rates have been intractable to measure, and measuring both concurrently is extremely challenging. The majority of published estimates on rorqual prey consumption have been calculated via extrapolations of metabolic rate rather than by measuring foraging rates and prey concentrations directly. Using high-resolution biologging technology (95 deployments on humpback, fin, blue, and Antarctic minke whales), drone photogrammetry, and active acoustic prey mapping, we report estimates of prey consumption in four lunge-feeding rorqual species. Our results indicate prior estimates of maximum daily and annual consumption are likely underestimated by a factor of five. The implications of our findings are wide-ranging. This includes re-evaluations of the net primary productivity and krill biomass required to sustain historical and current populations of rorqual whales globally, the amount of nutrient recycling and redistribution (e.g. Fe, N, P) due to fecal deposition, and food-web interactions with other krill predators. We conclude that although the magnitude of these impacts on the ecosystem provided by rorqual whales have been dramatically reduced due to industrial whaling, these estimates increase their considerable ecological role particularly as their populations continue to recover.

The cave use of Mediterranean monk seal (Monachus monachus) in the Gökova special environmental protection area between 2016 and 2018

This study was conducted between 2016 and 2018 in the Gökova Special Environmental Protection Area. The purpose of the study was to identify monk seal caves and classify them according to frequency of use, and to estimate the local monk seal population in the area to identify primary monk seal habitats as core zones.

First, the local fishers and sailors were interviewed for the location identification of the seal caves. Afterwards, these caves were checked by skin diving whether they are suitable for monk seal use,

and the camera-trap installations. Six camera-traps in four caves were mounted for monitoring. The camera trap settings were adjusted motion trigered in hybrid-mode taking both video images (10 - 20 sec) and three photos. After photo shootage 3 to 7 min-pause was also set. The recordings (N= 6,778 events comprising both three photos and a video footage) from all caves were analysed to determine the use (resting and/or breeding) and its frequency, seasonal and circadian cave usage, and identified individuals' gender and the age group.

Three of the caves mounted with cameras were identified as possible breeding and/or nursery grounds, confirmed by the presence of monk seal juveniles inside. It is found out that the cave usage increases in Spring. Besides, the existence of juveniles in early winter proved breeding. The data were compared with Pearson's Chi-squared test, and it is found out that there were significant differences among the caves according to their location and use of day-periods. Monk seals were mainly using the caves nocturnally, and revealing a diurnal activity pattern. During the study, four adult females and two juveniles were identified. The main observations of mother-juveniles highlight the important breeding/nursery grounds where core protection areas to be considered. This study was funded by the Zoological Society of London The EDGE of Existence Programme.

Mother-offspring and sibling whistle comparisons in bottlenose dolphins

Sayigh, Laela[1]; Rozas, Adriana[2]; Wells, Randall[3]; Janik, Vincent[4]

Corresponding Author: lsayigh@whoi.edu

The factors governing signature whistle development in bottlenose dolphins are still largely unknown, even after decades of research. A 1995 study of 42 long-term resident mother-calf pairs recorded in Sarasota Bay, Florida, found that males were significantly more likely to produce whistles similar to those of their mothers than were females, and that females were more likely than males to produce whistles highly distinct from those of their mothers. We sought to investigate whether this pattern upheld with a much larger sample size. Similarity of whistles from 158 mother-calf pairs (80 male, 78 female) was quantified on a scale of 1 to 5 by multiple judges. Unlike the 1995 study, we did not find a significant difference between males and females; 29 males and 26 females, comprising 35% of all calves, produced whistles highly similar to those of their mothers (values greater than 3.7). We looked more closely at patterns of similarity among the 40 mothers in our sample that had two or more calves (mean = 3, total 122 calves), and found four patterns of mother-calf whistle similarity (numbers in parentheses refer to mothers): all calves different (17), all calves similar (4), more than 1/2 similar (3), 1/2 or fewer similar (16). In several cases, we noticed striking similarities among whistles of siblings. Half of the mothers (20) had at least two calves with whistles similar to each other, and all of the calves (17) of six mothers produced whistles similar to their siblings. Yet in only three of these six cases did the calves also produce whistles similar to the mother. Thus, siblings appear to play a role in signature whistle development. Gaining a better understanding of the process of signature whistle development will provide insight into how signature whistles function in the natural communication system of dolphins.

Acoustic harassment devices (seal scarers) can affect harbour porpoise hearing temporarily

Schaffeld, Tobias[1]; Ruser, Andreas[2]; Schnitzler, Joseph[3]; Woelfing, Benno[1]; Baltzer, Johannes[4]

Acoustic harassment devices (AHD) are regularly used to deter marine mammals, e.g. prior to pile-driving activities in German waters to deter harbour porpoises from the vicinity of the construction site. While AHD are applied to prevent a TTS from pile driving noise, these acoustic signals itself have the potential to induce a TTS. This study investigated the potential of artificial seal scarer signals to induce a TTS in harbour porpoises, by experiments with an animal in human care, funded by the Federal Agency for Nature Conservation (BfN). Baseline hearing thresholds were determined at 20 and 28 kHz, by measuring auditory evoked

potentials. The animal was exposed to an artificial seal scarer signal, consisting of a 0.5 s sine tone at 14 kHz and four overtones with decreasing amplitudes at 28, 42, 56 and 70 kHz. Hearing thresholds were determined prior and post exposure to evaluate effects of exposure on hearing. One sound exposure was conducted per day, starting at a low sound energy level which was gradually increased day by day. We found significant temporary hearing shifts at both tested frequencies. The TTS onset, defined as a hearing shift significant from baseline hearing, was determined at 142 dB re 1 µPa²s at 20 kHz and at 137 dB at 28 kHz. We provide evidence, that single pulses of seal scarers, which are currently applied, have the potential to induce a TTS, leading to potential hazard zones between 50 (deep water) and 1000m (shallow water), depending on sound propagation. Effects of multiple exposures are difficult to predict, due to the randomized intervals between signals between 0.6 and 90 s. In order to prevent a TTS by seal scarers, we suggest slowly increasing source levels, allowing the harbour porpoise to flee.

Spatio-temporal patterns in humpback whale acoustic behavior in the Southern Ocean

Schall, Elena[1]; Müller, Simone; Boebel, Olaf[2]; Thomisch, Karolin; Van Opzeeland, Ilse Catharina[3]
(1) Alfred Wegener Institute for Polar and Marine Research (Department: Ocean Acoustics Lab), Bremen

Corresponding Author: elena_schall@web.de

Evidence for off-season humpback whale (*Megaptera novaeangliae*) acoustic presence in high latitude feeding areas is accumulating for Northern Hemisphere waters. By contrast, to date, long-term studies investigating humpback whale vocal behavior in the Southern Ocean are limited to the coastal region. This study uses multi-year data from the HAFOS (Hybrid Antarctic Float Observing System) recording network in the Weddell Sea to investigate spatio-temporal patterns in humpback whale vocal behavior. Between 2010 and 2017, passive acoustic data were collected along the Greenwich meridian, in the central Weddell Sea and off Elephant Island. Humpback whale calls were automatically detected and manually verified to obtain hourly presence information. Humpback whales were acoustically present primarily during austral summer and autumn (March, April, May, June and July). Acoustic presence was most pronounced (>60% of recording days per month containing calls) when sea ice concentration was close to zero. Furthermore, humpback whale song was present at various recording sites in April, May, June and July. The length of the period during which songs were present, as well as the number of song hours per day, increased with decreasing latitudes of the recording sites. At least seven distinct phrase types are identifiable across all recording sites. This study demonstrates that substantial humpback whale presence in the Southern Ocean is not limited to the coast, but extends to pelagic regions. The presence of social sounds and song during extended periods suggests that whales were not just transiting the area, but occupied the area for some time, possibly exploiting local food patches. Additionally, the presence of song on the Antarctic feeding ground indicates that some individuals mix feeding or migratory movement with reproductive behavior. In an ongoing project, further analyses will provide additional insights into the acoustic behavior and population identity of humpback whales on the Antarctic feeding grounds.

Visual and passive acoustic monitoring of the diel activity of wild harbour porpoises (Phocoena phocoena) in Fyns Hoved, Denmark

The harbour porpoise *Phocoena phocoena* is the only resident cetacean species in the Baltic Sea. Since it has been classified as "Critically Endangered" in the Baltic Sea in 1996, protection of this species is immediately necessary. In this study, the activity pattern of the harbour porpoise in the coastal waters of Fyns Hoved, Denmark was investigated acoustically using passive acoustic monitoring devices (C-PODs) as well as visually with a tachymeter. 10 C-PODs were deployed continuously from 30th July to 2nd September 2018 in Fyns Hoved. The visual observation was conducted during daytime from a cliff in the study area. The results demonstrate that the detections of porpoises were significantly higher at the deeper C-POD stations than at the shallow stations during the evening. We found that significantly more harbour porpoises were detected during night than during the rest of the day. The comparison of visual and acoustic porpoise detections has shown that more porpoises were detected visually than acoustically. The results have extended the current knowledge

about the diel activity pattern of harbour porpoises in three ways: 1) This is the first study which indicates that the occurrence of harbour porpoises varied on even a very small space. 2) We assume that the harbour porpoise may be hunting during the day mainly with the special feeding behavior "bottom-grubbing". We conclude that the harbour porpoise could not be detected by the C-PODs during this behavior. These findings should be taken into consideration when planning further monitoring studies. 3) Because of the result that more porpoises were detected visually than acoustically, we recommend to compensate this potential limitation of the C-PODs during the day with visual monitoring to secure precise data collection. However, we suggest to conduct more research on this topic before a general conclusion can be made.

The effect of multi-target protocol on cetacean detection and abundance estimation in aerial surveys.

A double-platform protocol was implemented in the Bay of Biscay and English Channel during SCANS-III survey (2016). Two observation platforms using different protocols were operating on-board a single aircraft: the reference platform ("Scans"; the same protocol as implemented during all SCANS surveys), targeting cetaceans, and the "Megafauna" platform, recording all the marine fauna visible at the sea surface (jellyfishes to seabirds; as implemented during SAMM, REMMOA, ObSERVE and ASI surveys). We tested for a potential bias in small cetacean detection and density estimation when recording all marine fauna. At a small temporal scale (30 seconds), our results provided overall similar perception probabilities for both platforms. Small cetacean perception was higher following the detection of another cetacean within previous 30 seconds in both platforms, but decreased following the recording of any seabirds in the Megafauna platform only. However, at a larger scale (>10 km), this small-scale perception bias had no effect on the density estimation, since the two protocol provided similar small cetacean density estimation. As a result, there was no evidence of lower performance regarding small cetacean population monitoring for the multi-target protocol in our study area. As it was characterised by moderate densities and small spatial overlap of cetaceans and seabirds, any extrapolation requires caution. Nonetheless, by permitting the collection of cost-effective quantitative data for marine fauna, anthropogenic activities and marine litter at the sea surface, the multi-target protocol is a valuable option of scientific survey optimisation to achieve efficient biodiversity monitoring.

World Heritage Site "Wadden Sea" – a challenging habitat for cetacean conservation and management.

The Wadden Sea is an area in the southern North Sea consisting of a complex landscape including islands, mud flats, tidal channels, estuaries, rivers and a highly convoluted coastline. In 2014 national parks and EU - Special Areas of Conservation in Danish, German and Dutch waters were combined under the umbrella of the World Heritage Site (WHS) "Wadden Sea".
In the last decades the distribution of the North Sea harbour porpoise has changed notably by shifting south. Numbers in coastal areas, in particular the southern German Bight and along the Dutch coast, have increased substantially, with indications that this increase extends into the Wadden Sea as well as estuaries and rivers.

To provide a first insight on the conservation status of harbour porpoises in the WHS we compiled available information from aerial surveys, satellite telemetry, acoustic monitoring, incidental sightings, drivers for prey availability as well as the potential impact of predation by grey seals. This unique habitat with strong tides, narrow channels and turbid waters poses a challenge to porpoises that need to navigate and find food. New studies

with tagged porpoises provide evidence that some animals have specialized to live in this habitat year round. Passive acoustic studies indicate that others may seasonally follow migrating fish up rivers or adapt their feeding activity to tidal patterns.

The WHS is not only a highly complex habitat, it also has a highly diverse management set-up. The patchwork of regional stakeholders with different interests co-existed in this area long before the WHS designation. We highlight how the mandate of the WHS relates to those defined under EU and national laws/agreements to identify mismatches. Our aim is to clarify what role of the WHS can play to find a way forward to determine the conservation status of the harbour porpoise in the WHS.

Accounting for positional uncertainty when modeling received levels for tagged cetaceans exposed to sonar

Exposure to anthropogenic sound can have various negative behavioral and physical effects on marine mammals and is of increasing ecological and regulatory concern. In particular, the response of cryptic deep-diving beaked whales to military sonar is a pressing and complex issue. To make inference on the response of individual whales to noise, it is critical to know what received levels (RLs) the animal actually experienced. Most behavioral response studies to date have used relatively short-term, high-resolution acoustic tags that provide direct RL measurements. Because of their short duration these tags do not allow for assessments of longer duration behavior, both before and after a disturbance, that may tell us more about the nature of response. In contrast, most longer-duration tags lack high-resolution kinematic data and the ability to directly measure RL. Here we address these issues and efforts to derive robust statistical characterizations of RLs using animal movement and sound propagation modeling for longer-duration tags in the context of a behavioral response study off Cape Hatteras, NC, USA. In the autumn of 2017, we tagged 9 Cuvier's beaked whales and 3 short-finned pilot whales and conducted controlled exposure experiments using simulated and operational military mid-frequency active sonar. We used sound propagation modeling methods and modeled positions of individual animals to estimate RLs and statistically describe uncertainty. When properly accounting for positional error, single median RL estimates drastically underestimate the full range of plausible values, with ranges in estimated RL variance for beaked whales often exceeding 40 dB. Additionally, ancillary data from focal follow research can significantly narrow estimated RL ranges. Results suggest that though satellite tags record data over longer timeframes, the deep-diving behavior of beaked whales means that estimates of received level can vary broadly. Accounting for this uncertainty using robust statistical modeling is critical when assessing exposure-response relationships.

Population structure characterised by high within-area relatedness in North Atlantic and Mediterranean Sea fin whales (Balaenoptera physalus)

Detecting weak population structure based on estimates of allele/haplotype frequency divergence alone depends on the degree of divergence, statistical power and genetic markers, but holds low power at "ecological" dispersal rates. Kinship-based methods, on the other hand, are better suited at "ecological" rates and complementing traditional population genetic approaches. We combined conventional *F*-statistics and coalescence methods with kinship-based approaches to assess the population structure of the North Atlantic (NA) and Mediterranean Sea (MED) fin whales (*Balaenoptera physalus*). An analysis based upon 20 microsatellite loci and 450 base pair mitochondrial DNA control region sequences from ~1,600 individuals identified a break in gene flow between the NA and MED (F_{ST} = 0.005, $P < 0.001$ and F_{ST} = 0.17, $P < 0.001$ for nuclear and mitochondrial markers, respectively), connected by asymmetric gene flow. Among NA sampling areas, a low degree of isolation-by-distance was detected between the western and eastern NA at both nuclear ($r = 0.30$, $P = 0.018$) and mitochondrial ($r = 0.32$, $P = 0.016$) markers. Average pairwise relatedness among individuals was higher within compared to between regions ($t = -10.62$, d.f. = 911.83, $P < 0.001$). We identified 140 parent-offspring dyads among which were 125 dyads with both individuals sampled in the same area and 15 dyads where members were sampled in different areas, ranging up to 3,300 km apart. In the western NA, evidence of weak, fine-scale structuring was detected between the Gulf of Maine and Gulf of St. Lawrence. The high within-area relatedness coupled with substantial connectivity among areas suggests that fin whale migratory behaviour differs from species with well-characterised seasonal migratory patterns, such as humpback whales (*Megaptera novaeangliae*). While fin whales have the capacity of wide-ranging movements, the low heterogeneity among areas was consistent with maternally-directed site-fidelity and short-range seasonal movements.

Variation in ringed seal (Pusa hispida) bone mineral density from 1897-2018.

Various factors, such as contaminants, might affect process of bone structuring and can lead to an imbalance causing systemic or local bone mass. In the Baltic Sea, pollution with DDT and PCBs have been claimed to influence bone structure and composition as well as reproductive success leading to a decrease in the local ringed seals populations in the 1970's.

The aim of the present study was to analyse temporal changes in bone mineral density

(BMD) over time in Baltic ringed seals using samples of the Swedish Museum of Natural History. 106 skulls were used for bone investigations and were divided into three periods according to the collection year: between 1897 and 1905, between 1973 and 1985 and after 1985 up to 2018. All skulls were examined by dual-energy x-ray absorptiometry and the obtained results on BMD were correlated with the historical PCB and DDT presence with the potential risk of influencing bones constitution. It seems that males had a higher BMD than females (linear model: *p*-value=0.0579, F-value=32.07). Bone mineral density fluctuated between the three study periods (linear model: *p*-value=6.98e-09, F-value=39.87) with the lowest BMD content found between 1897 and 1905. An ANCOVA to test BMD versus period and skull length revealed a decreasing, non-significant trend (*p*-value=0.0738, t-value=-1.855, F-value=2.908) with respect to the relationship between length and the second period. Moreover, this study links these findings with the contaminant values of PCB and DDT for the respective years. The highest peak was observed in the Gulf of Bothnia in the second period.

In conclusion, the variations between 1897 and 2018 may to a certain extent reflect normal fluctuations; however, an effect of PCBs and DDTs cannot be excluded. It was explored if the contaminant burden may explain the difference between early years showing low BMD and late years showing higher.

Sound propagation changes formant-like spectral peaks in humpback whale song.

The aim of this study was to assess the viability of acoustic communication of size-related cues (specifically, formants) by baleen whales. Songs often travel many kilometers before reaching potential recipients and are therefore susceptible to propagation degradation. Spectral cues are susceptible to modification during transmission as reflections from the surface and bottom result in frequency-dependent constructive and destructive interference, possibly masking information cues typically found in terrestrial mammal vocalizations. Playback studies were conducted off the west coast of Puerto Rico using synthetic sounds, without formants, and humpback whale song units, with formants. Sounds were recorded at various distances (up to 1500 m) from the source, and the spectral content at varying distances was compared. Formant-like peaks and notches were found in the recordings of synthetic sounds, which were not present in the source recording. Spectral envelopes of the same sounds of both types also differed between recording distances. In addition, a recording was made of a singing whale over approximately 40 minutes as the boat drifted at different angles from the whale and a steep underwater slope. Spectrograms of the same phrase type at different points in the recording also showed shifts in formant peaks. The addition and modification of formant-like peaks indicate that size-related cues are not reliable transmitted over long distances. If baleen whales do produce reliable, formant-based size cues in their vocalizations, then these cues may only be reliable at short distances, such as within feeding, social, or competitive groups.

An alternative to captive cetacean displays in the Mediterranean: The Aegean Marine Life Sanctuary.

The future of captive cetaceans comes into question as the popularity for their use for entertainment purposes declines. More travel companies are no longer offering visitation to facilities holding captive cetaceans; new technology is effectively replacing the educational function of dolphin displays and research innovations are taking place on-site via non invasive studies on free living animals. Therefore, captive cetaceans should be rehomed and their welfare should be the priority when keeping them for a lifetime.

The Aegean Marine Life Sanctuary will provide home to dolphins at a natural environment, providing them expert veterinary care at a research and educational facility at the Greek bay of Lipsi.

After a comprehensive analysis of different potential sites, the setting at Vroulia Bay fulfills all necessary environmental and social criteria: the geomorphic and oceanographic characteristics, high biodiversity and water quality, overwhelming

local support at a remote but easily accessible island in the northern Dodecanese.

So far, negotiations for land agreement, mapping the extent and assessing the health of seagrass meadows, analysis of species biodiversity and water quality and preparation of the veterinary clinic have been the main actions of the team along with the numerous protocols prepared and the licensing process.

Using renewable energy sources, under an strict non-breeding policy will make sure no new cetaceans are required to remain at the sanctuary, and an invitation-only policy for visitors will ensure the minimal disturbance to the animals.

The project is an innovative endeavour based on a scalable and cost-efficient model that can be easily replicated.

Quantifying and characterizing acoustic activity patterns of Indo-Pacific humpback dolphins (Sousa chinensis) in Hong Kong's waters using Passive Acoustic Monitoring.

Understanding the behavioural ecology of cetaceans in environments with high human pressure can increase our effectiveness in minimizing the conflicts between the needs of cetaceans and humans. Indo-Pacific humpback dolphins (*Sousa chinensis*) of Hong Kong's waters are threatened by many human activities and declining in number as a result. Cetacean Porpoise Detectors (CPODs) offer a non-invasive method to study these dolphins and reduce several limitations of visual observations and thus, can provide valuable information on the occurrence, daily activity and habitat use of the dolphins. As part of a passive acoustic monitoring study to understand the occurrence of the dolphins within two marine protected parks in Hong Kong (Sha Chau and Lung Kwu Chau Marine Park - SCLKCMP and the Brothers Marine Park - BMP), three CPODs were deployed within each of the marine parks between June 2017-18. A diel pattern in acoustic activity was found with significantly more detection positive minutes (DPMs) per hour recorded at night than during the day. Acoustic activity also varied throughout the year with the highest number of DPMs in November to January in SCLKCMP compared to the highest numbers from January to March in BMP. Lastly, DPMs also varied greatly among the six CPOD sites with the highest DPMs observed at the central site within SCLKCMP and lowest at the northwest site within BMP which is closest to a major development project. In addition, the mean DPMs per day was higher at the SCLKCMP sites (combined) than at the BMP sites (combined). The results of this passive acoustic monitoring study compliment information obtained through visual surveys and together provide a better understanding of dolphin activity patterns within the two marine protected parks, which can help to improve the conservation of humpback dolphins in Hong Kong's waters.

Cuvier's beaked whales in high fidelity: Medium-term archival tags allow for detailed behavioral studies.

Previous studies of the behavioral response of Cuvier's beaked whales (*Ziphius cavirostris*) to Navy sonar have relied on a dichotomy of either high-resolution short-duration tags, or low-resolution long-duration tags. We utilized new multi-sensor, high-resolution dart-attached archival tags to collect behavioral data from Cuvier's beaked whales exposed to operational naval sonar at a training area in Southern California, bridging the gap between earlier techniques. Tag sensors included a Fastloc GPS with depth, temperature, and a 3-axis accelerometer sampling at 16 Hz, and in some deployments a hydrophone (96 kHz) and additional 3-axis magnetometer and accelerometer sampling at 50 Hz. Tags remained attached for up to 19.2 days, and FastLoc GPS locations were often obtained at every surface series, allowing the first robust assessment of horizontal displacement during exposure. Tagged animals were exposed to ship or helicopter sonar 23 times during deployments, at distances as close as 8 km. Apparent responses varied with sonar type,

distance, and behavioral state, and included a 30-min surface bout during which the whale displaced at > 10 km/hr, and a 163-min dive reaching 1,657 m, during which the whale moved > 7 km horizontally. The high-resolution accelerometry data allow for detailed analysis of fluking, jerk, and ascent/descent rates which can provide new insights into the energetics and dive physiology of this species as they pertain to both stranding risk and long-term fitness. With attachment durations lasting multiple days to weeks, this new tag technology provides a way to assess responses to anthropogenic impacts by collecting adequate baseline data at high fidelity to account for individual variability in diving behavior.

Comparison of eye dimensions in toothed whales

Schroeder, Sophia[1]; Hamacher, Christoph; Huggenberger, Stefan[2]

Corresponding Author: sophia.schroeder@uk-koeln.de

The eyes of cetaceans and other marine mammals are well adapted to life underwater by a thick sclera protecting the eye from high pressure or temperature related damages and the almost spherical lens compensating the low refraction power of the cornea. However, there are few detailed data about the composition and sizes of cetacean eyes. In this study, eyes of five different cetacean species were imaged by CT and MRI. 3D models of the eyes were reconstructed and the volumes of the sclera, the vitreous body and the lens were measured in relation to the size of the skull. The Amazon river dolphin (*Inia geoffrensis*) had the smallest eyes among the species studied here (864mm³). The closely related Franciscana dolphin (*Pontoporia blainvillei*) had similar eye volume (985mm³). The harbor porpoise (*Phocoena phocoena*) had more than 7 times voluminous eyes (7,323mm³) than the first two species. Bottlenose dolphins (*Tursiops truncatus*) had an eye volume of 12,714mm³. Interestingly, the late-fetal Sowerby's beaked whale (*Mesoplodon bidens*) had the biggest eyes (33,773mm³) These results reveal that the eyes of the so-called river dolphins (*I. geoffrensis, P. blainvillei*) are far smaller than the eye of the harbor porpoise despite their similar body length. This fact is also reflected by the data of eye axis length in relation to skull width (*I. geoffrensis* 11%, *P. blainvillei* 12%, *P. phocoena* 19%). The functional background, however, of this fact is not clear.

How strong is the link between the distribution of sand eels and harbour porpoises in the north-eastern German Bight?

The seasonal abundance and distribution of harbour porpoise (*Phocoena phocoena*) in the German North Sea shows a strong variation. However, on a more local scale the seasonal occurrence may follow a constant pattern in consecutive years. We conducted digital aerial surveys covering all seasons over several years to obtain abundance and distribution of harbour porpoise in a ca. 3300 km² study area in the north-eastern German Bight. In parallel, we collected continues data on porpoise acoustic activity with C-PODs at 12 different positions inside the study area. Based on ICES fish bottom trawl survey data we inferred sand eel distribution within the survey area. By comparing harbour porpoise distribution to sand eel distribution a close connection during spring and summer could be proven.

Effects of whale watch tourism on humpback whale (Megaptera novaeangliae) behavior and understanding passenger attitudes toward regulations in Juneau, AK.

Corresponding Author: alicia.r.schuler@gmail.com

The North Pacific humpback whale's feeding grounds in Juneau, Alaska have rapidly developed into a popular whale watch destination during the summer months (May-September). The Juneau whale watch industry has tripled in size in the last 18 years, currently numbering over 65 vessels. Viewing guidelines/regulations established in 2001 are outdated and may no longer be effective to manage the industry. The aim of this study is to provide a holistic understanding of whale watch tourism in Juneau by assessing 1) humpback whale movement and behavioral responses to vessel presence and to the number of vessels present and

2) passenger attitudes and knowledge regarding whale watching guidelines/regulations. Data were obtained during summer 2016-2017, comprising shore-based tracking and observations of 201 humpback whales and surveys completed by 2331 passengers. Linear mixed effects models indicated that whales in the presence (vs. absence) of vessels exhibited a 40% higher deviation in linear movement ($p = 0.001$), a 6% increase in swimming speed ($p = 0.047$) and a 7% decrease in inter-breath intervals (IBI) ($p = 0.025$). For each additional vessel present, deviation in linear movement increased by 6% ($p = 0.022$) and IBI decreased by 4% ($p = 0.001$). Compared to before a whale-watching tour, passenger awareness of whale watching guidelines/regulations doubled and strong support for guidelines/regulations increased immediately following a whale-watching tour and six-months after the tour (all $p < 0.010$). It is recommended that management revisit the current measures in place to better suit the industry today and that passenger education during whale watching tours be included as a potential management tool to encourage operator compliance. As vessel presence increases in this region, adherence to updated whale watching guidelines/regulations is likely to become increasingly important to mitigate the cumulative effects of short-term changes to whale behavior.

Veterinary Expert System for Outcome Prediction (VESOP): A Bayesian model to predict changes in cetacean population vital rates from measures of individual health.

Understanding the connections among stressor exposures, health, and population vital rates is important for effective management, yet developing quantitative models of these connections is challenging. To address this need, we collated data from bottlenose dolphin (*Tursiops truncatus*) health assessment studies conducted at 8 sites along the southeast U.S. coast over a range of stressor conditions. We sought two types of data: 1) health measures from hands-on veterinary assessments, and 2) sighting histories from longitudinal photo-identification studies on the same populations. We compiled 839 dolphin health records, which include stress and reproductive hormones; hematology; serum chemistry; immune indices; pulmonary score; and body condition. We then developed the Veterinary Expert System for Outcome Prediction (VESOP), which uses the collection of health measures organized into expert rule-based panels to estimate probability of 2-year-ahead survival and successful reproductive outcome for pregnant females. VESOP is implemented as a logit model in a Bayesian framework and simultaneously fits conditional distributions from which missing health parameters can be drawn, allowing use of health records even if one or more values are missing. VESOP was trained using actual outcomes when observed (i.e., carcass retrieved or animal sighted alive after 2 years). Additionally, to aid in training VESOP we developed capture-mark-recapture models for the various populations, which independently estimated individual survival probabilities for dolphins whose survival outcome was not observed. VESOP analyses found that measures of chronic disease are the best predictors for 2-year survival. Dolphins with diagnoses of inflammation or anemia had a 4-fold (95% CI = 2.11-19.66) and 7-fold (95% CI = 1.48-10.66) increased risk of mortality, respectively, and those with both conditions had only a 50% chance of surviving 2 years. We combined the relative risks with prevalence estimates of the various conditions for each population to examine differences in predicted vital rates across the sites.

The deep, the shallow and the indecisive: Foraging strategies of Galápagos sea lions.

Hunting in the tropical waters off the coast of Ecuador, Galápagos sea lions are confronted with strong, irregular fluctuations in prey abundance due to El Niño and La Niña events. Despite living in dynamic environments, marine predators frequently exhibit different, stable individual foraging strategies. Different foraging strategies are especially closely connected to the survival of an individual or its offspring, with large effects on population dynamics. Hence we studied individual differences in foraging behavior of Galápagos sea lion mothers during the 2018 El Niño conditions. The study colony, located on an islet in the center of the archipelago, has been part of a long-term study, providing life history data for the focal animals since 2003. Eighteen adult females, nursing a pup or one-year-old, were equipped for two weeks with biologgers collecting dive depth, location, and acceleration data. Exploring the dive data, we run a Principal Component Analysis followed by a Hierarchical Cluster Analysis, identifying four different foraging strategies. To get a better understanding of those strategies, dive depth and volume of 3D utilization distribution was analyzed, as well as the state-dependent distributions, calculated with hidden Markov models. To study the mechanisms and consequences of those strategies, we (1) used the long-term dataset to investigate the influence of those strategies on the mothers' body conditions and on the weight gain of their pups, two important components of individual fitness; and (2) compared the individual diving behavior to the space-use and behavior in the colony, obtained through resight rounds, focal animal observations and behavioral response tests. Studying the different diving strategies of this decreasing population of pinnipeds, and their consequences, not only gives an insight into how these animals handle current and future challenges, but also contributes to gain a better understanding of how these strategies develop.

How to get mutual benefit for whale watching companies and cetaceans

Educational outreach can be achieved through responsible Whale Watching (WW). Here, we investigate the factors affecting customers' satisfaction on WW experience in the Strait of Gibraltar Important Marine Mammal Area. Between July and September 2017 and 2018, guides of the WW company TURMARES Tarifa submitted 398 questionnaires to customers randomly selected during the final part of each trip. Collected data included a general evaluation of the WW experience (a binary satisfaction index), an evaluation of the WW company (a mark from 1 to 10) and details on the profile of the customers, their evaluation of the educational activities associated to the experience, the perceived compliance with current legislation for WW activities, and the customers' change of awareness. Sighting and trip details were associated to the customers' answers to identify the factors affecting their opinion on the WW experience and on the company. 96.48% of customers expressed a general positive evaluation of the WW experience and most customers positively evaluated the WW company (mean ± SD = 8.6 ± 1.1). Results from multiple linear regression analysis and generalized linear models indicate that customer satisfaction and their evaluation of the WW company are not related to customer profile and trip details. Conversely, they are correlated to the overall quality of the WW experience and they significantly increase when customers are fulfilled with the information received during the trip and with some aspects related to the animal welfare, such as a slow approach to cetaceans. Customers asserting their awareness about cetaceans increased after the trip also better judged the WW company. In conclusion, improving education outreach and communication, and a respectful attitude during sightings, could produce higher customers satisfaction rates changing their level of awareness, with mutual benefits for the WW company, cetaceans and related potential conservation issues.

Acoustic analysis as a methodology for assessing stress in belugas (Delphinapterus leucas)

Marine mammals are routinely exposed to a plethora of acute and chronic stressors, both natural

and anthropogenic. Effects of these stressors range from short-term changes in behaviour to long-term changes in reproductive fitness, foraging effectiveness, and spatial habitat usage. Concentrations of cortisol, a stress hormone, are used as a quantifiable measure of stress in free-ranging animals. Traditionally, cortisol levels are analysed from blood serum or plasma. However, sample collection is invasive, and confounding effects from the stress of research handling may make it challenging to get accurate baseline cortisol measurements using this technique. Acoustic behaviour could provide an alternative matrix for measuring stress non-invasively and at a fine time scale. In this study, acoustic and hormonal data collected during health assessments conducted on the Bristol Bay beluga population were used to evaluate belugas' vocal behaviour as it relates to the stressor of live capture. Acoustic recordings made during each animal's assessment (n=19) were analysed, and trends in vocal behaviour were related to serum cortisol concentrations measured at the beginning and end of each assessment. Acoustic and movement data collected remotely using DTAGs were used to relate vocal behaviour to the expected decrease in stress after release for eight of the 19 animals. Metrics measured by the DTAG's accelerometer and magnetometer, such as swim speed and circular variance in heading, were calculated to assess changes in the tagged whales' behavioural patterns. Characteristics and acoustic parameters of calls made throughout the tag deployment were compared to those made during the health assessment process. This allowed for fine-scale analysis of how vocal behaviour differed across stress contexts. Preliminary evaluation of acoustic recordings suggests that the assessment process had a silencing effect on beluga calling behaviour. Few phonations were recorded during assessments and in DTAG recordings made immediately following release.

Baseline soundscape analysis of a humpback whale breeding ground before port construction in the Gulf of Tribugá.

Humpback whales annually migrate to Colombian waters to mate and give birth. The acoustic communication system of the humpback whale relies on an individual's ability to establish and maintain contact with conspecifics across vast and proximate distances. Current levels of tourism and artisanal fishing activities that support the livelihood of local communities in the Gulf of Tribugá (Colombia) are low, but a significant increase in industrial and commercial maritime traffic could mask critical communication space for whales to find, mate with, and protect one another. Considering the current government's interest in building a port in the area, a passive acoustic monitoring device (Ecological Acoustic Recorder (EAR)) was deployed in the Gulf of Tribugá between September and November 2018. Acoustic data were processed using an in-house Matlab GUI. Power spectral densities (PSDs) were computed in dB re 1 µPa2/Hz and estimated to 3-Hz resolution each minute, by averaging FFT snapshots (overlapped 50%) over one minute intervals. Results show that dominant sound contributors are humpback whale song, boat traffic, snapping shrimp, and fish, with some contributions from delphinid species and unidentified distant sound sources. Observations of spectrograms indicate that humpback whale songs stop during boat passes with enough acoustic energy to mask the song units. Three-dimensional propagation modeling maps have been generated to illustrate the ranges over which humpback whale song and boat engine noise could spread through all directions in the water column. These baseline levels of sound sources, the observed acoustic behavioral responses to noise, and maps of masking potential in the area will be discussed as the first part of a Before-After Control-Impact (BACI) marine study.

Immune-mediated hookworm clearance and survival of an otariid decrease with warmer ocean temperatures

Seguel, Mauricio; Montalva, Felipe; Perez-Venegas, Diego; Gutierrez, josefina; Paves, Hector; Gottdenker, Nicole
University of Georgia
Corresponding Author: mseguel@uga.edu

In the northern and southern Pacific Ocean, increases in ocean temperature are associated with a decline in marine productivity and fish stocks. These changes alter the foraging regimes and maternal attendance patterns of otariids, causing starvation and mortality among pups when changes in temperature are extreme (*e.g.* during el ENSO events). However, it is not well understood if subtle changes in sea surface temperature affect offspring health and survival. Additionally, besides direct mortality due to starvation is not well understood how changes in maternal attendance affect the health and survival of otariids. To investigate these questions, we assessed over a 10-year period the

satellite sea surface temperature data, the maternal attendance patterns and the immune and health parameters of South American fur seals (n=956) in a rookery where hookworm (*Uncinaria sp.*) disease is the main cause of pup mortality (Guafo Island, Northern Chilean Patagonia). Additionally, from 2012 through 2017 we performed field immune challenge and deworming experiments to explore pups' immune reactivity and hookworm pathogenesis and transmission dynamics. Pups receiving higher levels of maternal attendance had a positive energy balance and more reactive T lymphocytes. These pups were able to expel hookworms through a specific immune mechanism that involved proliferation of T lymphocytes and production of parasite specific IgG. This group of pups survived infection and recovered the weight lost due to hookworm infection by the end of the study. Pups that failed to mount an adaptive immune response died due to hookworm disease. Maternal attendance was lower in years with high sea surface temperature, therefore, the mean hookworm burden and mortality increased with sea surface temperature over a 10-year period. We provide a mechanistic explanation regarding how changes in ocean temperature and maternal care affect infectious diseases immunity, health and survival of a marine mammal.

Brachial plexus and segmental innervation of the forelimb in the Pacific white-sided dolphin (Lagenorhynchus obliquidens).

Corresponding Author: sekiya@niigata-cn.ac.jp

When considering the dolphin evolution, actual morphological characters of target structures, which subject to the selective pressure, should be observed and described with extreme care.

We dissected both forelimbs of one Pacific white-sided dolphin to observe the brachial plexus morphology and nerve distribution to the flippers. Spinal segmental levels of the nerves were examined by the fascicle and fiber analyses.

The brachial plexuses were formed by the union of the ventral rami of the lower six cervical nerves and the first thoracic nerve. These roots fused with each other to form three trunks in the left cervical region and four trunks in the right. These trunks fused into a flattened nerve cords. At the axilla, the cords gave off nerves to supply muscles and skin of the flippers.

The phrenic nerve (C3-5) and the suprascapular nerve (C3-6) arose from the cranial margin of the plexuses. The pectoral nerves (C5-7) arose from the ventral surface of the plexus. In contrast, the dorsal scapular (C4), the subscapular (C4-7), the axillary (C4-7), and the radial (C5-8) nerves arose in turn from the dorsal surface of the brachial plexus. The median and ulnar nerves reached the forearm as a common trunk and gave off many cutaneous nerves for the skin of the flipper.

The boundary between the distribution areas of the median and ulnar nerves was on the third digit in the palmar side, and on the third digit or in the cleft between the third and fourth digits in the dorsal side. Most of the intrinsic muscles of the forelimb have degenerated except for some scapular muscles. The results of this study suggest that motor innervation has been lost in the flipper while the sensory nerve remains in the same pattern as that of the terrestrial mammal forelimb.

A comparison of Northeast Atlantic killer whale (Orcinus orca) stereotyped call repertoires

Killer whale call repertoires can provide information on social connections among groups and populations. Killer whales in Iceland and Norway exhibit similar ecology and behaviour, are genetically related and were presumed to have been in contact prior to the collapse of the Atlanto-Scandian herring in the 1960s. However, a lack of photo-identification matches suggests no recent movements between these two locations. In contrast, part of the whales sighted in Iceland regularly travel to Shetland. Here, we used acoustic recordings collected between 2005-2016 in Iceland, Norway and Shetland to undertake a comprehensive comparison of call repertoires of Northeast Atlantic killer whales. Measurements of time and frequency parameters of calls from Iceland (n = 4037) and Norway (n = 1715) largely

overlapped in distribution, suggesting little differentiation between both populations, which was supported by a low correct classification rate in a discriminant function analysis. Due to a small sample size (n = 24), calls from Shetland were not included in quantitative analyses. Calls from Iceland were assigned to 74 call categories (43 call types and 31 subtypes). From Norway 54 call categories were described, (32 call types and 22 subtypes). Fifteen call categories (13 call types and 2 subtypes) from Shetland previously described in a separate study were also used. No call type matches were confirmed between Iceland and Norway or Shetland and Norway. Three call type matches between Iceland and Shetland were confirmed. Therefore, this study suggests overall similarities in time and frequency parameters but some divergence in call type repertoires. The call type matches between Iceland and Shetland but lack of matches to Norway support current knowledge of connectivity between the three locations. This stands in contrast to the presumed past contact between Icelandic and Norwegian killer whales and suggests that they may not have been one totally mixed population.

Interactions between killer whales (Orcinus orca) and the Patagonian toothfish (Dissostichus eleginoides) fishery at Crozet Archipelago: Insights from preliminary signature fatty acid analysis.

Crozet Archipelago killer whales are known to feed on elephant seals, penguins, large whales, and to depredate Patagonian toothfish (*Dissostichus eleginoides)* from the local fishery. We used combined and complementary biochemical techniques to elucidate the trophic position of killer whales at Crozet Archipelago. Blubber biopsies of killer whales (*Orcinus orca),* sampled in proximity of the Patagonian toothfish fishery at Crozet, were analysed for signature fatty acids and amino acid compound- specific stable isotope analysis (CS-SIA). Potential prey species of killer whales were also analysed with a view to understand the diet of distinct killer whale social units in this area. Fatty acid profiles of fishery associated killer whales known to depredate longlines were distinct from the non-fishery associated killer whales. These differences were driven by six exogenous fatty acids (22:6ω3c (docosahexaenoic acid: DHA), 20:5ω3 (eicosapentaenoic acid: EPA), 20:1ω9c, 18:2ω6, 22:1ω11c, and 22:1ω9c). Fatty acid profiles of both fishery associated killer whales and Patagonian toothfish were also distinctly different, suggesting metabolic modification of fatty acids is taking place or an alternative non-sampled prey source is contributing, possibly juvenile toothfish. Trophic interactions between killer whales, elephant seals (*Mirounga leonina)* and potential prey fish species were inferred from fatty acids profiles, with the fatty acids data also suggesting a fish based diet for the non-fishery associated killer whale. We will also present CS-SIA using amino acids of killer whale biopsies (extracted blubber tissue) and potential killer whale food sources. The power of the CS-SIA approach lies in the differential fractionation of individual amino acids during trophic transfer. CS-SIA has allowed an examination of resource utilisation and trophic dynamics in the Crozet Archipelago.

The curiosity of metabolism of lipids in toothed whales; Multi-omics approach.

Lipids in toothed whales are unusual compared to the other mammals. The lipid synthesis pathways in the suborder Odontoceti, the toothed whales might be evolved for various adaptations from the terrestrial environment to the marine environment like fast swimming, deep diving, feeding and echolocation. Therefore synthesis and function of these groups of endogenous lipids are still curious. In this study, we are focusing to identify possibilities of technologies to discover unsolved synthesis of lipid classes of wax esters and branched-chain fatty acids (BCFA) in toothed whales. In this review, various sources of information and literature were categorized into four major study areas of lipidomics, proteomics, transcriptomics and genomics. All the references were screened under each study area and finally possibilities to identify unusual lipid synthesis pathways of toothed whales were suggested for further investigations. In lipidomics studies, recent mass spectroscopic methods like HILIC and C30RP chromatography are identified to study neutral and phospholipids separately, however, determination of the structure of lipids is very challenging. As lipids interact with proteins in the animal body, lipidomics and proteomics need to be correlated by creating lipid-binding proteome maps

to easily understand metabolism pathways. Recent advances of Illumina Hiseq NGS of RNA and DNA helps to identify positive genes for the lipid metabolism in these animals. The results of this literature review concluded that a combination of four of these study areas can make a clear picture of curiosity of metabolism of lipids in toothed whales.

Fitness cost of food-provisioning on bottlenose dolphins can be related to an impoverished social environment.

Tourism-oriented wildlife food-provisioning can profoundly impact the targeted species. In Bunbury, Western Australia, provisioned female bottlenose dolphins (*Tursiops aduncus*) suffer reduced reproductive success—only 38% of calves from provisioned females survive to three years of age while 77% of the calves from non-provisioned do (Senigaglia *et al*., accepted). However, the proximal causes for this long-term effect remains unknown. Using behavioural data from individual focal follows, we explore three hypotheses for how food-provisioning can lead to negative fitness consequences: 1) food-provisioning modifies behavioural budget (i.e. altered proportions of time foraging, travelling, socialising and resting); 2) provisioned females provide less maternal care to dependent offspring (i.e. calves spend less time in infant position); and 3) calves of provisioned females experience lower levels of sociality. Using Markov chain analyses, we found that provisioned dolphins spent less time socializing than non-provisioned dolphins. Using Generalised Linear Mixed effect Models, we found that the time calves spent in infant position was driven by their age and behavioural state but not whether their mothers were provisioned. By evaluating group size, social differentiation and social network centrality, we found that provisioned dolphins travel in smaller groups and have lower variability in their relationships, although females do not differ in number and strength of social associations. These findings indicate that food-provisioning can directly affect the social environment of the dolphins. The observed reduction in reproductive success of provisioned females may relate to the fact that their calves experience a modified, likely depauperate, social environment imposed by the mother's foraging strategy, rather than by reduced maternal care. Less time spent socializing can translate into fewer opportunities for calves to acquire proper foraging skills and to form social bonds that can improve their fitness. Our study strengthens the evidence that tourism can have short-term negative consequences that can affect fitness of wildlife.

Vulnerability of a marine top predator to coastal storms in central chile

The frequency and intensity of coastal storms in Central Chile has increased in the last decades, affecting many species, including the South American sea lion (*Otaria byronia*). The breeding colony of Cobquecura, the most important for this species in central-south Chile, is highly exposed and it is located in front of a long sandy beach with no protection to ocean waves. In recent years, the stranding record of pups at the beach during the summer have notoriously increased, presumably due to the increase in the frequency and intensity of coastal storms. To validate this hypothesis, a database with historical sea states was built from the coupling of a generation wave model (WAVEWATCH III) and a coastal wave propagation model (STWAVE), in order to correlate the statistical wave parameters in the vicinity of the colony with stranding records of pups during summer, from 2009 to 2018. For the first half of January and the last of February, the comparison between the number of pups drowned per day have a low correlation with the wave period, the significant height wave and the normalized wave power parameters. These correlations significantly increases when compared wave parameters and pups stranded in the second half of January and the first of February. Three massive strandings in 2011, 2017 and 2018 coincide with normalized power values exceeding 100 m^2/s. Thus, the number of stranded pups is very sensitive to wave power above a certain threshold corresponding to extreme events. The

stranding records during intense coastal storms represent ca.10% of the annual birth rate at the Cobquecura colony, so they can have critical effects on the survival of the pups, and consequently on the population growth in the sector.

Comparison of photographic and observer-based aerial surveys for monitoring marine litter and mega-fauna

Floating marine macro litter is known to cause severe environmental problems, particularly in closed seas where it may accumulate and threaten endangered marine fauna. Density and distribution of marine litter and mega-fauna (i.e. cetaceans, turtles and large fish) have traditionally been monitored through observer-based surveys, including aerial ones. However, the use of photographic-based methods has developed rapidly in recent years. To make possible the inclusion of new photographic-based results in previous data base, a validation of data collected through the two methods is needed. The aim of this study was to compare the observations obtained from the concurrent application of both methodologies during aerial surveys. Data were collected from four aerial surveys performed in March 2018 over the Spanish Mediterranean coast. Observer-based surveys covered 515.70 km^2 and allowed the detection of 472 targets. Photographic-based surveys covered 101.85 km^2, and 331 marine targets were detected in the 10,000 images collected. Both techniques allowed the identification of anthropogenic debris such as marine litter (i.e. plastic items), natural debris and mega-fauna. Results showed that marine mega-fauna densities obtained through the two methods were comparable, while floating marine macro-litter density was higher using the photographic-based method and birds density was higher using the observer-based one. The results of this study offer a first validation of the photographic-based method for monitoring floating marine macro-litter and mega-fauna.

The sensory science discipline applies the principles of experimental design and statistical analysis to human senses (sound, sight, smell, taste, and touch) for the purposes of evaluating consumer products. These principles can be applied to just about anything that is perceived. Our linguistic ability makes humans particularly well suited for the task of analyzing humpback whale sounds, as they vocalize predominantly in the human frequency range and produce songs that are syntactical, rhyming, rapidly evolving and culturally transmitted. Here we apply sensory science methods to describe and classify humpback whale feeding calls. The goal is to develop additional objective measures for improved vocal fingerprinting and provide insight into pod leadership and task specialization. Feeding calls are used by North Pacific humpback whales to herd herring schools toward the surface. Unless foraging alone, it has not been possible to assign the calls to flukes, as calling typically occurs from individuals hidden in large, compact, subsurface groups. In this study, we recruit three groups of respondents (bio-acousticians, sensory scientists and musicians) for on-line interviews using the repertory grid methodology. The panelists evaluated 12 of 18 humpback whale bubble net calls in an incomplete block design of 4 triads. Data was analyzed by Generalized Procrustes Analysis (GPA) and frequency counts were utilized to generate consensus terms. Descriptors were derrived that contribute to call differentiation, including those already measured instrumentally and those likely to be most accurately measured by a trained panel. These techniques aim to improve communications between research groups via a well-developed lexicon and augment instrumental methods via new sensory measures.

White-beaked dolphin hotspot and seasonal site fidelity identified off Northumberland, North Sea

White-beaked dolphin (*Lagenorhynchus albirostris*) occupying North Sea and UK waters are considered a separate management unit to other North Atlantic populations. The species is listed as a priority under the UK's Biodiversity Action Plan but limited data on population sub-structuring, distribution, abundance and movement have prevented effective conservation and management. To investigate suggested high sighting rates near the Farnes Deep glacial trench, North Sea, 36 opportunistic surveys were conducted between 2013 and 2018 during summer months. A total of 35 dolphin groups were encountered during which a diver recorded underwater video using GoPro Hero 3&4. Data on location, group size, group composition, foraging activity and association with other animals were collected.

Individual dolphins were photo-identified from high quality still frames using unique marks on the body, head and dorsal fin. Distinctive individuals were catalogued when both right and left sides of the individual were available. Sighting location data were projected in Arc GIS and 50 and 95 percentage volume contours (PVC) were created from kernel density estimation. Difference in group size between foraging and non-foraging groups and the relationship between group size and depth were investigated.

A total of 69 individuals were identified over the study, within year resightings were low but 22% were observed in more than 1 year, demonstrating some level of site fidelity. The 50 PVC contour covered a 13.8km^2 area located south of an area of deep water (>100m). Group size was significantly larger for foraging groups and foraging groups were often associated with gannets (*Morus bassanus*). There was no significant relationship between group size and depth.

This study highlights the importance of a relatively discreet area of the North Sea as important habitat for white-beaked dolphins. Foraging opportunity for epipelagic prey species may be an important driver for seasonal habitat use.

Behavioral responses of humpback whales (Megaptera novaeangliae) to approaching ships in Virginia Beach, Virginia, USA

Ship strike mortality is a major conservation concern for humpback whales along the U.S. Atlantic coast. Nearly 90 humpbacks have stranded since 2016 and the National Oceanic and Atmospheric Administration has declared these strandings to be an Unusual Mortality Event; half of the necropsies show evidence of ship strikes or entanglement. One of the most intense conflicts occurs at the mouth of the Chesapeake Bay during winter, where the foraging area of juvenile humpback whales overlaps with shipping channels that are intensively used by large ships. Unlike other balaenopterid whales, humpbacks are "fight" rather than "flight" strategists when responding to predators, which could affect how they respond to other potential threats, such as approaching ships. In this project we are deploying digital sound and movement recording tags (DTAGs) and conducting focal follows of humpback whales, while simultaneously collecting Automatic Identification System (AIS) data from transiting vessels, to analyze the behavior of humpbacks during close ship approaches in the Virginia Beach shipping lanes. Eight tags were deployed in 2017 and two in 2019, with additional deployments planned in 2020. We will use fine-scale accelerometry from the DTAGs to determine if and how animals react to oncoming vessels, and, if so, at what distance or sound level threshold. We will examine how reactions vary with vessel distance, speed, and acoustic profile, to evaluate which ship characteristics elicit responses. We will also analyze whether the animal's behavioral state (foraging or non-foraging) affects their likelihood of response. Foraging behavior has not been described in this area, where juvenile humpbacks are foraging primarily on Atlantic menhaden *Brevoortia tyrannus* in extremely shallow water. Understanding the behavior of humpback whales around ships is critical to developing measures to reduce the risk of ship strike mortality and promote the recovery of this population.

A novel use of unoccupied aerial systems for 3-dimensional photogrammetry: Tracking grey seal maternal-offspring energy dynamics across lactation.

Pinnipeds reliably haul-out on shore for pupping each year, accompanied by dramatic female-to-pup mass transfer over a short lactation period. This provides a particularly tractable study system for validating the use of unoccupied aerial systems (UAS; drones) as a completely non-invasive tool for tracking energy dynamics in wild populations. Here, we present a novel application of UAS technology for mass estimation, using fine-scale three-dimensional photogrammetry. In January 2019, we collected UAS imagery of grey seal (Halichoerus grypus) female-pup pairs at Saddle Island, Nova Scotia. A multirotor UAS was flown 360-degrees around study animals at ~20, 30, and 40-meter altitudes, and collected 53-231 photos at 0.43-0.80cm ground-sampling distance. For each flight, georeferenced images were stitched together for construction of a 3-dimensional point cloud, orthomosaic, and Digital Surface Model from which animal volume was measured (0.121-0.159 pixel reprojection error). Female-pup pairs were weighed directly following UAS survey (n=17 pairs), and a suite of morphometric measurements (lengths, heights, widths, girths, and blubber depths) were collected for determination of animal total body volume using a series of truncated cones (n=12 females). Both methods captured female mass loss (-5.3±1.2kg/day) and pup gains (+1.9±0.5kg/day) across the ~18-day lactation period. UAS-measured animal length and body volume measurements were within 1.8% and 8.4% of hand-measurements, respectively, and were not statistically-distinguishable. Moreover, UAS-measured body volume could accurately predict animal body mass ($P<0.001$; root-mean-square-error: 11.0kg or 5.8%). UAS images were also collected for ~70 additional female-pup pairs to begin characterizing volume and mass dynamics across lactation for a much larger sample size, working towards 'weighing the breeding colony'. To our knowledge, this is the first time that UAS has been used for 3-dimensional photogrammetry in any wild animal, and this method is likely to be widely-applicable across marine and terrestrial species.

Trends in strandings of dead California Sea Lions (Zalophus californianus) along the northern California coast, 1972 -2018

California sea lions (*Zalophus californianus*, CSLs) are considered a sentinel species whose population status reflects the health of coastal California ecosystems. Using multiple data sets collected and maintained by the California Academy of Sciences (Level A Stranding Reports submitted to the Marine Mammal Health and Stranding Response Program database, the museum's collection catalog, and Fish & Game Marine Mammal Reports), we performed a preliminary analysis of dead-stranded CSLs (n=3127) reported near the San Francisco Bay Area from 1972 to 2018. Our goal was to describe trends within the data and explore how this long-term data set reflects CSL growth and spatial distribution at the population level. Stranding numbers generally increased throughout the forty-seven-year period, as is consistent with the steady increase in the total CSL population since the United States passed the Marine Mammal Protection Act in 1972. Males (n=2293) stranded in higher numbers than females (n=596) in every year analyzed, and female CSLs were rare in our response area until the mid 1990s when they began to strand regularly. Four peaks in sea lion strandings (1983, 1998, 2009, 2015) were observed during known El Niño and ocean warming events. These peaks remained after standardizing the data by population estimates, despite biases in the data set from variable and inconsistent effort over the years. In addition to demonstrating that these opportunistic records signaled when CSLs were impacted by large-scale oceanographic changes, these results highlight the importance of maintaining long-term records of marine mammal strandings. These baseline records will be essential to interpreting future sea lion stranding patterns and the response of the CSL population to environmental change.

Expansion of wintering ground of the humpback whales in the North Pacific: Beginning of the seasonal migration to around Hachijo Island, Izu Archipelago.

Around Japan, it was considered that humpback whale (*Megaptera novaeangliae*) migrate to Okinawa (26°13'N, 127°41'E) and Bonin Islands (27°04'N, 142°13'E) for breeding. Hachijo Island (33°06'N, 139°47'E) is one of Izu Archipelago and located further north than those wintering grounds. In the winter of 2015/16, a number of humpback whales were confirmed around Hachijo Island, and a monitoring project of humpback whales around Hachijo Island has been initiated since the 2016/17 winter season. Here, we report the results of two subsequent year monitoring since the 2016/17 season with some new sporadic findings obtained from the 2018/19 season. We established track lines around the island, and whales were searched and photo-identified from a dedicated vessel (12t). The survey was carried out two times a month in average from November to April, totally 32 days in the first season and 34 days in the second. Humpback whales were sighted from November to March in the both seasons, and total sightings were 205 and 397 animals in the 2016/17 and 2017/18 seasons, respectively. Sightings per unit effort in the 2017/18 season (11.7 animals/day) was approximately twice as large as the first season (6.4 animals/day). Some individuals were photo-identified repeatedly during the same season, suggesting that the area is not just a migrating corridor but the one for other purposes to stay. Songs and competitive behaviors, relating to breeding activity, were recorded in the both seasons. In late March of the 2018/19 season, two pairs of mother and calf were confirmed, although it is unclear whether the calves were born around Hachijo Island or not. However, it seems appropriate to consider that Hachijo Island is their new wintering area. We should continue monitoring to further clarify the cause for humpback whales in the North Pacific to expand their wintering ground.

Seasonal characteristics of diving behavior of spotted seals in Rebun Island, Hokkaido, Japan

Our previous research found that the adult spotted seals (*Phoca largha*) inhabiting Rebun Island, Hokkaido, Japan mainly breed in the sea-ice area of the Tatar Strait, and their breeding season is between January and April, and molt after April. However, how their diving behavior and the range change by various annual life events or the season has not yet been clarified. In this study, we aim to identify changes in the diving behavior of spotted seals equipped with satellite transmitters during their annual life events with relation to age class and sex. We used the finite mixture model and the regression was carried out using the R version 3.3.1 (R Core Team, 2016) and flexmix package version 2.3-13 (Gruen et al., 2015; Gruen and Leisch, 2008). It is a combination of two or more probability density functions. By combining the properties of the individual probability density functions, mixture models can approximate any arbitrary distribution. In this analysis, we created mixed models of dive duration and depth. As a result, during the breeding period in the Tatar Strait, the diving patterns of adult seals differed from the patterns before and after the breeding period. Both the adult female and male used the shallow water for a short time only during the breeding period. They probably limited their foraging behavior and hauled out frequently to devote themselves to breeding activity during the breeding period. Also, it is likely that the diving behavior of adult seals during the breeding period becomes passive. Furthermore, the female conducted deeper and longer dives before the breeding period than the male. This is probably because females need to accumulate more energy resource than males in order to maintain the growth of their fetus and prepare giving birth and nursing.

Distribution and habitat of deep diving predators, sperm (Physeter macrocephalus) and Baird's beaked whales (Berardius bairdii), around Hokkaido, Japan

Sperm whale (SW) and Baird's beaked whale (BBW) coming around Hokkaido, northern Japan in Autumn, have similar feeding habits; feeding depth and diets. Previous sighting surveys conducted in North Pacific off Honshu showed that BBWs distribute nearer coast than SWs, however, it is unclear how both species segregate around Hokkaido. In this study, we conducted sighting survey in Autumn around Hokkaido, in order to quantify habitat preference of SW and BBW. Sighting surveys were conducted from the T/S Ushio-maru (Hokkaido university) in September and October (2009-2018) in the Pacific coast of Hokkaido (PCH) and the Nemuro Strait. Their habitats were estimated using software Maxent with five factors; depth, slope, distance from coast and, distance from 1000- and 3000-m isobath. Off PCH, SWs were found in the Kushiro Submarine Canyon, whereas BBWs were found in the Hidaka Bay. There were significant differences in slope and distance from 3000-m isobath. SWs were observed in steeper, closer to 3000-m isobath area than BBWs. As results of habitat estimation, SWs were predicted to be distributed in 800-3000m depth, while BBWs were predicted to be only in the Hidaka Bay. This prediction of SWs distribution was caused by the Kushiro Submarine Canyon. Difference between two species distribution was probably affected by their migration routes. BBWs were distributed on the continental shelf off northeastern Honshu, and migrate northward to the Hidaka Bay along 1000-m isobath. While SWs migrate northward from offshore isobath (> 3000-m isobath) to Kushiro Submarine Canyon. In the Nemuro Strait, both species were observed in the northern area, where steep slope deeper than 2400 m exists in the north-central part. There were no significant differences in environmental factors. Therefore, the different distribution of these species off PCH may be caused by distance of their most prefered isobath.

Investigation for the helminthic parasites of odontocetes using stranded/by-caught individuals in Japan.

Helminth parasites of cetaceans are usually studied on stranded or by-caught individuals, and the helminth studies are scarce in Asia. In this study, the odontocetes stranded or by-caught in Japanese coasts were examined and the helminth fauna was investigated. Totally 194 individuals of 11 species were collected during the year 2012 to 2019 (narrow-ridged finless porpoise, harbor porpoise, striped dolphin, spinner dolphin, bottlenose dolphin, Indo-pacific bottlenose dolphin, melon-headed whale, Risso's dolphin, false killer whale, pygmy sperm whale, and dwarf sperm whale). The cranial air sinuses, lungs, liver, stomach, and intestine were observed macroscopically, then washed and precipitations were inspected under stereomicroscope to collect helminthes. 11 species of nematodes: *Anisakis* spp., *Crassicauda grampicola*, *Halocercus lagenorhynchi*, *H. pingi*, *H. sunameri*, *Pharurus asiaeorientalis*, *P. sunameri*, *Stenurus globicephalae*, *S. minor*, *S. nanjingensis*, and *Torynurus convolutus*; 11 trematodes: *Brachycladium nipponicum*, *Brachycladium* sp., *Campula oblonga*, *Nasitrema globicephalae*, *N. gondo*, *N. spathulatum*, *N. sunameri*, *Nasitrema* sp., *Oschmarinella laevicaecum*, *Synthesium nipponicum*, *S. tursionis*; 2 cestodes: *Diphyllobothrium* sp., *Tetrabothrius* spp. and 2 acanthocephalans: *Bolbosoma* spp., *Corynosoma* sp. were found. Many of the helminthes of narrow-ridged finless porpoise (*H. pingi*, *H. sunameri*, *P. asiaeorientalis*, *P. sunameri*, *S. nanjingensis*, *N. spathulatum*, and *N. sunameri*) were host-specific. Finless porpoises (genus *Neophocaena*) are distributed in Asian coastal waters, thus these helminthes are limited to Japanese or Asian waters. Three species (*B. nipponicum*, *N. gondo*, and *O. laevicaecum*), which are rarely found in previous studies in areas other than Japan, were found from the delphinid hosts. *N. gondo* and *Brachycladium* sp. were in cranial air sinuses and liver of dwarf sperm whale. The latter might be an undescribed species and this is the first record of trematodes from the genus *Kogia*. The helminth fauna in Japanese waters was suggested to be characterized by several endemic species.

NOAA and navy sound monitoring in sanctuaries

As part of a settlement agreement, the U.S. National Oceanographic and Atmospheric Administration (NOAA) and the U.S. Navy are engaged in a multi-year effort to monitor underwater sound within the U.S. National Marine

Sanctuary System. The agencies are working with numerous scientific partners to study sound within seven national marine sanctuaries and one marine national monument, including waters off the U.S. east coast, west coast and Hawaiian archipelago. The project is designed to provide standardized baseline information important for contextualizing both how much sound is introduced within these protected areas by specific sources and the potential for each type of source to impact the areas' marine taxa and habitats.

The agencies selected approximately 30 recording locations where sound conditions and acoustically sensitive species are of management interest. Regional teams began deployment rotations using identical, temporary bottom-mounted sensors at these locations in fall 2018. Recording efforts will continue for 3 to 4 years. Collaboration with partners will make use of other technologies and existing acoustic recordings at locations where further time series or comparisons are of interest.

To inform the project's development, the agencies sponsored an expert workshop in May 2018. Workshop participants emphasized standardized approaches to facilitate comparison in soundscape attributes among international projects with longer-term and larger-scale monitoring focus. Discussions also highlighted the importance of defining ecologically meaningful measures and producing visualization methods that can support both management processes and public communication. These recommendations have guided the project's priorities and work to develop analysis techniques for characterizing both the overall sound levels and specific contributions from marine animals, physical processes and human activities. Unprocessed data will be archived and made publicly available through NOAA's National Center for Environmental Information. A web portal for further access and exploration of products is also under development.

Using subsistence-harvested bowhead whale baleen as a multi-decadal contaminant recorder

Potentially harmful concentrations of heavy metals have been recorded in marine mammals as far north as the Arctic Beaufort Sea. Bowhead whales (*Balaena mysticetus*) annually migrate from their winter foraging grounds of the Bering Sea into the Chukchi Sea and eastward to the Beaufort Sea (summer). A single baleen plate from a bowhead whale grows continuously and can store more than 20 years of dietary and, subsequently, environmental data. Analysis of heavy metals in western Arctic bowhead whale baleen plates, via atomic absorption spectrophotometry, confirmed successful detection of twelve heavy metals (Cd, Co, Cr, Cu, Fe, Hg, Mn, Ni, Pb, Se, V, Zn). Baleen plates obtained from subsistence-harvested bowhead whales between 1966 and 1999 were analyzed, providing first-ever heavy metal data from 1947-1999. Previous stable carbon and nitrogen isotope analyses from the same baleen of these whales ascertained the general locations and seasons (Beaufort Sea in summer/fall; Bering/Chukchi seas in winter/spring) along the western Arctic population's migration path. Comparing heavy metal concentrations to the respective stable isotope values of the same sample allowed concentrations to be attributed to general season and region. There were significant differences among elements ($X^2(11)=341.44$, $p=<2.2e-16$), with copper, vanadium, and zinc having the highest average concentrations (338 ppm, 835 ppm, 226 ppm, respectively), and cadmium, chromium, and manganese having the lowest (4 ppm, 2 ppm, 3 ppm, respectively). All metal concentrations fluctuated temporally, but did not increase nor decrease over time. Seasonally, nickel and zinc were highest in winter and spring (Bering and Chukchi seas), while mercury was generally highest in summer and fall (Beaufort Sea).

Estimating work and power during a controlled swimming task

How efficiently marine mammals swim directly affects oxygen management and determines both dive duration and activity levels that can be maintained. Therefore, an understanding of energetic cost during these behaviors is critical for determining the physiological (and thus behavioral) envelope of diving animals, and the consequences of anthropogenic stressors on their fitness.

However, direct measurements of energetic cost or external forces (thrust for propulsion or drag on the body) are challenging to obtain in swimming animals. While recent work has been conducted to directly measure thrust created by swimming bottlenose dolphins using particle image velocimetry, these studies are limited by camera-based kinematic data collection in controlled environments. Such a method is not practical for use with wild animals. As such, energetic expenditures of free-swimming whales and dolphins can be estimated only by using proxies such as heart rate, respiration rate or body acceleration, though experimental validation of these proxies has been limited. Our research seeks to create the knowledge necessary to estimate mechanical work, a key contributor to the overall metabolic cost of free-swimming cetaceans. Here we present results that combine data from multi-sensor tags, an overhead camera, and models of drag to estimate per-lap work and power. These estimates were evaluated in a controlled experimental environment with managed animals during prescribed swimming tasks. Six animals swam a ~63 m lap at regular and fast swimming speeds. The analysis used data from 14.7 km (233 laps) of straight-line swimming to calculate per-lap work and power during active swimming. The animals had an average speed of 3 m/s (0.6 SD) with average lap speeds ranging from 1.7-4.7 m/s. The resulting fit of speed to power, $P(u)=13.5u^{3.5}$, was both significant ($Adj.\ R^2 = 0.80$) and compares well to published values in the literature.

Using marine mammal key habitats for developing a Pan-Arctic network of Marine Protected Areas

Rapidly changing Arctic presents challenges for conservationists and environmental managers. One of the most effective ways to protect the biological diversity and ecological processes of the marine environment is to design an ecologically connected and representative network of conservation areas. *Pan-Arctic marine protected area network* (PAMPAN) project, initiated by WWF, aims at designing a network of priority areas for conservation (PACs) using integrated ecosystem approach. Marine mammals (MM) are the top predators in the Arctic ecosystems. Assessing and mapping their key habitats plays a fundamental role in defining PACs. Twenty-seven MM species encountered in the project area were selected. We have collected best available up-to-date information on the areas (and, where possible, core-areas) important for MMs, such as breeding and feeding grounds, molting, whelping patches, haul-outs, polar bear denning sites. In total, 235 data layers were created for different stocks or "geographic variations" of MM species across the Arctic. Conservation target was assigned to each data layer based on the formula, which considered IUCN conservation status of the unit, whether the species is full-year Arctic resident, seasonal resident or a visitor, its biomass, importance to Arctic ecosystem, importance to indigenous and coastal communities. A series of expert-advised spatial analyses using a decision-support tool Marxan was conducted to define PACs. For the purpose of PAMPAN, MM data were integrated into the dataset containing similarly collected data on birds, fish, plankton and benthic communities. As a result, a network of geographically and ecologically connected representative PACs was produced using systematic, transparent and reproducible method, based on best available data. In current work, we show how MM data contributed to the results of analysis, and how the designed network could contribute to MM conservation in the Arctic.

Leucism in Brazilian dolphins: A phenotypic trait associated to specific populations?

Siciliano, Salvatore[1]; Bonvicino, Cibele[2]; Cardoso, Júlio[3]; Francisco, Arlaine[3]; Pacheco, Shirley[4]; Hauser-Davis, Rachel[5]
(1) Instituto Oswaldo Cruz/FIOCRUZ

Corresponding Author: gemmlagos@gmail.com

Leucism is defined as a total lack of pigmentation throughout the entire body. This type of

hypopigmentation occurs despite the normal production of the enzyme tyrosinase and melanin, as no melanin deposition occurs in skin cells, hair follicles or feathers, due to an inherited defect in the pigment transfer process. Leucism can be caused by one of several different mutations and gives rise to seemingly similar phenotypes. Thus, leucistic animals are white or whitish all over but have normally colored eyes. The very rare occurrence of leucistic individuals is normally due to the mating of two heterozygous, normal-colored individuals each carrying a rare, recessive leucism allele. Recently, in Brazil, cases of anomalously white dolphins have been reported, involving one juvenile rough-toothed dolphin (*Steno bredanensis*), as well as recurrent cases in Guiana dolphins (*Sotalia guianensis*). The leucistic *S. bredanensis* was reported off Ilhabela, São Paulo, on 9 December 2017. In addition to this single record of an anomalously white-pigmented *S. bredanensis* in Brazilian waters, photograph comparisons of previously catalogued individuals suggest a common hypopigmentation pattern, *i.e.*, whitish patches throughout large portions of the body, observed off the coasts of São Paulo and Rio de Janeiro, SE Brazil. It is generally believed that leucistic animals present reduced fitness, perhaps due to higher predation risks or pleiotropic effects on other physiological functions. However, although often reported as a deleterious trait, adult leucistic dolphins have been reported globally in cetaceans, from cold to tropical waters. As such, as evidenced in two coastal species of dolphins off Brazil, this study provides evidence of maintenance of geographical color variations in small cetacean populations in a particular habitat or area. Further investigations concerning the prevalence of such an anomalous coloration in coastal dolphin populations are essential for assessing the prevalence of leucistic individuals in this habitat.

Acoustic examination of non-song call production as a function of humpback whale (Megaptera novaeangliae) pod composition and subsurface behavior in Hawaii.

Siddiqui, Sabena[1]; Pack, Adam[2]; Stimpert, Alison[3]; Hart, Patrick[1]
(1) University of Hawaii, Hilo, HI
(2) University of Hawaii at Hilo, Hilo, Hawaii
(3) Moss Landing Marine Laboratories
Corresponding Author: siddiqui@hawaii.edu

Despite the dominance of male song in the humpback whale communication research literature, increasing attention has been paid to non-song calls. However, relatively few studies have examined these calls in the humpback whale breeding grounds, and currently there are no descriptions of call characteristics in conjunction with underwater video in non-calf pods. Thus, little is known about the relationships between non-song calls, pod type, and subsurface behavior during adult interactions such as mate competition or stationary pair associations. This study characterizes call types in relation to pod type and composition, sea state, and behavioral state. The dataset consisted of subsurface video and audio recordings from an archival database collected from humpback whales in different pod types in waters off Maui from 1998-2007. Video and audio data were recorded using a mini-DV camera in an underwater housing outfitted with a single uncalibrated hydrophone (useable system response: 7Hz ≥ 20kHz). Calls were manually identified in spectrograms in Raven Pro, and cluster analysis was used to classify call types. Approximately 75 hours of acoustic recordings containing non-song calls were analyzed. Over the study period, 1,533 pods were recorded and 372 (24%) pods were found to contain non-song calls. Of these 372 pods, competitive pods were found to contain non-song calls more frequently than any other pod type (53%), followed by dyads (19%) and mother-calf escort pods (17%) with all other pod types accounting for only 11%. Non-song sound production may be important for male-male aggressive interactions, or female communication with potential mates. The results of this study will allow for comparisons in behavioral usage between non-song call types in Hawaii and other populations with already established call types in very different behavioral contexts across the wide geographical range of this species.

Beaked whale (Hyperoodon ampullatus) body condition and the starvation-predation trade-off

Siegal, Eilidh[1]; Hooker, Sascha[2]; Isojunno, Saana[3]; Miller, Patrick[4]
(1) University of St Andrews

Corresponding Author: es250@st-andrews.ac.uk

The starvation-predation trade-off is vital to an animal's fitness. Central to how animals balance foraging against predation risk is energy store body condition: animals in poor condition should accept greater predation risk to maximise foraging gain. Such state-dependent risk-taking concepts are well-established; however few studies have assessed how body condition influences the starvation-predation trade-off in marine mammals. We investigated if beaked whales exchange foraging

for anti-predation behaviour and whether body condition drives this trade-off, as predicted by the starvation-predation trade-off and state-dependent theory. Using hydrodynamic models, tissue body density (an indicator of lipid energy store) was estimated for 15 northern bottlenose whales tagged with DTags near Jan Mayen. Measures of foraging (diving, echolocation clicks, prey capture attempts) and anti-predation (shallow ascents, silence near the surface) behaviours were combined as composite indices of foraging and anti-predation. Increased foraging index predicted a decreased anti-predation index (slope=-.43, $t(13)$=-3.66, p<.01); indicating that predator avoidance decreased when foraging increased, consistent with the starvation-predation trade-off. Anti-predation indices increased and foraging indices greatly decreased after sonar exposures (n=3). There was strong support for tissue body density as a predictor of the ratio of the anti-predation index to the foraging index. Increased tissue body density (a lower proportion of fat) predicted an increased ratio of anti-predation to foraging behaviour (slope=.23, $t(13)$=2.68, p<.02). Despite a small sample size, this indicates that animals with poorer body condition took fewer predation risks and foraged less, contrary to state-dependent decision-making theory. Given animals in better condition foraged more, body condition could be a consequence, rather than driver, of behaviour. Body condition might drive behaviour at more extremes of condition than were observed here. Bottlenose whales were heavily affected by whaling, and our results indicate that a perceived anthropogenic threat (sonar) may increase predation avoidance behaviour and reduce foraging, exaggerating foraging-predation risk trade-offs.

Electronic camera monitoring of harbour porpoise (Phocoena phocoena) bycatch in bottom-set gillnet fishery: A matter of perspective.

Siemensma, Marije[1]; Scheidat, Meike[2]; Couperus, Bram[3]

Corresponding Author: m.siemensma@msandc.nl

In this study we present the results of an assessment of bycatch of harbour porpoise (*Phocoena phocoena*) in the Dutch commercial bottom-set gillnet fishery using Remote Electronic Monitoring (REM). We focus in particular on the challenges encountered, how we dealt with them (both successful and unsuccessful) and provide advice based on our experience.

This project was initiated by two ministry departments, fishery and nature conservation, following guidance from the Dutch Harbour porpoise conservation plan. A total of fourteen fishing vessels participated voluntarily. For the study period (1 June 2013 to 31 March 2017) 900 fishing days of 8133 fishing days of the overall fleet (11%) were analysed. Bycatches occurred in both single-walled gillnets (GNS) and trammel nets (GTR), with an average annual mortality of 23 porpoises (95% C.I. 2-44).

REM provides valuable data for bycatch monitoring, particularly on smaller vessels. However, the limitations of space mean it intrudes on the privacy of the crew and installation options are restricted. During the study technical and non-technical challenges continuously emerged, leading to a critical project stage within the first year. However, through a number of interventions these difficulties could be resolved and over the next five years the project turned into an example of a successful cooperation between scientists, fishermen and the government.

Analyses of the project procedure highlighted that the main issues were not logistical challenges but instead intrinsic (traditional believes) and extrinsic (changes in policy) factors that influenced the perspectives of the stakeholders in combination with inadequate communication and an atmosphere of distrust.

A successful cooperation is only possible when each other's perspectives are understood and respected. Planning an REM project with a small scale fishing community needs to include as much effort and attention to ensure effective communication as much as the challenges of collecting and analysing the data.

Testing of two commercially available porpoise bycatch reduction devices in a Sub-Arctic bottom set gillnet fishery

Sigurdsson, Gudjon Mar[1]; Haney, Georg[2]

Various sound based devices have been designed to reduce bycatch of porpoises in gillnet fisheries, and several such products are available commercially.

Such devices have not been tested or used in the Icelandic set gillnet fishery for cod, which has some bycatch of marine mammals, predominantly of harbour porpoise. In this study, we tested two devices, one "pinger" and one "porpoise alert device" in the Icelandic cod gillnet fishery. Three commercial vessels were used for the experiment, in three regions were most bycatch had been observed in the past. Each of the devices were tested for a week in each region, and in each region 3-4 paired 0.4 nautical mile long sets of nets were set, where half of the sets were deployed with the devices according to the manufacturer's description, and the other half acted as a control.

In the pinger trial, eleven cetaceans were caught, nine harbour porpoises, and two white beaked dolphins. Six of those cetaceans were caught in the pinger sets, while 5 animals were caught in the control, suggesting no effect of the pinger on bycatch rates. The size and gender composition of the bycaught animals was similar between the two treatments, and no difference in the catch of fish was observed.

In the porpoise alert device trial, 23 harbour porpoises were caught, but no other cetaceans. Twelve porpoises were caught in nets with the alert devices, while eleven were caught in the control sets, suggesting no effect on bycatch rates. Interestingly, eleven out of twelve porpoises caught in the device sets were large adult males, while the gender ratio was six males to five females in the control sets. Eight of those males in the device sets were caught right by the device, suggesting possible attraction of adult male porpoises towards the device.

High collocation between humpback whales and sand lance in the southwestern Gulf of Maine

The abundance and distribution of forage fishes can have major impacts on the abundance and distribution of marine mammals. In the Gulf of Maine (USA), a preferred prey of humpback whales is sand lance (*Ammodytes* spp.). General fluctuations in humpback whale abundance in the southwestern Gulf of Maine have been correlated with shifts in sand lance abundance, but overlap between whales and sand lance on a fine spatial scale has not been investigated. We explored spatial relationships between humpback whales and sand lance in Stellwagen Bank National Marine Sanctuary, an important humpback feeding area in the southwestern Gulf of Maine. Counts of sand lance and humpback whales were conducted at 44 sites in spring and fall from 2013-2018. We used spatial metrics and collocation indices to quantify overlap between humpback whales and sand lance at two spatial scales (site-level (local) ~1 km and sanctuary-level (global) ~2180 km^2) and developed a hierarchical Bayesian model to predict humpback whale density based on sand lance density. Based on collocation indices ranging from 0 (no co-occurrence) to 1 (local -- species density proportional at sites; global -- population centers coincide), we found weak collocation between sand lance and whales at the site-level (local index range: 0 - 0.28), but strong collocation at the sanctuary-level (global index range: 0.7-0.98). Preliminary model results suggest humpback whale density increases with sand lance density and also varies with season and region within the sanctuary. Our results suggest humpback distributions can be tightly linked with sand lance abundance and that long-term changes in sand lance abundance could impact ecosystem structure and the effectiveness of the sanctuary in contributing to the fitness of humpback whales. Our work also provides context for understanding potential species distribution shifts due to climate change, and for predicting acute whale-human conflicts in space and time.

The occurrence and behaviour of harbour porpoises around Scottish salmon farms

The nature and extent of interactions between cetaceans and aquaculture are largely unexplored, a key knowledge gap**.** Potential interactions may represent a trade-off between foraging opportunities and exposure to industry activities. In

Scotland, Atlantic salmon (*Salmo salar*) farming industry is mainly on the west coast, northern and western islands, waters that host some of the highest densities of harbour porpoise (*Phocoena phocoena*) in Europe. The aim of this study was to determine when and how often porpoises approach fish farms on Scotland's west coast. Passive Acoustic Monitoring (PAM) for porpoise echolocation using SoundTraps and C-PODs was undertaken at seven farms and nearby navigation buoys. Hydrophone arrays were deployed to understand the fine-scale movement and behaviour of porpoises around farm infrastructure. The fish farm soundscape was recorded to identify noise characteristics emitted by industry activities. Wild fish aggregations around farms were surveyed through video recordings and sonar to establish if they may be prey for porpoises. Results indicate porpoises are found around salmon farms, but presence varies between locations and may be dependent on time of day, tidal state, site bathymetry, and farm activity. Frequent detections and the occurrence of feeding buzzes suggest that porpoises forage around farms. Soundscape analysis revealed distinctive acoustic characteristics of activities such as fish feeding, electricity generators, acoustic deterrent devices (ADDs), and net cleaning. The significant background noise associated with these activities affected C-PODs through masking, clipping and sensitivity loss, and subsequent bespoke configurations successfully optimised the recorders. The present study affirms that interactions between aquaculture and porpoises commonly occur on the west coast of Scotland, and that farms may represent a foraging resource. The precise nature of the relationships between industry infrastructure, farmed salmon, discarded salmon feed, wild fish and porpoises remain to be investigated.

Sex differences in skin marks patterns in common bottlenose dolphins (Tursiops truncatus).

Simões, Sara[1]; Methion, Séverine[2]; Díaz López, Bruno[3]

Cetaceans frequently display skin marks which can be caused by diseases, parasites, and interactions among conspecifics and with human activities. For the present study, we used one year of photo-identification data for resident bottlenose dolphins of the Ría de Arousa (NW Spain). The aims of this study were to assess the types of skin marks found on bottlenose dolphins and compare them between adult males and females. Four body sections (anterior, ventral, central and posterior) were defined to assess the prevalence, abundance, richness, and distribution of the marks. Boat-based surveys were carried out on 65 days between January and October 2017 for a duration of 352 hours, with 218 groups of dolphins observed during 98 hours. A total of 178 individuals were identified, and 21 adult sexed individuals (12 males and 9 females) were used for the analysis. Social-induced marks (tooth-rakes, nicks, and linear marks) and skin disorders (diseases and parasites) were observed, but none of the individuals showed human-induced injuries. All skin marks, except parasitic marks, were found on all individuals. The abundance of marks was higher in males (mean ± SD = 130.7 ± 20.7) than in females (mean ± SD = 88.3 ± 17.5). The richness in tooth-rakes was significantly higher in males, while the richness in skin disease marks were significantly higher in females. Skin mark types were dependent on body section, with the posterior section exhibiting the most skin marks for all individuals. The differences in social-induced skin marks between the sexes may be explained by behavioural variation, with males exhibiting more aggressive and agonistic behaviour than females. These results show that photo-identification provides an efficient approach to recording body marks in bottlenose dolphin as a way to understand the social behaviour of this species.

Predator controls: Lessons from land to sea. A comparison of how marine and terrestrial mammals are managed in human-wildlife conflict scenarios in Europe.

Simmonds, Mark Peter; Nunny, Laetitia
HSI, London, United Kingdom
Corresponding Author:
mark.simmonds@sciencegyre.co.uk

Wild animals come into conflict with humans in Europe in a number of circumstances and, although both marine and terrestrial mammal predators are involved in such conflicts, their situations are rarely compared. The predation of livestock and other animals reared for human use, such as farmed fish, is a key area of conflict and predators are managed in a variety of ways to prevent them from injuring and killing these animals. Other areas of human-wildlife conflict include the perceived competition for wild prey (for example lynx and wolves competing with hunters for deer, and seals competing with fishermen for salmon). We compare methods of conflict reduction used for terrestrial large carnivores (bear, wolf, wolverine, lynx) and marine mammals (seals). Both lethal and

non-lethal management methods are considered. Areas where lessons can be learned from experiences on land are identified for their potential to guide conflict reduction in the marine environment. We also consider how control methods are chosen. In some cases, the most effective method is not always the one that is implemented and factors such as practicality, cultural norms, cost effectiveness and others may strongly influence the methods used. We highlight the importance of carrying out humaneness assessments to ensure that the control methods that are chosen are as humane as possible so that animal welfare is not negatively impacted. Potential humaneness assessment protocols are presented and a call to further develop these for wildlife control is made.

Marine mammals, sound and the Global Ocean Observing System: Implementing a globally sustained observing system for these essential ocean variables.

The Biology and Ecosystem Panel of the Global Ocean Observing System (UNESCO/IOC/GOOS) is responsible for identifying Essential Ocean Variables (EOVs) for biological components of the oceans and supporting their observation in a globally sustained system. Increased and better focused ocean observations supported in a sustained way by the international scientific, governance and policy communities are needed to (a) globally determine and monitor appropriate trade-offs between conservation and sustainable use, (b) effectively mitigate or manage adverse changes including climate change, and (c) predict and prepare for potential future changes. Here we focus on two of the EOVs identified by the panel: "marine mammal abundance and distribution" and "ocean sound." We present how these EOVs are specified and describe work being done to establish a framework that will allow development of globally sustained observation systems for each EOV, including identifying existing networks or programs aggregating relevant data. We invite community input from the marine mammalogy audience on this framework and the implementation timeline, and seek partners interested in contributing observations or shaping the implementation process. Our aim is to build on existing efforts to achieve a globally standardized, open access and sustained observing system which will deliver societal benefits by contributing to the UN Decade of Ocean Science and informing national reporting activities such as the World Ocean Assessment, Sustainable Development Goal 14, and updated Aichi targets, among others. Observations from the system will also support a new treaty for conservation and sustainable use of marine biodiversity beyond national jurisdiction and organizations managing activities in these regions.

Are there relationships between contaminant exposure and gene transcripts or metabolite profiles in the endangered St. Lawrence Estuary beluga (Delphinapterus leucas) population?

Belugas from the St. Lawrence Estuary population in Canada are highly contaminated. It has been postulated that exposure to elevated concentrations of polychlorinated biphenyls (PCBs), chlorinated pesticides and flame retardants (polybrominated diphenyl ethers (PBDEs) and emerging compounds) might play a role in the non-recovery of this endangered population. *In vitro* and *in vivo* studies of mammals have shown that PCBs, PBDEs and chlorinated pesticides can perturb the homeostasis of circulating thyroid and steroid hormones, or alter the expression of genes involved in their regulation. A growing number of studies also indicate that endocrine disrupting compounds may be linked to metabolic disorders, and that amino acids and fatty acids could be used as biomarkers. In this study, a suite of organic contaminants (i.e., PCBs, chlorinated pesticides, short-chained chlorinated paraffins (SCCPs),

PBDEs, and emerging flame retardants) was measured in blubber biopsy samples obtained from 40 free-ranging male St. Lawrence Estuary belugas to examine their link with the regulation of endocrine or metabolic axes. Contaminant concentrations were related to 10 gene transcripts (thyroid and steroid regulation and metabolism of pollutants) and profiles of a suite of metabolites (21 amino acids, 22 biogenic amines, 18 fatty acids, and 17 energy metabolites) measured in skin biopsy samples by RT-qPCR and HPLC, respectively. Concentrations of several contaminants (PCBs, organochlorine pesticides and emerging compounds) correlated with the transcription of steroid- and/or thyroid-related genes (*Esrα*, *Dio2*, *Hsd11β2*, *Nr3c1* and *Thrβ*). SCCP concentrations also correlated with fatty acid profiles (C16:1n7, C18:0, C18:1n9, C20:5n3 and C22:5n6). Several biological functions including growth, development, reproduction, and energetic metabolism may be related to contaminant exposure in this population. Results further indicated that the use of omics represents a valuable screening tool to assess the impacts of environmental contaminants in cetaceans.

Co-occurrence of beaked whale strandings and naval sonar in the Mariana Islands, Western Pacific.

Mid-frequency active sonar (MFAS), used for antisubmarine warfare (ASW), has been associated with multiple mass stranding events of beaked whales. International naval exercises using ASW have been conducted in the Mariana Islands semi-annually since 2006. We report beaked whale acoustic activity detected from two acoustic recorders deployed off Saipan and Tinian (Mariana Islands) from March 2010 through November 2014. Signals from Cuvier's (*Ziphius cavirostris)* and Blainville's beaked whales (*Mesoplodon densirostris*), and a third unidentified beaked whale species were detected throughout the recording period. Both recorders documented the presence of MFAS on 21 August 2011 before two Cuvier's beaked whales were discovered stranded on 22-23 August 2011. We compared the history of known naval operations and beaked whale strandings from Guam and Saipan to consider potential threats to these whale populations. Between June 2006 – January 2019 four of eight beaked whale strandings occurred during, or within 6 days after naval activities. A simulation suggests that the probability that these four strandings were randomly associated with naval events is 0.1%. We highlight the importance of ongoing passive acoustic monitoring, especially for beaked whales that are difficult to visually detect at sea, and monitoring beaches for stranded cetaceans before, during, and after naval exercises.

Mesoscale dynamics of blue and fin whales and Antarctic krill off East Antarctica

Blue and fin whales occur seasonally in the Southern Ocean to forage, primarily on Antarctic krill. These species are typically found in different pelagic environments, with blue whales often associated with sea ice and fin whales occupying areas away from sea ice. When they co-occur, however, it is not known if they compete over the same type and size of krill swarms, or if they have distinct swarm size, density, or krill life stage preferences. We investigated co-occurrence of blue and fin whales and krill in an open water area off East Antarctica using a bottom-moored passive acoustic recorder and an echosounder over one week in early February 2019. Using only calls with high signal-to-noise ratios, we measured whale occurrence in the vicinity of the moored recorders. Fin whale 20 Hz and 40 Hz calls were commonly recorded during the first four days, but almost entirely absent during the last three days. Blue whale song and D calls, on the other hand, were persistent during the first six days, but substantially decreased on the seventh day. Both 40 Hz and D calls were more common than songs for both species, possibly indicative of social and foraging behaviors. The distribution and abundance of acoustically-detected krill varied throughout the

study period. Dense backscatter layers at 20-40 m depths were common during the first three days, but they were largely absent in subsequent days, replaced by more dispersed layers. On the sixth day, a dense, shallow backscatter layer appeared and coincided with an increase in blue whale D calls and fin whale 40 Hz calls. Backscatter substantially decreased after that event, coinciding with the cessation in detection of calls by either species. These data shed light on foraging preferences of these two large krill consumers in the Antarctic ecosystem.

Identification of discrete and persistent high density offshore areas of mobile marine mammals – lessons learnt from the selection of potential EU special areas of conservation for harbour porpoise in the UK

The EC "Habitats Directive" requires Member States to contribute to a coherent European ecological network of protected sites through designation of Special Areas of Conservation (SACs) for species (and habitats) listed on its Annexes. Site identification is based on Directive criteria, including evidence of physical and biological factors essential to these species' life and reproduction. While some wide-ranging highly mobile aquatic species have clearly-defined breeding/nurturing/feeding areas, the harbour porpoise *Phocoena phocoena* does not. The Joint Nature Conservation Committee and DHI undertook a detailed statistical analysis of 18 years of survey data collated through the Joint Cetacean Protocol (JCP) to identify discrete and persistent areas of relatively high harbour porpoise density within the UK Exclusive Economic Zone. This presentation describes the modelling framework developed, and discusses the challenges and solutions to circumvent the potential bias introduced by the spatio-temporally skewed multi-platform survey data. Although JCP comprised data from at least 545 distinct ship and aircraft surveys different parts of UK waters have received a variable survey coverage over the 18 years. Consequently, many areas have been surveyed on few occasions making reliable predicted estimates of yearly distributions a challenge. Additionally, smaller areas typically associated with marine wind farm development have received intensive spatial survey coverage but over relatively short periods of time which could give rise to mean densities becoming biased in these areas. To address these challenges dynamic distribution models capable of making predictions based on oceanographic conditions, sediment characteristics, shipping intensity and "three-dimensional" space-time smoothers were developed. The model results indicate that densities of harbour porpoises are influenced by both oceanographic and anthropogenic pressure variables. A number of areas with predicted persistent high densities of porpoises were identified by the study and underpinned the identification of the SACs. Four of these are the largest SACs ever designated in Europe.

Where are those Maui dolphins?

An individual-based model was used to analyse the movements and distribution of Maui dolphin *(Cephalorhynchus hectori maui)*. For each run of the model, simulated movements were compared with field data. The resulting Goodness-of-Fit estimates were used to calibrate the model. The number of 1 kilometre moves per hour varies for each dolphin and every hour in the model. The number of moves per hour follows a Poisson distribution which the scaling exponent μ. This resulted in movements that approximate a Weibull distribution, resulting in a very good fit to the field data. The dolphins' depth preferences follow a sigmoid function: $(1 + 0.01^{1-d/\delta})^{-1}$ where d is water depth (in metres) and δ is the depth-preference exponent. We used a simple step function for the dolphins' schooling preference, with dolphins moving to a new location at each time step with preference = 1 if there are no dolphins present and 1+ σ if there are other dolphins present in the new location. After calibration, the best fitting parameters were: Movement exponent μ = 5.1, depth preference δ = 50, home range exponent η = 27.5 and schooling preference σ = 322. The resulting maps of Maui dolphin distribution show considerable overlap with gillnet and trawl fisheries. We recommend adjusting the boundaries for protected areas in which gillnets and/or trawling is banned, to provide more effective protection. Recommendations by the International Whaling Commission (IWC) and IUCN are included in the set of management options. The IWC has

recommended extending protection to 20 nautical miles offshore for Maui dolphins. The IUCN has recommended extending protection to the 100 metre depth contour for both Maui and Hector's dolphins. The New Zealand government is currently considering improvements to the protection of Maui and Hector's dolphins, with a decision expected in August 2019.

Particle motion in vocalizations of the endangered North Atlantic right whale (Eubalaena glacialis) and humpback whale (Megaptera novaeangliae): Implications for communication and anthropogenic noise impacts.

Smith, Adam[1]; Mooney, Aran[2]; Kaplan, Maxwell; Lammers, Marc[3]; Moore, Michael J[4]; Parks, Susan E[5]; Corkeron, Peter[6]

It has been hypothesized that mysticetes hear and utilize the particle motion component of sound for communication, similar to some other large mammals with low-frequency ears. However, most research on mysticete communication has focused on the pressure component of acoustic signals and overlooked the paired particle motion component. The goal of this project is to investigate the particle motion component of vocalizations from multiple mysticete species. We deployed an M20 Particle Velocity Sensor (GeoSpectrum, Inc) near vocalizing individuals to measure and describe acoustic particle velocity and pressure generated by vocalizations from two mysticete species; endangered North Atlantic right whales (*Eubalaena glacialis*) in Cape Cod Bay, Massachusetts, and singing male humpback whales (*Megaptera novaeangliae*) near Maui, Hawaii. A total of 42 gunshot and upsweep calls were recorded from *E. glacialis* in 2018, and over 1000 song units were recording from *M. novaeangliae* in 2016. Both *E. glacialis* and *M. novaeangliae* produced acoustic fields with considerable received particle velocity magnitudes (-125 to -95 dB re: 1 m/s at distances up to 423 m) which contained directional information available to conspecifics. Particle velocity magnitudes attenuated at a similar rate to acoustic pressure, thereby also providing an available distance cue. Additionally, opportunistic recordings showed that small neighboring ocean vessels also generated particle motion components of -109 to -111 dB re: 1 m/s at a distance of 700 meters. Although mysticete hearing is largely unstudied, these vibratory particle components may play a role in auditory reception by stimulating bone conduction to the ears. These results indicate particle motion is a possible pathway for acoustic communication in mysticetes that has been largely unexplored and could be a valuable component of understanding potential impacts of anthropogenic noise, particularly for endangered species such as *E. glacialis.*

River and Ocean Guardians Protect Endangered Cetaceans in Asia

Smith, Brian
Wildlife Conservation Society, Arcata, California
Corresponding Author: bsmith@wcs.org

Fatal entanglement in gillnets is the most critical threat facing small cetaceans. A promising conservation approach entails engaging fishers as river and ocean guardians. In the Mekong River, Cambodia, fishers are engaged as river guardian to enforce the ban on gillnets threatening a critically endangered population of Irrawaddy dolphins. In coastal waters of Bangladesh gillnet fishermen are engaged to release cetaceans, turtles and whale sharks found alive in their nets and record geo-referenced data on catches used to establish new marine protected areas and as part of a spatial planning process to optimize protecting threatened marine wildlife with sustainable fisheries.

Permanent placement trends and survivorship of stranded, non-releasable marine mammals

The National Marine Fisheries Service (NMFS) Marine Mammal Stranding Network program attempts to successfully rehabilitate and release back to the wild each stranded marine mammal that is admitted into rehabilitation, as intended by the Marine Mammal Protection Act. However, in some cases, the attending veterinarian of the rehabilitation facility may determine that the release of a rehabilitated marine mammal is unlikely to be successful given the physical condition, age, and/or behavior of the animal, as

outlined in the NMFS Marine Mammal Release Criteria. In these cases, NMFS may deem the marine mammals non-releasable and subsequently place themwith a permanent care facility for the purposes of public display, research, or national defense. We evaluated more than 150 individual placements, representing 13 unique species (4 cetaceans and 9 pinnipeds), over a seven-year period (2012-2018) and identified leading causes for non-releasable determinations (e.g., physical condition, age, or behavioral), factors influencing placement timelines, and survivorship of marine mammals following permanent placement. Results from this study will be used to inform stranding partners, placement facilities, and NMFS managers regarding future rehabilitation and placement efforts.

New diagnostic techniques to characterize fetal, placental, and maternal health in bottlenose dolphins following the Deepwater Horizon oil spill

Corresponding Author: Cynthia.Smith@nmmf.org

In the aftermath of the *Deepwater Horizon* (DWH) disaster, a high rate of reproductive failure persists in bottlenose dolphins (*Tursiops truncatus*) living within the oil spill footprint. Proposed causes include poor maternal health, direct oil-related toxic effects to the reproductive system or fetus, complications related to adrenal system dysfunction, and/or immune system perturbations leading to increased susceptibility to reproductive pathogens. To better characterize reproductive health, new diagnostic techniques were developed with dolphins in human care and applied to free-ranging dolphins living in oil-impacted Barataria Bay, LA (BB). An expanded reproductive ultrasound protocol was developed to evaluate fetal, placental, and maternal health; diagnose fetal and placental disease; and potentially predict reproductive outcome. To establish measurements and descriptive findings correlated with reproductive success, serial ultrasonographic evaluations were performed with 12 dolphins in human care during 16 successful pregnancies (2010-2017). A total of 203 ultrasound exams were included, measuring up to 70 parameters per scan. Fetal biparietal diameter (BPD), thoracic width in dorsal and transverse planes, thoracic height in a sagittal plane, aortic diameter, and blubber thickness were correlated with date of gestation (r^2>0.94, P<0.001). A refined equation for prediction of parturition date in bottlenose dolphins was developed [days to parturition = 348.16-(26.03*BPD(cm)) (r^2=0.99)]. Regional uteroplacental thickness significantly increased with each trimester (range 0.22-0.40cm; P<0.001 cranial and caudal uterus; P<0.001 mid-uterus). To evaluate fetal lung health, the lung:liver echogenicity ratio was established as 2.57 (95% CI = 2.47-2.67). The protocol was applied to BB dolphin pregnancy exams (N=38) performed during capture-release health assessments (2011-2018). Fetal and placental abnormalities were detected with ultrasound examination, including fetal distress, placentitis, and umbilical cord torsion. Ultrasound findings will be combined with additional measures of reproductive health to help elucidate etiologies of pregnancy failure in BB dolphins.

Impacts of shipping on a humpback whale breeding ground in a multiple use Marine Park: The Great Barrier Reef.

Smith, Joshua[1]; Erbe, Christine; Kelly, Natalie[2]; Peel, David
(1) Murdoch University, Perth, Australia
(2) Australian Antarctic Division, Kingston, Australia
Corresponding Author: joshua.smith@uqconnect.edu.au

The Australian east coast population of humpback whales (E1 sub-population) annually migrate to the Great Barrier Reef (GBR) for mating and calving, an area where there is a high level of co-occurrence between shipping and whales. Here we assess the distribution of mating and calving areas in the GBR

Marine Park (GBRMP; an area of 344,400 km^2) and quantify the risk of ship strike and cumulative ship noise to humpback whales at a spatial scale appropriate for risk assessment frameworks. Using a combination of aerial surveys and satellite tag data, we identify for the first time the migration and breeding grounds and a clear demarcation between core calving and mating areas. The core area (> 90% predicted density) for groups with calves constituted > 90% of ship strike risk and was situated in a different area to the core area for non-calf groups of high (> 90%) ship strike risk. Calf groups had a higher relative risk of ship strike compared to non-calf groups (when standardised for group size) and we demonstrate a change in the distribution of calf groups to near-shore areas over the breeding season, resulting in increased exposure to shipping traffic. Using source spectra measurements of large vessel noise, we calculated significant levels of noise exposure on singing humpback whales based on their auditory sensitivity threshold. These results clearly identify core areas of breeding humpback whales, which overlap with the inner shipping route and pose the greatest risk of ship strike and effects from noise. 'Special Management Areas' (SMA) are a potential legislative tool for regulating human activities on the whale's breeding ground, although currently no SMA exists but could now be implemented. A 'Whale Protection Area' does exist, primarily to manage whale tourism operations, although does not cover the core mating and calving areas identified.

Mitochondrial genetics of narwhals (Monodon monoceros): A study in a minimally destructive method of ancient DNA extraction in narwhal tusk material.

Narwhals, *Monodon monoceros,* are elusive animals, and have inspired myths, legends, and awe for centuries, which is exacerbated by their inaccessibility in the heavily iced high Canadian Arctic waters. With a current "Near Threatened" classification by the International Union for Conservation of Nature and Natural Resources (IUCN) and a total population estimate of roughly 80,000 animals, unlocking the genetic code of this species may be the key to beginning to unravel much of the mystery that surrounds them, both in the past and the future. This study aims to provide a reliable, minimally destructive method to extract ancient narwhal DNA from samples that wish to remain physically unmarred for display purposes. Short pieces of unprocessed pre-1972 narwhal tusk (n=50) have been obtained by the author from Pond Inlet, Nunavet Canada. This study utilized narwhal cytochrome *b* mitochondrial gene data from the National Center for Biotechnology Information's (NCBI) GenBank, where two primers, NAR-4 (581 bp) and NAR-6 (241 bp), were created for use in this study during Polymerase Chain Reaction (PCR). Using a grinding technique on the tusk surface, the study outlines a reliable method to extract ancient deoxyribonucleic acid (DNA) from narwhal tusk and amplify it for further analysis using PCR. The amplified DNA from the grinding method was compared to the traditional drilling method using electrophoresis and demonstrated that the grinding method yields the same level of amplification level of DNA as the drilling method. The extracted DNA was then sequenced using the designed primers and compared to narwhal mitochondrial gene samples in GenBank to positively confirm narwhal tusk sample's identity. This study's grinding technique showed significant reduction in physical marring to the surface of the narwhal tusk samples and provides evidence for a reliable method to extract ancient narwhal DNA while preserving historical samples for unmarred display.

Shifting focus: Using stable isotope analyses to distinguish carbon sources of Alaskan polar bears.

We analyzed collagen stable isotopes of two Alaska polar bear (*Ursus maritimus*) subpopulations over the past 60 years. The Southern Beaufort Sea (SBS) polar bear subpopulation is declining in response to sea ice loss, while the Chukchi Sea (CS) subpopulation appears stable. We used polar bear bones from 1954–2018 provided by the University of Alaska Museum and samples collected by Native subsistence hunters. We developed a stable isotope timeline of bone collagen to explore polar bear carbon sourcing within the SBS and CS subpopulations, e.g., switch from marine to terrestrial carbon. A total of 104 samples were extracted for bone collagen and analyzed for bulk $\delta^{13}C$ and $\delta^{15}N$. In addition, we analyzed collagen for compound-specific stable isotopes of

amino acids (AA). Our aim was to determine if there is a shift towards more terrestrial carbon sources following the North Pacific regime shift of 1976/77 and after a major Arctic sea ice minimum of 2007. After Suess correction, CS and SBS bears had significantly different bulk $\delta^{13}C$ (-13.0±0.6‰ and -14.8±1.1‰, respectively) that was mirrored in phenylalanine $\delta^{13}C$ (-20.2±2.4‰ and -24.5±1.3‰, respectively) speaking to different primary production baselines in the two ecosystems. Bulk $\delta^{13}C$ and $\delta^{15}N$ of SBS bears declined over the 60-year period by 2‰ and 1‰, respectively. $\delta^{13}C$ of glycine of SBS bears significantly declined (before 76/77 (B): -7.5±2.7‰; after 76/77 (A1): -9.9±4.1‰; after 2007 (A2): -23.2±1.2‰), as did serine (B: 0.9±4.7‰; A1: -4.2±4.1‰; A2: -12.6±3.0‰), and isoleucine (B: -14.0±1.2‰; A1: -15.3±2.0‰; A2: -17.9±2.2‰). Polar bear values after the regime shift closely reflect or approach those of brown bears (*Ursus arctos*) sampled from the coastal Beaufort Sea from 1960–2005 (glycine: -26.0±1.7‰; serine: -7.1±2.0‰; isoleucine: -24.2±1.7‰). Together with published accounts on $\delta^{13}C$ values of AA in aquatic and terrestrial foodwebs, our results suggest a gradual increase of terrestrial carbon in polar bear diets.

Osmoregulation and electrolyte balance in a fully marine mammal, the dugong (Dugong dugon).

Dugongs (*Dugong dugon*) are fully marine mammals that live entirely independently of fresh water, but little is known about how they regulate water and electrolyte balance in a hyperosmotic environment. To investigate the osmoregulatory capabilities of dugongs, osmolality and electrolyte (Na^+ and K^+) concentrations were measured in matched plasma and urine samples collected from 51 live wild dugongs in Moreton Bay, Australia. Maximum values for urine osmolality (1468 mOsm kg^{-1}) and Na^+ and K^+ concentrations (757 mmol L^{-1} and 131.3 mmol L^{-1}, respectively) indicate that dugongs are capable of concentrating urine above seawater and could potentially realise a net gain of free water from mariposia (the drinking of seawater). However, mean urine osmolality of 932.57 (± 46.29) mOsm kg^{-1} suggests that mariposia is unlikely to be an important osmoregulatory mechanism. Dugongs may obtain enough preformed water from their seagrass diet and through metabolic oxidation to maintain homeostasis in the absence of fresh water. Mean plasma osmolality was 339.46 (± 1.75) mOsm kg^{-1}, which is higher than in manatees but within the range reported for fully marine cetaceans. Relatively high mean plasma Na^+ (175.19 ± 1.72 mmol L^{-1}) and K^+ (6.9 ± 0.1 mmol L^{-1}) concentrations, as well as mean urinary Na^+ (469.55 ± 22.05 mmol L^{-1}) and K^+ (32.17 ± 4.46 mmol L^{-1}) concentrations were observed and can possibly be explained by the dugong's diet of salt-rich seagrasses. Pregnant females had higher mean plasma osmolality (355.3 ± 4.9 mmol L^{-1}) than males and non-pregnant females (337.9 ± 1.7 mOsm kg^{-1}), suggesting that fluid retention was not a feature of pregnancy, however, no evidence of electrolyte retention was found. Further research is required to better understand water and electrolyte balance in this species, including differences observed between population cohorts.

Analysis of growth layer groups in harp seal (Pagophilus groenlandicus) teeth reveals temporal changes in stable isotope ratios.

Changes in the trophic level of apex predators can reflect variations in the availability and quality of food resources, with pinnipeds widely used as indicator species for marine conditions in polar regions. Harp seals (*Pagophilus groenlandicus*) are the most abundant pinniped in the North Atlantic and remove appreciable quantities of commercial fish prey, along with crustaceans e.g. amphipods associated with the ice edge. The diet of foraging seals is expected to reflect the local food web baseline. Satellite telemetry shows harp seals travelling between subarctic and Arctic waters, suggesting that their foraging success may depend on them integrating conditions across wide geographic areas during their seasonal migrations.

The chemical and mineral composition of tooth dentine is stable over time, potentially providing a through-ontogeny archive of seal diet. Dentine (containing collagen) is deposited annually, and can be subdivided into clear growth layer groups (GLGs). We describe a methodology whereby collagen from harp seal teeth GLGs can be separated and analysed to allow age and year specific estimates of stable isotope ratios ($d^{13}C$

and $d^{15}N$). We present initial results from the analysis of historical archives of harp seal teeth from the North West Atlantic and from the Barents Sea (East Ice). Individual variation between animals is pronounced, but temporal variation in both populations is detectable despite this 'noise' in the data. The North West Atlantic harp seal teeth show significant differences in stable isotope ratios for $d^{13}C$ and $d^{15}N$ between decades (1981, 1991 and 2001). Harp seal teeth from the East Ice in the Barents Sea also revealed significant temporal trends in $d^{13}C$ and $d^{15}N$ from 1950 to 2000. Given substantial environmental change in the Arctic region, these observed changes may be caused by shifts in the baseline, the food web structure, or both.

Review of specific night vision technologies for cetacean detection

Smultea, Mari[1]; Silber, Gregory K.[2]; Donlan, Paul; Wilson, Stephanie[3]; Morse, Laura[4]; Fertl, Dagmar[5]; Steckler, Dave[6]

Data are sparse on specific model, specification, and cost- and at-sea effectiveness of vision-enhancing devices for detecting cetaceans during low-light conditions (e.g., darkness). We identified, evaluated, and compared 15 specific vision-enhancing devices used or useful to meet U.S. regulatory requirements for marine mammal mitigation/monitoring during low-light periods of offshore wind development activities for Ørsted and Deepwater Wind in the U.S. Atlantic. Evaluation focused on cetacean detection at distances of 200, 500 and 1000 m from a vessel. Information compiled included available literature, personal communications with experts, our own in-field results and internet searches of equipment. Results indicate that for regulated zones <200 m in radius, recently used specific hand-held infra-red (IR) and hand-held light-enhancing devices are considered reasonably effective. At distances of 200-500+ m, more expensive yet reasonably priced mounted IR devices providing automatic detection software, image stabilization, remote display, and/or delineation of mitigation zones improve objective mitigation decision-making and alleviate observer eye strain associated with handheld devices. Multiple camera use and video or still image review capability improve sighting effectiveness and reduce false negative indications. Device performance is influenced by weather conditions (e.g., fog, rain). Our field results indicated that mounted IR cameras detected whales and delphinid groups 2+ km away in good conditions (low sea state, minimal ambient light, clear conditions). Newly available devices should be reviewed on a continuum to identify improvements/affordability. Testing of night/low-light vision devices via controlled systematic studies is needed for regions where offshore wind development and operations occur during low-light conditions, focusing on seasons and areas where sample sizes of cetacean visual detections can be maximized. Compilation and statistical comparisons of our field data with data already collected using such devices during other U.S. Atlantic marine mammal monitoring is highly recommended to examine robustness and effectiveness under various conditions.

Guiana dolphin skin disorders as proxies for short-term anthropogenic disturbances in port areas

Soares, Estela[1]; Frederico Rodrigues Loureiro Bracarense, Ana Paula; Cantor, Mauricio[2]; Domit, Camila[3]

Anthropogenic activities can impact the marine ecosystems functioning and biodiversity health. Port areas are of particular concern for marine megafauna due to the typical intense boat traffic and sources of noise and chemical pollution. The synergistic effect of such disturbances can lead to increased stress levels and immunological depression in marine animals, decreasing their overall health. In cetaceans, poor health status can be visually detected as skin diseases and lesions. Here we compare such visual cues of health status in Guiana dolphins, *Sotalia guianensis*, inhabiting one of the largest port areas in southern Brazil and an adjacent marine conservation area. From 18 daily surveys actively searching for Guiana dolphins, we encountered 70 groups (33 in the port, 37 in the protected area) and photographed their dorsal fins for individual identification and all their body visible above water to investigate skin lesions and diseases. After cataloguing all groups, we compared all skin lesions with those reported in the literature for cetaceans. The most common skin diseases were lobomycosis-like and nodules, and the most common lesion of intraspecific

interactions were tooth marks, while the most common lesion of possibly infectious were hyperpigmentation and hypopigmentation. We found that resident dolphins from the port area showed proportionally higher evidence of skin diseases and lesions associated (70%), while dolphins resident in the protected area showed only lesions (51%). While revealing a causal relationship between anthropogenic activities, skin diseases, and health status requires future research, our current findings suggest that the port areas may indeed pose a higher risk to the dolphins' health.

Pseudomonas stutzeri and Candida spp. isolated from blowhole samples and associated with free-ranging killer whale (Orcinus orca) in coastal waters of Kamchatka Peninsula.

Experts in marine biology face the challenge of finding ways to assess the health risks of free-ranging populations of cetaceans. One possible solution is to conduct research into the interactions and relationships between hosts and their microbiota, revealing the relationship between many aspects of host's biology, health and associated microorganisms. In this connection, killer whale blowhole samples was conducted in the area of Starichkov Isl., Far East, Russia in August 2018. One individual of killer whale was identified - AV062 – "Ikar". Microbiota was sampled in sterile Petri dishes according to the Karina A. Acevedo-Whitehouse method. Then blowhole samples was transported by sterile tubes with Amie's bacterial transport medium with activated carbon that to remove bacterial waste products. Also, bacterial water control of same area was conducted directly during blowhole sampling. Bacterial seeding was carried out on culture media: meat-peptone agar, meat-peptone broth, blood agar, Endo agar, mash agar, Czapek-Dox agar. Isolated pure bacterial cultures were identified by a mass-spectrometer Microflex Brucker Daltonik MALDI Biotyper, BRUKER, Germany. As a result, *P. stutzeri* and *Candida spp.* were identified. *P. stutzeri* is a nonfluorescent denitrifying bacterium widely distributed in the environment. *P. stutzeri* strains have natural transformation properties, making it relevant for study of the transfer of genes in the environment. *P. stutzeri* several strains are able to fix dinitrogen and others participate in the degradation of pollutants or interact with toxic metals. Also may be isolated as an opportunistic pathogen from different species of *Mammalia*. The obtained data can be used for comparative characteristics with microbiota isolated from killer whales contained in captivity for correct diagnosis in case of disease. Potential pathogens of significance to humans and other species of animals were recovered.

Gulf of Mexico Bryde's whales in the Northwestern Gulf: Call variation and occurrence.

Soldevilla, Melissa[1]; Debich, Amanda[2]; Garrison, Lance; Hildebrand, John[3]

The Gulf of Mexico (GOM) Bryde's whale, the only year-round resident baleen whale in the GOM, currently has an estimated abundance of 33 whales, is found within a restricted range along the northeastern GOM shelfbreak, and was recently listed by NMFS as endangered under the Endangered Species Act. Human activities such as oil and gas exploration and extraction, fisheries, and shipping in the GOM could pose additional risk to this already small population, and it is necessary to better understand their distribution and ecology. While current sightings are rare, historical whaling records suggest Bryde's whales range may have included the northwestern and northcentral GOM, and it is unknown whether or not they currently occupy these areas. Use of autonomous passive acoustic methods are the best tool for finding rare whale species where they occur infrequently and where they have been historically sighted. To determine if the whales occur beyond the northeastern GOM, acoustic recording packages (ARPs) were deployed at five shelfbreak sites in the northwestern and northcentral GOM from July 2016 to May

2017. By manually reviewing long-term spectral averages, individual calls were detected, and hourly and daily occurrence and number of calls were derived for each site. High quality ARP recordings were obtained for the complete deployment period at four sites and over 1500 novel stereotyped tonal calls were detected. These calls appear to be variants of the long-moan call produced by GOM Bryde's whales in the northeastern GOM. Calls were detected on 12% of days at the westernmost site and call detections decreased heading east across sites. Seasonality was not evident. This information is crucial for understanding GOM Bryde's whale distribution and will be useful in designating critical habitat and determining whether human activities pose a risk to this species.

Hydrostatic analysis to design a buoyancy prosthesis for a negatively-buoyant West Indian manatee (Trichechus manatus).

Corresponding Author: lauravsoler@gmail.com

The West Indian manatee is endangered due to anthropogenic activity, most often in the USA due to water-craft collisions. If the animal survives the collision, they are commonly scared or permanently injured, as in the case of a subadult Florida manatee rescued and rehabilitated in 2008, but with a permanent negatively buoyancy condition due to scar tissue in the caudal section of its right lung, thus not a candidate for release. Other than this condition, the animal is healthy and has been able to compensate to breath at the surface in a shallow water tank under human care. To enhance his general welfare under human care, we seek to develop an appropriate prosthesis to bring back his neutral floatation capacity and allow him to swim normally in the water column. To accomplished this, it was necessary to calculate the current position of manatee's center of gravity (CG) and center of buoyancy (CB), as it is understood that both CG and CB have suffered some displacement in this particular manatee as compensation to his negatively buoyant condition. We investigated this by means of hydrostatic analysis using data from necropsies performed in manatees in Puerto Rico and morphometric data from manatee itself. The density of the manatee was obtained using two methods, the water displacement method, and a cinematic/dynamic analysis. The model described in previous literature was applied to obtain the position of the CG and the CB of the manatee. In addition, to compare the results obtained, the manatee was modeled using the SolidWorks software to obtain the CB. In the case of CG, the second method used was by obtaining the net torque. With this information, a study of the characteristics of possible materials for the construction of the prosthesis and a tentative design was conducted, and is here presented.

Movements of three species of seals tagged in 2013-2014 in the Okhotsk Sea.

Solovyeva, Maria[1]; Glazov, Dmitry[2]; Kuznetsova, Daria[2]; Rozhnov, Vyacheslav[2]

True seals (Phocidae) remain poorly studied in Russian seas. From 2013-2014 we installed satellite transmitters on 10 bearded (Erignathus barbatus), 5 ringed (Pusa hispida) and 2 largha (Phoca largha) seals in the Sakhalin Bay of the Okhotsk Sea, an area and adjacent waters of eastern Sakhalin characterized by high anthropogenic load (fishing and oil production).

All animals resided close to the tagging site during summer and autumn and almost all movements were restricted to waters of shallow depth, less than 20 m deep. With the onset of early fast ice formation, ringed and largha seals moved away to areas not yet covered with ice. In contrast, bearded seals, did not avoid ice, changing their resting ground from land to ice. This behavior relates to the benthic feeding of bearded seals in shallow waters. With increased ice formation, bearded and ringed seals were almost never recorded in waters deeper than 100 m, excluding one region: during migrations along the eastern coast of i. Sakhalin all animals move around oil platforms in deeper waters. In ice period, all three species of seals preferred one-year ice of high concentration.

To study population structures of seals in Okhotsk Sea, it is necessary to understand the relationship between feeding and reproductive areas. Both tagged larghas spent the winter in the region of the known reproductive area in the Tatar Strait. Bearded seals were registered in Sakhalin Bay and on northern and eastern coasts of i. Sakhalin. Key

habitats of ringed seals were located in all the above regions.

Thus, dynamics of the ice formation determined migration times between seasonal areas for all three species. Water depth had the strongest influence on seasonal habitat choice for bearded seals, while for largha and ringed seals the presence and type of ice cover was the key factor.

Population structure and patterns of habitat use of sperm whales in the Gulf of Mexico revealed by seven years of passive acoustic monitoring

The Gulf of Mexico is an important habitat for globally endangered sperm whales (*Physeter macrocephalus*), which may use the region as a breeding or nursing ground. Their population structure and seasonal movements in the Gulf are poorly understood. Presence of sperm whale echolocation clicks was documented in nearly continuous passive acoustic recordings collected at three long term monitoring sites in the Gulf from 2010 to 2017. Sperm whales show strong sexual dimorphism in body size, therefore a method was developed to determine population structure using the distribution of distinct inter-click intervals (ICI) and correlated with inter-pulse intervals (IPI) as a proxy for body size. The inter-pulse intervals were converted into size categories using an established method for estimating animal acoustic length and further correlated to the inter-click intervals. Distribution of inter-click intervals were compared across sites and over time. Three different classes were found, one with a mean ICI and IPI of 0.8 s and 4.6 ms respectively, which corresponds to adult males, a second with mean ICI and IPI of 0.6 s and 3.6 ms respectively, which corresponds to social units of sperm whales (mixed groups with adult females and their offspring), and a third class with mean ICI and IPI of 0.7 s and 4 ms respectively is believed to contain adult females and sub-adult males. A majority of detections consisted of small females and mid-sized animals. The mixed group was present all year at two northern sites in the Gulf but was only seasonally present at one southern site. In contrast, only three percent of observations consisted of adult males, which were occasionally present throughout the year at the two northern sites. This supports the prior hypotheses that the Gulf of Mexico may be an important location for sperm whale reproduction.

Skin conditions and body anomalies of humpback whales, Megaptera novaeangliae in Sainte-Marie channel (North east of Madagascar).

Corresponding Author: sophia@wcsmad.org

Skin lesions are frequent in cetacean populations worldwide and we describe the occurrence of skin conditions in mysticete whales among the Western Indian Ocean Region. Cetacean skin lesions are studied from photo-identifications, strandings, and by-catch data. We assess skin lesions from 4858 photos of humpback whales *Megaptera novaeangliae*, taken near Sainte-Marie, Madagascar, during 2012 and 2013. Our study found 286 clinical cases of individuals with one or more types of skin lesion and we detected 7 different types of skin conditions. The skin conditions observed and body anomalies observed include : pigmentation anomalies (35%), skin lesions (47%), parasitic infection (6%), deformities (9%), and miscellaneous traumata (2%). These conditions were observed on all parts of the body and some individuals had multiple occurrences of conditions. Our results also suggest that all group type of humpback whale can be affected by different skin diseases. This study demonstrates that photo-id data offers a non-invasive, cost-effective approach to study disease in wild cetacean populations. Further, while many skin diseases are not considered fatal, lesions detected on free-ranging animals may serve as indicators of other health concerns or environmental threats. Our study increases the knowledge and understanding of diseases and abnormalities in cetaceans in the Western Indian Ocean Region.

Acoustic properties of male sperm whale (Physeter macrocephalus) slow clicks with implications for their function.

Sorensen, Pernille[1]; Madsen, Peter Teglberg[2]
(1) University of Bristol, Bristol, United Kingdom
(2) Aarhus university
Corresponding Author: pernille.sorensen@bristol.ac.uk

Sound is the primary sensory modality of cetaceans, enabling navigation, prey detection, predator avoidance and communication. Whereas some toothed whales employ different sounds for

different functions, such as whistles for communication and clicks for echolocation, others such as sperm whales (*Physeter macrocephalus*) use clicks to fulfil both functions. Sperm whales produce at least four types of clicks or click sequences; usual clicks, buzzes, codas and slow clicks. Interestingly, the latter is only produced by males suggesting a communicative function of sexual display, but not much is known about the acoustic properties of slow clicks and their implications for function. We tested the hypothesis that slow clicks are used for long-range communication of size in male sperm whales by quantifying the acoustic properties of slow clicks from a close encounter with a male sperm whale emitting slow clicks in the proximity of a group of females off the coast of the Seychelles. The male produced numerous multi-pulsed slow clicks (N = 66) at known (measured with a range finder) ranges from the hydrophone at a mean apparent source level of 201±8 dB re 1µPa peak-peak (up to 229 dB re 1µPa peak-peak), a mean centroid frequency of 5.2±1.2 kHz and a mean inter-click-interval of 4.8±0.1 seconds. While previous findings have proposed that the inter-pulse-interval may allow females and other males to assess the size of the male source, the multi-pulse structure will not travel far, limiting such assessment to short ranges. Slow clicks have the lowest frequency emphasis of any sperm whale click and instead, we therefore suggest that females may choose males by selecting for those producing slow clicks of the lowest frequency. Thus, males may be producing an honest signalling of size when emitting slow clicks, being constrained by their size, and hence the size of their sound-producing organ.

Developing shared socioeconomic pathways for whale watching to support climate impact assessments in European islands

Sousa, Andreia[1]; Encarnação Coelho, Ricardo[2]; Costa, Hugo[2]; Capela Lourenço, Tiago[2]; Nunes, João Pedro[2]

Climate change is altering chemical, physical and biological processes in the marine environment, further exacerbating environmental pressures on ecosystems and interfering with human activities and economic sectors related to the Blue Economy. The need for methodologies that improve our understanding of climate impacts, vulnerabilities and risks has led to the development of the Shared Socioeconomic Pathways (SSPs), a new scenario framework describing a set of alternative future trends in the evolution of the environment and society. In our work narrative scenarios were extended to whale watching, aiming to serve as input to a set of climate impacts, vulnerability and adaptation assessments and ultimately as part of a decision support tool for this sector. Four whale watching SSP narratives were developed from the European scale SSPs through the identification and description of key elements relevant for the activity. The SSPs elements and assumptions were validated by experts and local stakeholders, namely whale watching companies. The extended whale watching SSPs were regionally assessed for the Macaronesia Atlantic region. Current and projected trends for each element were then evaluated through expert judgment elicitation methods and further quantified using available socioeconomic data. The consistent and harmonized narrative scenarios for whale watching in the Atlantic region are intended to assist comparability across study areas and to be combined with Representative Concentration Pathways (RCPs). This will produce the basis for an integrated scenario analysis and the development of future climate adaptation and biodiversity conservation measures across European Islands.

Behavior of humpback whale singers in the Abrolhos Bank, Brazil

The Abrolhos Bank (AB) is located off the East coast of Brazil where approximately 80% of all humpback whales that visit the coast of Brazil concentrate. Social dynamics in this region are thought to enable reproduction and calving as well as mediate sexual selection. Males use complex vocal displays to mediate intra- and inter-sexual interactions. Using different arrays of synchronized marine recorder units (MARUs) between 2003 and

2005, we were able to estimate the localization of multiple singers in short time intervals, which allowed us to count them and trace their trajectories in fine scale. This way we could visualize when males concentrate their singing activity, how and where singers move, the characteristics of their trajectories, if they interact among themselves and with vessels. Singing activity at AB is high. In a 391-h recording at the beginning of the reproductive season in 2005, more than 90% of the hours showed singing activity of at least two males simultaneously. Models were able to identify two distinct movement patterns in singers: slow, short and uniform steps lengths which suggests an exploratory behavioral state interpolated by rare fast and long steps which characterize a directional movement. Motivation for switching between behavioral states probably involves decisions about optimal reproductive strategies. There is an increase in the number of males singing as the season progresses even though the number of individuals present in the AB decreases after a mid-season peak. The overall temporal pattern in singing activity shows a decrease in song detection in the middle of the day in all years where vessel traffic is present, whereas in a quieter area, song was detected continuously. Noise from boat engines that may compromise humpback whale communication apparently elicits a reorganization of the timing of male vocal displays to avoid acoustic competition with the noise.

The song of the humpback whale (Megaptera novaeangliae) in the Abrolhos Bank across 18 years

The Abrolhos Bank off Brazil receives, during every austral winter and spring, humpback whales that are thought to reproduce and calve in the region. During this period males present vocal displays that are considered one of the most complex behaviours in nature: the song. It is comprised of long repetitive patterns structured hierarchically into units, phrases and themes. Each population converges to a specific version of the song that changes over time in variable rates. Given the recovery of the stock A of humpback whales, we were interested in tracking the song versions across time, defining the song structure from 2000 to 2018 and comparing the inter-annual variation of themes sung in the Abrolhos Bank. Recordings were made from vessels while monitoring the behaviour of individual males. Sounds were acquired using portable recorders at a sampling rate of 48kHz for at least 20 minutes. In order to quantify the annual changes in song structure, we calculated song similarity using the Levenshtein distance following the most recent methods described in the literature. The results enabled verifying song cultural evolution in small temporal scale when comparing consecutive years, and medium temporal scale when assessing a longer time interval (2000 to 2018). Inter- and intra-individual variation were found in different hierarchical levels of the song: unit, phrases and themes, probably reflecting the dynamics of the species' sexual selection process. Qualitative analyses showed different rates of change in the song over the years, demonstrating no single pattern. These results indicate that song cultural evolution within the population that visits Abrolhos is not directed by a single force driving this phenomenon.

To eat of not to eat: tradeoff between food and fear in fecal ingestion from communal latrines of a semi-aquatic mammal

Communal latrines have important biological and ecological roles for the latrine builder species and for other taxa that visit these sites and use feces to obtain nutrients and microorganisms that aid in digestion of compounds hard to process. Nonetheless, coprophagous animals must deal with the costs associated with parasites and other pathogens present in the latrines. Parasites and pathogens are found in Neotropical otter latrines. This species is piscivorous and uses latrines for territorial marking. The objective of this study was to identify vertebrate species

associated with otter latrines and species that use feces as food resource. Latrines were monitored with camera traps monthly in 24-hour cycles. We recorded nine species of vertebrates visiting these sites. Latrines are visited by birds, reptiles and mammals. Feeding dependency from latrines in the Atlantic Forest may not be related to less productive periods (dry season). Visitors that ate at the latrines do not have the same feeding habits as otters. The assumption that mammals would fear diseases caught in the latrines did not hold, since two mammals did not avoid ingesting feces. We speculate these two species might be less resistant or less susceptible to pathogens found in otter latrines.

Atlantic behavioral response study – Responses of Cuvier's beaked whales and short-finned pilot whales to military sonar off Cape Hatteras, North Carolina, USA

We conducted field controlled exposure experiments (CEEs) to quantify the behavioral response of Cuvier's beaked whales and short-finned pilot whales to tactical mid-frequency (3-4 kHz - primary signal energy) active sonar (MFAS) off Cape Hatteras, North Carolina. Our objective was to provide direct empirical measurements of behavioral response in relation to key exposure variables, including received exposure level, proximity to the source, and behavioral state. We employed a multi-scale approach, with simultaneous deployment of high-resolution, short-duration, archival acoustic and movement tags and lower-resolution, longer-term, satellite-linked depth-recording tags. Unlike many previous studies, our work was not conducted on a training range, where animals are exposed to frequent bouts of intense sonar activity, but, instead, an area where MFAS is used infrequently, so that animals may be familiar with, but not habituated to sonar. We used real-time noise propagation modeling to direct source vessels, such that received levels ranged up to 130 and 150 dB re 1 mu Pa for beaked and pilot whales, respectively We validated modeled levels relative to calibrated received levels on acoustic tags and bottom-mounted acoustic recorders. During the first two years of this project, we tagged 28 Cuvier's beaked whales and 44 short-finned pilot whales. We conducted 10 controlled exposure experiments (CEEs), each with multiple tagged individuals of both species, including three trials with full-scale tactical MFAS systems from Navy ships, five trials with a high-power simulated MFAS, and two no-sonar controls. We noted behavioral response in some, but not all, individuals, including short-term changes in diving behavior and horizontal avoidance. We did not observe any large-scale abandonment of habitat in either species, and behavioral responses were generally ephemeral, with animals resuming typical diving behavior within hours of exposure to MFAS transmissions. We will conduct additional field CEEs during summer 2019.

How much is too much? A global review of thresholds of 'acceptable' impacts on marine mammal populations.

Predicting the level of change that marine mammal populations may undergo as a result of an anthropogenic stressor is a complex task, which requires an understanding of the biological and ecological processes governing populations as well as the nature and scale of stressors. Furthermore, deciding how much change may be "acceptable" requires not only an understanding of population dynamics but also the legal framework and societal context of any particular species, population and stressor. We review the methods that have been used across the world to decide on 'acceptable' levels of population change and manage marine mammal populations under a variety of stressors, legislative frameworks and management regimes. We present a number of case studies to illustrate that the typical approaches that have been adopted fall into three categories: predictive population modelling, rule or algorithm based approaches and simple percentage based approaches. The degree of variability presented across all examples highlights that this is not a simple issue to solve – the same issue has been tackled by a variety of experts across the world and no universal solution has been found. Despite this, there is some commonality across different legislative frameworks, ecosystems and stressors in the principles applied and the factors driving decisions. The key factors influencing decisions on acceptable levels of impact are as follows: legislation, conservation status of the species or population concerned, data availability/uncertainty, stakeholder influence and the societal or economic value of the driver responsible for the change. In particular, the sustainable development of the renewable energy sector, with its importance for the mitigation of climate change and the development of a low carbon energy future provides a new context for decisions on acceptable impact in the permitting/licencing process. We present a number of guiding principles for setting thresholds of impact for such projects.

Environmental and individual influences on diving behaviour and foraging success in female Australian fur seals.

Understanding the factors which influence foraging behaviour and success in marine mammals is crucial to predicting how their populations may respond to environmental change. While its population is still recovering from the over-exploitation of the commercial sealing era, the Australian fur seal (*Arctocephalus pusillus doriferus*, AUFS), the largest of the fur seal species, represents the greatest marine predator biomass in south-eastern Australia. The area is currently one of the fastest warming oceanic regions in the world, with anticipated changes to oceanographic conditions likely to greatly impact the distribution and abundance of prey species. Adult female AUFS forage almost exclusively on the seafloor of the shallow continental shelf of Bass Strait and are, thus, highly susceptible to fluctuations in prey availability within this restricted foraging range, with direct consequences for reproductive success. Therefore, knowledge of how environmental variables influence foraging behaviour and success in the species is crucial to predicting how its population may respond to the climate change. The present study analysed diving behaviour in 135 adult females provisioning pups during the winters of 1998-2019, covering 8.05 ± 9.10 foraging trips per individual (total 1086) and 201.5 ± 62.5 dives per individual per day (total 592,159). Successful foraging dives were identified from ascent/descent rates using previously video-validated relationships, and indices of foraging success were calculated as the proportion of successful dives and successful dives per metre of vertical distance travelled. The results revealed complex relationships in the influence of broad-scale environmental indices and individual characteristics on diving behaviour and foraging success, with inter-annual variability suggesting cycles in prey availability linked to patterns in the prevailing oceanographic currents. These findings provide insights into the potential population trajectory of the Australian fur seal population in response to the predicted changes within its broader ecosystem.

Noise drives behavioural responses of humpback whales to whale-watching boats.

Whale-watching is a profitable business that is increasing globally. However, it can cause short-term behavioural impacts on animals with potential long-term consequences for their fitness. Despite

mounting evidence for disturbance, it remains unclear whether the sensory stimuli that trigger responses are visual or auditory. Here, we test the hypothesis that noise exposure, rather than boat proximity, is the primary driver of disturbance. To do this, we used humpback whales (*Megaptera novaeangliae*) as a model species, it being the most targeted species for whale-watching globally. We conducted controlled exposure experiments (n= 42) in a remote area serving as a humpback breeding ground in Exmouth Gulf, Australia. Controlled exposure experiments consisted of a 5m research boat passing a resting mother and calf pair at the same speed (1.5 knts) and distance from the whales (100 m) and only changing the boat noise level from a large Lubell LL-1424HP loudspeaker (control= SL 148 dB re 1 µPa @1m, medium= 160 dB re 1 µPa and high= 172 dB re 1 µPa, all rms). The behavioural responses (proportion time logging, presence of behavioural events, respiration rate) of whales were recorded 15 min *before*, *during* and *after* boat passes, using an unmanned aerial vehicle. Using mixed models, we show that compared to control noise i) the proportion of time logging for mothers decreased by ~27% during high noise, ii) mothers dove more frequently during medium and high boat noise, iii) the respiration rate of mothers increased two-fold during high noise at the same distance. We conclude that boat noise is the primary driver of short-term behavioural responses to whale-watching activities. These insights can directly inform whale-watch regulators on acceptable emission standards of boat noise to minimise negative effects on cetaceans and thereby facilitate the sustainability of the whale-watch industry.

DNA profiling by SnotBot® sampling from the spout of a whale

Sampling the spout of a whale using an aerial drone or SnotBot®, offers a non-invasive alternative to biopsy sampling. However, most non-invasive sampling techniques provide low quantity and quality of DNA, reducing the success of a DNA profile. Here, we develop methods to extract DNA from the spout of the whale and to assess the quantity of DNA using digital droplet PCR (ddPCR). The estimated copy number of target DNA as determined by the ddPCR is compared to the 'success' of the sample as determined through conventional PCR and sequencing of the mtDNA control region. Spout samples were collected in several geographic locations from humpback and blue whales between 2016 and 2018. From 103 samples, we successfully sequenced mtDNA haplotypes from 63 samples (61%). Concentrations of DNA in 'successful' samples ranged from 0.25-100.25 copies/µl. The lowest concentration with a positive result was similar to the lower threshold for successful barcoding with environmental DNA collected from seawater in the path of whales. Success of amplification and mtDNA sequencing increased through time from 54% in 2016 to 92% in 2018. Success with amplification of other markers (e.g. sex and microsatellite loci) was more variable but also improved with time. The mtDNA haplotypes of SnotBot® samples were compared to worldwide databases and identified matches to blue whales reported in the North Pacific and humpback whales in the Gulf of Alaska and the Southern Hemisphere. In addition to confirming presence of haplotypes in sampled regions, we also identified previously unreported haplotypes. This research confirms the potential for SnotBot® samples to provide genetic information in parallel with high-resolution images for individual identification and photogrammetry. Further developments in drone piloting, with assistance from artificial intelligence, could enhance sampling opportunities, including launch and recovery from land stations or from large ships, while underway.

Indian humpback dolphin depredation in coastal purse-seine fisheries – An unrecognized problem

Interactions with fishing gear are a known threat to cetacean populations globally, including in India. However, threat assessments in India are restricted to unravelling the bycatch problem and not depredation. Depredation, a frequently under-reported issue, has serious implications for both the fishing community and the dolphins, which could escalate to conflict over resource use in this region. To obtain a preliminary understanding of

Indian humpback dolphin (*Sousa plumbea*) depredation in coastal purse-seine fisheries, and the broader ecological and economic implications, we collected fisheries-dependent data during multiple trips and seasons aboard a fishing vessel. A binomial exact test revealed a 49% probability of depredation occurrence based on observed fishing events (n = 70), resulting in catch loss as well as costly damage to fishing gear. Approximately, 48.64% of these events involved adults with calves, suggesting social transmission of this behaviour among dolphin groups. Standard mark-recapture and foraging ecology studies may explain if the problem is more widespread in the larger dolphin population than reported here. To propose potential mitigation measures, we tested which factors of the fishing operations, including location & habitat parameters and catch characteristics, might be predictive metrics of depredation. Binomial logit-link regression showed that catch species had no measurable influence on dolphin depredation (contrary to the fishers' beliefs, assessed via interviews); total catch quantity did influence it to some extent, while water depth and distance from shore had a stronger influence—based on a sample entirely within the spatial range of humpback dolphin occurrence in our study area. While fishing crews frequently and unsuccessfully employ underwater explosives to deter depredating dolphins, the sub-lethal effects of these deterrents are unknown and require further study. Our study provides important evidence that depredation is a rising problem in coastal waters and minor modifications in fishing operations could potentially, reduce conflict.

Epidemiologic survey on the period prevalence of pinniped ocular disease and husbandry conditions within central European facilities

(1) Freie Universität Berlin, Berlin, Germany
(2) Freie Universität Berlin, Berlin, Germany
Corresponding Author: Miriam.Stach@fu-berlin.de

A high prevalence of ocular disease from captive pinnipeds and its contributing factors from husbandry has been discussed in the past. However, there have been only a few primary studies and their data originates mainly from US-American marine parks. Therefore, an epidemiologic survey was conducted to assess pinniped morbidity as well as the husbandry of Central European facilities. The period prevalence of ocular disorders within a timespan of two years was analysed for interdependencies between management and husbandry parameters, such as (ocular) medical training, (supplemented) saltwater, water change/filtration system, ozone/chlorine disinfection and chemical/bacteriological water screenings. Twenty-five facilities from Germany, Austria and Switzerland, keeping 35 pinniped groups consisting of 209 animals, took part in the study. There was an overall period prevalence of 32 %. The data showed a difference between the period prevalence of otariids and phocids, and otariids were more often kept in disinfected water. The proportion of males was higher in groups of phocids, and there was a strong correlation between the number of male pinnipeds in a group and the number of diseased males, which was not the case amongst females. In addition, ocular trauma was only reported in phocids. A significant difference in period prevalence was found between animals kept only in fresh water and those living in saltwater or offered an additional saltwater pool. However, no difference resulting from salt concentration was detected. Within the study sample, lower period prevalence was seen in groups with medical training, filtration systems and water chlorination. In conclusion, intraspecific fighting might be the main cause of period prevalence differences between otariids and phocids and suggests that facilities should keep groups with a higher proportion of females or neuter males. In addition, saltwater, water filtration and disinfection can lower period prevalence. Frequent water screenings and daily medical training may help to prevent ocular disease.

Evaluating anthropogenic activities on humpback whales (Megaptera novaeangliae) using behavioral changes as a measure of impact: Two case studies.

Corresponding Author: stephaniestack@gmail.com

Tourism targeting marine mammals has expanded in recent years, and there is growing concern about the impacts of these activities on both the individual and population level. Here we present research examining anthropogenic activities with two types of interactions between humans and humpback whales (*Megaptera novaeangliae*): vessel interactions and swimmer interactions. For both interaction types, we observed whale behavior before, during, and after interactions to determine any significant changes. Vessel interactions were assessed in Maui, Hawaii, USA from 2016-2018, and data were collected from a land-based theodolite station to record whale responses to vessel approaches. Generalized linear models were used to determine if swim speed, dive time,

respiration rate, and directness of travel significantly differed before, during and after a vessel was present. Swimmer interactions were assessed in Hervey Bay, Queensland, Australia from 2018-2019, and behavioral observations were collected from a vessel to determine whale responses to swimmer presence. To assess impacts of swimmer interactions, changes in activity state were analyzed using Z-tests for proportions, and changes in transitions among behaviors were analyzed using Markov chain analysis. We observed significant changes in whale behavior in response to both swimmer and vessel interactions. After a vessel interaction, whales displayed significantly shorter dive times and more direct paths of travel. After a swimmer interaction, whales travelled more and rested less. If human activity causes whales to use more energy than their energy stores allow, this behavior change could, in turn, decrease the amount of energy available to feed, breed, migrate, and reproduce, which can have population-level impacts. We recommend that the behavioral changes reported here be considered in the development of regulations and management plans for each study area and highlight the need for continued monitoring of human activities on whale populations worldwide.

Of winds and ships and summer whales: Listening to climate change in the Arctic

Stafford, Kate
University of Washington, Seattle, Washington
Corresponding Author: kate2@uw.edu

The effects of climate change are especially pronounced in the Arctic, where temperatures are warming twice as fast as elsewhere on the globe and sea ice decline is reshaping polar habitats. These changes have profound impacts on the physical and biological environment of the Arctic, particularly as regards the underwater environment. The acoustic ecology of Arctic marine mammals is driven by biotic and abiotic factors, each of which is changing under a warming Arctic such that we can "hear" climate change in the Arctic even during the polar night and under (increasingly reduced) ice cover. Acoustic monitoring in the Arctic is documenting changes in the atmosphere through increased ambient noise levels, changes in human usage of the Arctic via detection of shipping and oil and gas prospecting, the "invasion" of the Arctic by subarctic species, as well as changes in the phenology of Arctic marine mammals.

Prey availability vs prey abundance: Understanding the mechanisms underlying a population decline though a long-term biologging study of Antarctic fur seals.

Staniland, Iain
British Antarctic Survey, Cambridge, United Kingdom
Corresponding Author: ijst@bas.ac.uk

The use of technology has increasingly revealed the cryptic behaviours of marine mammals such that biologging studies are now commonplace. However, because of financial, ethical and logistical constraints they are usually limited in duration or sample size. Here we report on the analysis of over 1400 deployments of telemetry tags (TDR,PTT and GPS loggers) on female Antarctic fur seals breeding at South Georgia spanning 17 years. This unique dataset is complimented by an acoustic survey, targeting the seals' main prey Antarctic krill, which is run annually in the waters where they forage. These data provide us an exceptional opportunity to determine how these predators adapt their foraging behaviour in the face of temporal fluctuations in local krill abundance. Antarctic fur seals at South Georgia, representing 95% of the world population, have recently shown local declines that are thought to be linked to global climate change and reduced prey availability. We show how using at sea foraging telemetry we can infer how changes krill abundance are manifested at scales pertinent to the predators such as swarm/patch size and distribution in order to better understand the mechanisms underlying these observed population changes.

What attracts Baltic Sea grey seals to seal-safe cod-pots, how do they behave and when do they attempt to attack fish in the pots?

Seals and coastal fishery depend on the same fish stocks in the Baltic Sea, leading to inevitable competition. Seals raid fishing gear resulting in a loss in fish catch, damaged gear, and also seals caught and drowned as by-catch. Researchers have been active in developing 'seal-safe' fishing gear (cod-pots) which will be unattractive to seals and resistant to attacks. This study investigated presence of grey seals (Halichoerus grypus) around these gears, and the attempts to take fish from them. Baited and camera-equipped cod-pots of

three designs and mesh types were set out close to a seal haul-out site east of the island of Gotland (Sweden) in the Baltic Sea, and the behaviour of visiting seals filmed with underwater cameras was observed and analyzed using a Generalized Linear Model (GLM). As well as the cod-pot characteristics, the variables used for modelling included the time of day, whether bait fish were alive or dead and the quantity of fish in each pot. Seal behaviour varied and was divided it into eleven categories. The most important cod-pot-characteristic for seal presence and 'attack behaviour' was the physical design of the cod-pot. The most attractive design had loose netting around the upper chamber, in contrast to the other two designs which had tightly stretched mesh. Neither mesh size nor material showed any correlation with seal presence or attack behaviour. It was also found that the most important overall factor for predicting attack behaviour was the time of day. The 'investigation' behaviour was most commonly observed and most attack behaviours were targeted towards moving fish and no attacks occurred on dead fish. These results could suggest that seals visit cod-pots because of curiosity and not primarily because of hunger.

New technology instantly shares sightings and protects North Atlantic right whales in real-time

Corresponding Author: davesteckler@mysticetus.com

Wind farm (pre)construction is ramping up along the North American east coast. At any given time, multiple vessels off the northeast United States coast could be involved in high resolution geophysical surveys, pile-driving, and other activities producing sounds exceeding NMFS-regulated noise exposure thresholds. Such sounds can overlap the acoustic range used by the critically endangered North Atlantic right whale (NARW) for communication. Thus, federal regulators typically require 2-6 Protected Species Observers (PSOs) per vessel to watch for animals and take prescribed mitigation action when necessary (e.g. shutdown and delay of sound sources, change course, etc.). Extant technology for sharing NARW locations (e.g. NMFS SAS and WhaleAlert) facilitates broad public input, requiring vetting by authorities; sightings can take over 24 hours to propagate into the field. As creators of the software (Mysticetus) used by many PSOs, we developed a system that instantly shares NARW sightings between vessels and projects to facilitate enhanced mitigation and monitoring across a large area of activity. When a PSO on one vessel sights a NARW, it is instantly displayed on the computers of all other nearby PSOs. An alarm sounds and the location, range and bearing is highlighted on a real-time map. This system dramatically decreases latency and provides recipients of these alerts (PSOs) greater detail to inform their mitigation decisions, and provide real-time, improved protection of NARW. Improved situational awareness serves as a tool for real time adaptive mitigation, allowing optimization of industry activities while reducing environmental risks. Shared sightings are also fed into other systems (e.g. NMFS SAS and WhaleAlert), leading to better coordination among all mariners and facilitating broad, long-term data integration.

Harbour porpoise hunting from a bird's eye view.

Studying animal behaviour is important not only for understanding the natural history and ecological impact of animals, but it is also essential for protecting animals from human influence. The harbour porpoise (Phocoena phocoena) is a small cetacean found in the coastal waters on the northern hemisphere. It is known to be vulnerable to human disturbance, but the ecology of the species is still unstudied in detail. The harbour porpoise has a high metabolic rate and need to feed almost continuously, mainly on small fish. The details of its prey capture have been studied in captivity and by acoustic tags, but few visual studies exist of harbour porpoises foraging in the wild. To better understand the feeding ecology and habitat requirements of harbour porpoises we here use visual recordings of harbour porpoise foraging events. The data was opportunistically collected by use of drones during 2015-1019 in Little Belt and Great Belt, Denmark, and used to analyze foraging behaviour and predator-prey interactions from above when wild harbour porpoises feed on both schooling and individual fish. Results from this project suggests that harbour porpoises have a number of foraging strategies they switch between. In addition, although harbour porpoises are mostly considered solitary animals, our data show potential collaboration between individuals. Our observations also confirm that harbour

porpoises spend considerable amounts of time and effort to capture their prey, which is in line with results from previous acoustic studies.

Genomic monitoring of New Zealand's Māui dolphins using ddRAD sequencing.

The Māui dolphin (*Cephalorhynchus hectori maui*), a subspecies of New Zealand's endemic Hector's dolphin (*C. h. hectori*), is considered 'critically endangered' by the IUCN and 'nationally critical' under the New Zealand Threat Classification System. To date, genetic monitoring of Māui dolphins has relied on standard DNA profiling, including mtDNA haplotype, sex and up to 25 microsatellite loci for genotype capture-recapture estimates of abundance and linkage disequilibrium estimates of effective population size. Here we describe efforts to enhance the power of this genetic monitoring with the use of double-digest, restriction-enzyme associated DNA (ddRAD) sequencing. Libraries for ddRAD sequencing were prepared from n = 65 skin biopsy samples collected from Māui dolphins during the 2015 and 2016 field seasons and n = 20 Hector's dolphin samples by digesting total genomic DNA and subsequently size selecting for 300 - 400 bp. The indexed libraries were then pooled and sequenced on an Illumina HiSeq 3000 (150 bp, paired end) for an average of 4.1 million forward reads per sample. We used strict filtering criteria (e.g. 20x minimum initial stack depth) within the program STACKS to identify 1,591 variable loci in Māui dolphins. Using these loci we confirmed the identity of n = 48 Māui dolphins previously identified by microsatellite genotyping, and the resulting abundance estimate of $N = 62$ individuals (95% CL, 55 to 73) using a closed population model. Effective population size (N_e) was estimated to be $N_e = 54$ (95% CL, 53 to 55) using the LDNe method. Further analyses are underway to assess biases in estimates of N_e when using genomic data and to identify parent-offspring pairs for improved estimation of both census and effective population sizes. Our results provide a transition from conventional DNA profiling to genomic monitoring of this critically endangered subspecies.

First insights into the ecology of false killer whales observed in the Azores.

Steiner, Lisa[1]; Estrela, Guillherme; Hartman, Karin[2]; Van der Linde, Miranda[3]

False killer whales, *Pseudorca crassidens*, are infrequently observed in the Azores. Since 1987, there have been roughly 125 sightings around various islands of the Archipelago.

Photo-ID analysis of dorsal fins shows several long term (13 year) and inter-island matches (80-125nm). Given the infrequency of sightings, the fact that there are multiple re-sightings of individuals combined with individuals sighted only once, indicates that part of the population shows some degree of residency in the Azorean archipelago. Several individuals have been re-sighted together over multiple years, supporting the known cohesive social structure of this species. Group size varies from 2-150 individuals. New-born calves have been encountered on multiple occasions, indicating that the Azores may serve as a nursery ground and constitute a critical habitat for this species. False killer whales have been observed multiple times in association with bottlenose dolphins, *Tursiops truncatus*, and occasionally other species. Aggression from resident Risso's dolphins, *Grampus griseus*, towards false killer whales has been documented off Pico Island.

False killer whales in the Azores have been observed feeding on tuna, snipe fish, mullet and wreck fish and may follow food resources around the archipelago and surrounding submarine mountains. These animals may require protection, since they interact with fisheries and at present there are 2 known by-catch events in the local long-line fishery.

To date, individual matches between the Azores and the other Macaronesian Archipelagos have not been verified for this species. Since other odontocetes, such as short-finned pilot whales, *Globicephala machrorhyncus*, and sperm whales, *Physeter macrocephalus*, have shown long range movements within Macaronesia, false killer whales may also move between these archipelagos. In the

future, matching will be done between the Azores and the remaining areas of Macaronesia, to gain insight into the movement patterns and distribution of this top predator.

Population genetic structure of harbour seals in Ireland – filling a knowledge gap to evaluate and monitor Good Environmental Status

Steinmetz, Kristina[1]; Murphy, Sinead[2]; Ó Cadhla, Oliver[3]; Brownlow, Andrew[4]; Davsion, Nick[5]; Mirimin, Luca[2]

The EU MSFD (2010/477/EU) is a key instrument for marine conservation in Europe. It establishes a framework for achieving/maintaining Good Environmental Status in the marine environment. Within this framework, Member States are to establish environmental targets and associated indicators, in addition to implementing monitoring programmes and programmes of measures for said indicators. Seals are top predators that have a crucial role in the marine ecosystem and can be used as indicators to assess its health. Currently, two seal biodiversity common indicators are being employed within OSPAR regions II and III, including an assessment of trends in seal abundance and distribution. To undertake such an assessment, delineation of biologically significant Assessment Units (AUs) is required, though no such AUs have been proposed for harbour seals in Irish waters due to a lack of genetic data and thus currently harbour seals are managed as a single nationwide population.

The present study utilises a combination of mitochondrial and nuclear genetic markers to characterise the population structure of harbour seals in Irish and adjacent waters thereby providing advice for the delineation of reproductively isolated and biologically significant AUs. Biological samples were collected non-invasively (e.g. scat, hair) from key haul-out locations (Ireland) and corroborated with samples from stranded/rehabilitated individuals (Ireland, UK, Germany). The mitochondrial control region (d-loop) and 14 nuclear loci were analysed for 240 individuals.

Analysis of mtDNA among distinct geographical areas based on the distribution of key haul-out sites identified a high haplotype diversity and indicated the presence of sub-structuring for harbour seals within Ireland as well as among adjacent waters. These findings suggest that the current management approach for Irish waters may be inappropriate. Once corroborated with nuclear genetic data, this analysis will provide crucial information for the conservation and management of the harbour seal in Irish and European waters.

How can citizen science contribute to marine mammal research? Challenges, best practices and the role of new technologies.

Stelle, Lei Lani
University of Redlands, Redlands, California
Corresponding Author: leilani_stelle@redlands.edu

Sustaining long-term ecological monitoring of marine mammals is difficult as it requires dedication of a researcher or organization, funding, and resources. Since marine mammals are charismatic megafauna and many species are observed by the public, citizen science can be an effective approach for research and conservation. Recruitment and retention of volunteers can be facilitated by working with a partner organization to manage logistics. A key measure of success from the volunteer perspective is feeling that they are actually contributing to scientific research, so it is essential to provide real opportunities for them to record data and be involved in analyses. Organization, with identified roles, clear protocols for data collection, and new technologies increase the effectiveness of volunteer contributions. Applications such as *Collector App* (Esri), can be customized with project specific fields, and drop-down menus reduce the risks of entry errors. They also allow direct upload of records into maps and databases, which reduces the time required in post-processing. The public can also contribute sightings independently with mobile apps; *Whale mAPP* is designed for users to record the location and details of sightings globally and the data is freely available. Matching photographs for identification of individuals has often relied on expert members of the research team and requires a steep learning curve, but automatic recognition software is increasing the efficiency of the process. *Wildbook* is an open-source algorithm used to match dolphin fins and can increase collaborations by identifying other researchers who have observed the same animals. Volunteer engagement after the project is best maintained via social media and frequent project updates. Successful citizen science projects can work as a true collaboration between trained scientists and the public, advancing scientific

research, while helping to break down artificial boundaries leading to a shared mission for conservation.

The 'whale trap': Will climate change benefit endangered NW Atlantic blue whales, (Balaenoptera musculus)?

Stenson, Garry[1]; Lawson, Jack[2]
(1) Dept. of Fisheries and Oceans, St. John's
(2) Fisheries and Oceans Canada, St. John's, Newfoundland, Canada
Corresponding Author: Garry.Stenson@dfo-mpo.gc.ca

Despite protection from hunting since 1964, the Endangered northwest Atlantic blue whale population has failed to recover, with an estimated population of less than 200 mature individuals. One factor that may be having a significant impact on potential recovery is mortality of adult blue whales due to sea ice entrapments off the southwest coast of Newfoundland, Canada.

Generally, ice entrapments occur in years when extensive ice blocks the entrance to the Gulf in the spring. Due to the geography of the coastline and the presence of a coastal current, a strip of open water usually persists along the southwest coast of Newfoundland which is utilized by blue whales for feeding. The "whale trap" occurs when strong westerly winds drive ice into this open water, entrapping the whales present. Entrapments have been reported since 1868, and since 1974 41 blue whales are know to have died including nine in 2014 alone, resulting in a high level of adult morality.

There has been a significant decline in ice in the Gulf over the past two decades and the number of years with sufficient ice to entrap blue whales has declined. Climate models predict that ice extent and thickness will continue to decline in this area which may reduce the likelihood of ice-related mortality among NW Atlantic blue whales. However, the reduced ice cover is more mobile in response to wind, and strong wind events are becoming more common which could increase the speed at which these entrapments may occur. Unless this ice entrapment mortality is reduced, recovery of the NW Atlantic blue whale population will be jeopardized.

Using prey availability and environmental covariates to forecast humpback and fin whale distributions in the Northeast United States

Predicting the distribution of large whales on the Northeast United States coast is important to mitigating the impacts of anthropogenic activities including ship strikes, entanglement in fishing gear, and offshore energy development. Direct measurements of prey availability are not typically available and thus environmental parameters are often used as proxies for prey distributions in predictive habitat models of whale distributions. To date, long-term marine mammal surveys conducted in the Northeast U.S. since 1993 and fisheries bottom trawl surveys conducted by the Northeast Fisheries Science Center since 1968 have been used independently to model single- or multi-species distributions but have not been combined to model the distribution of marine mammals as a function of prey availability. Recently developed dynamical forecasting systems provide the opportunity to predict distributions of cetaceans and their prey on subseasonal time scales (lead times of days to weeks). Our objectives were to integrate prey distributions into predictive models of fin and humpback whale distribution, and to compare the predictive capacity of these models with and without prey distributions using subseasonal (SubX) sea surface temperature forecasts. We develop generalized additive models for humpback whales and fin whales, respectively, based on both environmental covariates and predicted prey distributions and use SubX forecasts to generate probabilistic predictions of forage fish, humpback whale and fin whale distributions. We present forecasts with lead times of 5 to 30 days along with estimates of forecast skill for the northeast US. Preliminary results suggest that models integrating environmental and prey variables perform better than environmental models alone, and increase the predictive capacity of marine mammal models using forecasted products. These forecasts would provide fishermen and managers with information about times and areas where whales are likely to occur (i.e., high risk areas for ship strikes and entanglements).

Off-range Southern elephant seal (Mirounga leonina) and Antarctic fur seal (Arctocephalus gazella) stranded in the coast of Peru: A La Niña side effect?

Stepchew, Claire L.[1]; Yaipen-LLanos, Carlos[2]
(1) Organization for Research and Conservation of Aquatic Animals - ORCA PERU

Corresponding Author: stepchew@orca.org.pe

Off-range pinniped presence in the Eastern South Pacific coast is poorly documented. To improve our knowledge of extra-limital records found on Peru's coast, ORCA has recorded stranded specimens over the past 18 years. Here, we describe the occurrence of *Mirounga leonina* and *Arctocephalus gazella* stranded in Peru associated to cold temperature abnormality (La Nina). For every stranded pinniped, we recorded gender, biometrics, physical description, geo-location and stranding cause. Both species were identified according to their morpho-anatomy characteristics, body size, and teeth count to differentiate from similar species. All specimens monitored were found alive and returned to the ocean after stranding. ORCA Stranding Network has recorded 4 accounts of Southern elephant seals (*Mirounga leonina)* and one Antarctic fur seal (*Arctocephalus gazella)* in Peruvian beaches during the summer months (December-March) between 2016 and 2018. *A. gazella, and M. leonina have a known range surrounding the circumpolar region. M. leonina were found within the central coast of Peru and appeared having ailments;* a malnourished adult female *A. gazella* was recorded on RegatasSur beach in Lima, Peru, on December 28th, 2018, being the most recent and northern record for the species. These off-range pinnipeds were found within cold water temperatures ranging from 17°-21° degrees Celsius, indicating the presence of a cold water stream running along the coast of Peru at the time of the strandings, where regular SST is warmer for that time of the year (+2°/+4°C). *There are previous reports of these pinnipeds found in both Chile and Ecuador associated to cold temperature abnormalities as well.* Sightings of *A. gazella* and re-occurring sightings of *M. leonina* highlight the importance of Peru's ecosystem as resting site for these traveling pinnipeds. ORCA's observations of these stranded pinnipeds are significant to understand how the ocean is rapidly changing and potentially affecting the distribution of these species.

Per and polyfluorinated alkyl substances (PFAS) in coastal and estuarine Indo-Pacific bottlenose dolphins (Tursiops aduncus), Western Australia (WA)

Stephens, Nahiid[1]; Gaylard, Sam[2]; Holyoake, Carlysle[1]; Duignan, Pádraig J.[3]; O'Dea, Mark[1]; Warren, Kristin[1]

N.Stephens@murdoch.edu.au

PFAS have drawn increased focus in the past decade due to their persistence, bioaccumulation, biomagnification and global distribution. Synthetic compounds with surfactant and repellant properties, they have been used since the 1960s in numerous industrial and household substances. Perfluorooctansulfonate (PFOS), perfluorooctanoic acid (PFOA) and perfluorohexanesulfonate (PFHxS) are most commonly found. Due to global detection, the main producer phased out production of perfluorooctanesulfonyl fluoride (POSF), the major PFAS precursor, in 2000. In 2009, PFOS was added to Annex B of the Stockholm Convention, restricting its use; PFOA is proposed for listing. In Australia, PFAS (predominantly PFOS) was used at airports and military airbases in fire-fighting foams, contaminating several locations; consequently PFOS-containing foams have been largely phased out. PFAS coatings (predominantly PFOA) on fabrics and metal surfaces are also, to a lesser extent, responsible for environmental contamination in Australia. The highest concentrations of PFAS are measured in piscivorous apex predators such as marine mammals. We analysed liver samples from deceased *Tursiops aduncus* from three coastal and estuarine locations in WA; given their inshore distribution and site fidelity, *T. aduncus* are excellent biological sentinels, potentially facing increased risk from terrestrial pollution. Samples were selected based on proximity to industrialisation using stranding location and/or life history; we contextualised our findings with those reported both nationally and globally. The Swan River dolphins (Perth, WA) exhibited significantly higher concentrations than the other two WA locations, as well as elsewhere in Australia; comparison with the international literature found their hepatic PFOS concentrations to be amongst the highest reported in marine mammals globally. Whilst this is a preliminary PFAS exposure survey, assessing exposure helps understand potential sources. Evaluating the magnitude of exposure in resident sentinel dolphin populations is of interest from a conservation and public health perspective; given some PFAS are endocrine

disruptors, tumour promoters and immunosuppressors.

Using UAVs for morphometric measurements of harbour porpoises (Phocoena phocoena).

An animal's body condition directly influences its survival and reproductive fitness, and therefore also the health of the populations. Monitoring cetaceans' morphometric measurements are usually obtained from stranded or bycaught individuals. This may bias interpretations on age - and sex-related growth as well as the status of their populations. The purpose of this study was to determine morphometric measurements of harbour porpoises *(Phocoena phocoena)* by using overhead video recordings from commercial UAVs (Unmanned Aerial Vehicles). From a customised program that implements the UAV parameters (height, gimbal orientation, camera parameters and Field of View), we were able to obtain the length and girth of 7 individual harbour porpoises of known sizes, very similar to the actual measurements and with a maximum error of 7.4%. Using length and girth, enabled determination of a body condition score (BMI Index) for each animal with an overall average error of 0.8 points. The method was then applied on recordings of free-ranging harbour porpoises with calves to determine the body condition. Furthermore the length was used to predict an approximate age, that all corresponded with the calves being born during spring. This is a very cost-effective monitoring method and a valuable complement to the current body assessment methods from bycaught or stranded animals that can aid in monitoring the growth and health of calves and adults on population scales throughout various seasons.

A multi-method approach to evaluating patterns and variability in the diet of Baffin Bay polar bears.

Climate warming in Arctic ecosystems is having pronounced effects on top predators. The loss of sea ice affects polar bears (*Ursus maritimus*) by reducing access to ice-associated prey. Detailed studies of polar bear foraging are necessary for understanding how diet may shift over time. Use of multiple chemical tracers may provide dietary insights in the context of habitat use, as each tissue formation timeline may reveal temporal differences in diet and habitat. We elucidate the feeding habits of the Baffin Bay polar bear subpopulation through use of hair stable isotopes, hair mercury concentrations, and adipose tissue fatty acids. We collected 138 hair and fat samples from Baffin Bay polar bears captured in connection with satellite tagging operations in spring of 2009-2013. Hair samples were analyzed for carbon, nitrogen, and sulfur stable isotopes and total mercury concentrations while fatty acid signatures were extracted from adipose tissue biopsies. Together, these data were used to evaluate feeding strategies of different ages and sexes and to compare differences in diet between habitat types. Baffin Bay is an area of seasonal sea ice and bears have demonstrated differences in habitat use throughout the year. Most bears move across the pack ice to Baffin Island and fast on land over the summer ('pack ice bears') whereas others remain resident at glacier fronts in NW Greenland ('glacier bears'). A lack of significant differences between hair $\delta^{15}N$, $\delta^{13}C$ or $\delta^{34}S$ ratios and THg concentrations for glacier vs. pack ice bears suggested similarities in trophic position and feeding. Nonetheless, significant differences in dietary fatty acid signatures between the two groups indicated some differences in prey composition exist, perhaps during certain times of the year. This suggests multiple methods should be incorporated in polar bear feeding studies to detect how diet varies with changing sea ice availability in the Arctic.

The effectiveness and influence of training on marine mammal data collection within Ghanaian waters
Stevens, Anna
, Southampton, Hampshire, United Kingdom

Corresponding Author:
isabelle.rundle@gardline.com

Tullow Ghana Limited (TGL) have been gathering marine mammal and turtle sightings surrounding the Jubilee oil field and Tweneboa-Enyenra-Ntomme (TEN) fields, off the coast of Ghana for 8 years. A total of 1200 marine animal sightings have been recorded over these 8 years. Between 1-Jan-18 and 31-Dec-18, 51 sightings of whales, dolphins and turtle species were recorded. Opportunistic sightings data was gathered onboard by TGL personnel monitoring and recording the presence and absence of marine animals along with some behaviour description. Since August 2013, Gardline has provided marine animal identification and mitigation training to TGL personnel by experienced marine biologists, to increase the sightings accuracy and reduce anthropogenic impacts such as noise. After the training there has been an increase in both sightings and good quality photographs, as well as an improvement in accurate species description, resulting in 15 species of cetaceans definitively identified; including the first sightings of Risso dolphin (*Grampus* griseus) and Sperm whales (*Physeter macrocephalus*) in Ghanaian waters. In 2018, there was a great reduction of personnel that attended the training by Gardline onboard the vessels along with reduction in the number of vessels monitoring, contributing to the lowest number of sightings and several sightings being downgraded onshore by experienced Gardline staff (i.e. Definitive ID to probable). However, 8 years of continuous sightings has resulted in the largest dataset of marine mammal sightings for Ghanian waters. Respectively showing the effectiveness and influence of training to continue monitoring, the lack of knowledge concerning marine animals within Ghanaian waters and the importance of continuing this standard monitoring.

Noise and cognition in dolphins: A deeper look into anthropogenic effects on marine mammals.

Stevens, Paige[1]; Bruck, Jason[2]
(1) Oklahoma State University
(2) Oklahoma State University, Stillwater, Oklahoma
Corresponding Author: paigees@okstate.edu

Human generated noise pollution is an increasing threat to marine mammals, yet the extent of anthropogenic sound pollution's effects on cognition are poorly understood. Dolphins use cognitive skills to hunt, maintain social groups and communicate. For our study, we measured attention in bottlenose dolphins, *Tursiops truncatus*, during acoustic playback sessions at multiple human-care facilities, both inland (where the animals experience no boat or SONAR sounds), and coastal (where the animals experience regular anthropogenic noise from cruise ships and personal water crafts). During playback sessions, the duration of dolphin look responses to control, cruise ship, jet ski and SONAR noises projected out of an underwater speaker were taken as a dependent measurement. The results were compared between facility types as well as across individual, sex and noise-type. We propose a re-evaluation of expectations around which noises are acceptable when managing wild marine mammal populations as well as discuss broader implications for expectations related to habituation and sensitization in cetaceans.

Subcutaneous encapsulated fat necrosis and loose cavitary fat bodies in bowhead whales (Balaena mysticetus) from Alaska

Stimmelmayr, Raphaela[1]; Rotstein, David[2]; Sheffield, Gay; Brower, Sheldon[3]; George, John "Craig"[4]

The bowhead whale is, an ice-associated large baleen whale central to Inuit subsistence culture. Since 1977, aboriginal harvest of bowhead whales from the Beaufort-Chukchi-Bering (BCB) bowhead whale population is regulated under the authority of the International Whaling Commission (IWC). To date, few disease conditions have been described in bowhead whales despite their extreme longevity. We describe a case series of subcutaneous encapsulated fat necrosis and loose cavitary fat bodies in six bowhead whales harvested (2011 to 2015) North Slope, Alaska, USA. Sex and age class distribution was three immature females, two immature and one mature male with a mean (SD) total body length of 11.6 (2.4). Grossly, the firm elliptoid to round masses ranged in size from six to 15 cm in diameter and weighed between 25g to 1490g. They were beige to grey, firm and with a smooth-surface. On cut surface, subcutaneous masses had multiple irregular concentric layers with either discolored fatty tissue and calcifications. In 2/3 (66%) peritoneal encapsulated masses, adipose was yellow with surrounding layers of fibrous connective tissue. Pleural encapsulated masses (pendulant and loose) were characterized by thick fibrotic capsules, and a white caseated dry core.

The gross and microanatomical appearance of both lesion types in bowhead whales is similar to subcutaneous encapsulated fat necrosis (syn. nodular-cystic fat necrosis, mobile encapsulated lipoma, or posttraumatic fat necrosis; abacus tumor; mobile encapsulated adipose tissue) and loose peritoneal bodies, benign adipose lesions that have been described in humans and cows. The described condition is rare with only 6/121 (5%) observed from 2011-2015. The exact mechanisms of development of these encapsulated peritoneal and subcutaneous bodies in bowhead whales remains to be determined. Assessment of further cases in bowhead whales and other baleen whales is warranted to better understand their pathogenesis.

Mind the gap: A striking absence of welfare science in marine mammal conservation.

Stockin, Karen[1]; Boys, Rebecca[2]; Palmer, Emily[3]; Betty, Emma[4]; Clegg, Isabella[5]; Simmonds, Mark Peter[6]
(1) Massey University, Auckland, New Zealand

Corresponding Author: k.a.stockin@massey.ac.nz

Human activities influence not only the survival and fitness of populations but also the welfare of individuals. However, conservation biology and animal welfare science are often viewed as widely disparate scientific disciplines. Nonetheless, welfare science can inform conservation and there is growing recognition of how these disciplines can be united to significantly improve conservation outcomes. To determine how this critical nexus is reflected in the study of marine mammals, we examined the peer-reviewed literature. Since their 1972 and 1985 instigation, Aquatic Mammals and Marine Mammal Science have (up to Mar 2019) published a total of 1,202 and 2,349 peer-reviewed articles, respectively. However, of these only 3.5% (n=42) and 0.5% (n=11) respectively, feature 'welfare' either in the title, abstract or keywords. When expanding the same search to all English written peer-reviewed journal articles detailing any marine mammal taxa from 1972 to 2019 (n=8,998), the proportion of those articles detailing 'welfare' still only equated to 2.8% (n=255). The terms 'stress' and 'cortisol' (levels and/or concentrations) are often used by authors to infer welfare measures and/or impacts. However, both terms also reflected poorly in the broader scientific literature, accounting for just 5.7% (n=517) and 2.4% (n=212), respectively across all papers surveyed concerning marine mammals. Of these,1.0% (n=12) and 0.6% (n=7) featured in Aquatic Mammals and 0.6% (n=14) and 0.5% (n=12) featured in Marine Mammal Science, respectively. Based on these results, we propose that the benefits to be gained from increased integration of welfare science, including individual health studies, into conservation management efforts may not be fully recognised and/or utilised presently. We make recommendations to help address this apparent deficit, including a call for conservation biologists and marine mammal heath specialists to actively seek synergies in their work via the emerging discipline of conservation-welfare.

The origin and spread of distemper virus in phocids

Stokholm, Iben[1]; Bagger Terkelsen1, Thilde; Siebert, Prof. Dr., Ursula[2]; Olsen, Morten Tange[3]

Corresponding Author: ibenstokholm@gmail.com

Morbillivirus infections constitute an increasing and pressing problem to marine mammal populations worldwide. For instance, the Canine Distemper Virus (CDV) and Phocine Distemper Virus (PDV) have caused major mass mortalities in a range of Arctic, Antarctic and temperate phocid seals. However, little is known about the origin of distemper and the drivers spreading the viruses among phocid species and populations, as well as transmissions to and from terrestrial carnivores. Here we investigate the evolution and divergence of PDV and CDV by Bayesian phylogenetic analyses of 1,698 bp of the H gene from a total of 125 samples, as well as more than 6000 bp of the PDV and CDV genome in a smaller sample of 94 animals. The phylogenetic analysis supports the existence of several CDV and PDV clades, and several transmission events between phocid seals and terrestrial carnivores. Intriguingly, our results suggest that the CDV strains causing outbreaks in Baikal and Caspian seals are the CDV strains most closely related to PDV. Furthermore, it seems that PDV and CDV diverged as recent as in the late 17th century, possibly coinciding with increases in transmission rates among e.g. domestic dogs and phocid seals associated with Eurasian trade and colonialism.

How do marine mammals maintain blood flow while diving?

Storlund, Rhea[1]; Rosen, David[2]; Margiocco, Marco[3]; Haulena, Martin[4]; Trites, Andrew W.[5]

Marine mammals are known to constrict their blood vessels while diving, but it is unclear how their hearts compensate for the increased resistance to blood flow. We answered this question by comparing the anatomy and electrical activity of marine and terrestrial mammal hearts. We performed echocardiography on 8 Steller sea lions (SSLs) and electrocardiography (ECGs) on 8 SSLs, 5 northern fur seals (NFSs), and 1 walrus under anaesthesia—and compared ECG parameters of 17 species of marine mammals to 50 species of terrestrial mammals. The echocardiograms showed that SSLs have larger aortic roots, likely acting to decrease cardiac work. The SSLs also had relatively larger left ventricular end-systolic dimensions, meaning that the left ventricle contracts less than in similarly-sized terrestrial mammals. Characteristics of SSL, NFS, and walrus ECGs varied between species and among individuals. Sinus arrhythmia (heart rate variation) is thought to be associated with diving ability and was recorded in 5 of the 8 SSLs, but not in the NFSs or walrus. Unlike terrestrial mammals, the greatest electrical activity in 5 SSL and 2 NFS hearts was not in the left ventricle, suggesting that it is not their most muscular cardiac chamber. Our interspecific comparison of ECGs further revealed that marine mammals had 20% longer P-waves and 11% longer QRS intervals than terrestrial mammals, but that the duration of the overall cardiac cycle was the same between marine and terrestrial mammals. In other words, marine mammals had slower atrial and ventricular depolarization than terrestrial mammals, but similar heart rates. Overall, it appears that marine mammals can maintain blood flow while diving because they have larger aortic roots than terrestrial mammals. Differences in electrical activity and left ventricular end-systolic dimensions may also contribute to overcoming vascular resistance when heart rate is reduced.

Evidence of group density effect on behavioural differences in grey seal (Halichoerus grypus) neonates during lactation period.

The abundance of grey seals (*Halichoerus grypus*) in Atlantic and Baltic waters has been increasing in recent years. It is important to understand factors affecting this growth and how the growing population can influence the behaviour of individual seals. Individual behaviour during the lactation period is important for later development in many mammals and the social environment in which an individual is raised can influence their adult behaviour in the future. To broaden the understanding of how different social surroundings can influence grey seal neonate behaviour, 16 wild pups were observed during the suckling period of 2017 on the Isle of May, Scotland. Different social and non-social behavioural states and distances from mothers were recorded at 5 minute intervals for several hours during daytime. Locations of the mother and pup and all surrounding individuals were marked and maps visualizing daily individual locations within the breeding site were created. Nonparametric statistical analysis of the collected data showed that group density had a significant effect on the frequency of ALERT behaviour (Kruskal Wallis test, $\chi 2(2) = 14{,}774$, $p = 0{,}001$). Pups in densely aggregated areas expressed ALERT behaviour more often than pups in sparsely aggregated areas (Dunn's test with Bonferoni adjustment, $Z = 29{,}718$, $p = 0{,}001$). This difference was especially significant in male pups (Dunn's test with Bonferoni adjustment, $Z = 16{,}703$, $p = 0{,}014$). According to earlier studies of consistent individual differences in adult grey seals, differences in the tendency to perform vigilance behaviours such as ALERT comprises a key behavioural component that distinguishes behavioural types. The current study provides evidence of possible early development of this individuality during the suckling period, influenced by different group densities of the surrounding colony.

Heteroplasmy; Detection, verification and recurrence in baleen whales.

Heteroplasmy is defined as the presence of two or more different mitochondrial DNA (mtDNA) genomes in one individual. Heteroplasmy can arise from insertions or deletions (length heteroplasmy) or single nucleotide substitutions (point heteroplasmy). The phenomenon has been widely studied in humans and model species; however, reports from non-model species are rare, possibly because heteroplasmy was undetected or ignored during sequencing. Among cetaceans, a few studies have reported heteroplasmy and speculated on its possible effects, suggesting that heteroplasmy could be rare or simply ignored. The aim of the present study was to assess and confirm point heteroplasmies, as well as to determine their frequency in five baleen whale species. We analyzed 10,748 mtDNA sequence electropherograms of the mitochondrial control region obtained by Sanger sequencing. A pipeline was developed to detect potential heteroplasmy by analyzing chromatogram peak heights. Potential heteroplasmies were subsequently verified experimentally. A total of 7,882 samples were assessed, among which 326 (4,1%) presented potential point heteroplasmy at more than 35 different nucleotide positions. These results indicated that heteroplasmy is more frequent than previously reported. Several heteroplasmies were tracked across multiple generations, providing insights into the introduction of new mtDNA haplotypes. Ignoring heteroplasmy might bias relatedness analyses as well as estimates of genetic diversity and mtDNA mutation rates. Thus, it is extremely important to develop efficient ways to detect and verify heteroplasmy.

Heavy metal concentrations in Tursiops truncatus off central coast of Veracruz, México.

The National Park "Sistema Arrecifal Veracruzano" (Veracruz Reef System, VRS), located in the middle of the Gulf of Mexico, is a Federal Natural Protected Area with biological, economic and social importance, and where different ecological interactions occur. It is also the location of one of the most important urban development activities in the country: the Veracruz Port expansion. For this reason, it is of utter importance to develop in-depth research using bio-indicator organisms such as dolphins, which reflect the impacts of human activities on marine ecosystems. Besides collecting data on dolphin density, behavior and photo-identification, we analyzed heavy metal concentrations in the blubber of *Tursiops truncatus*. From June 2016 to July 2017 systematic boat-based navigations were conducted and five blubber samples were collected using a crossbow and modified arrows. Concentrations of six metals (Pb, Cr, Fe, Ni, Cu, Zn) were estimated using the total reflection X-Ray fluorescence spectroscopy (TXRF) technique. Mean and standard error concentrations were as follows: Pb 2.5±1.0µg/g; Cr 32.6±6.9µg/g; Fe 404±76.9µg/g; Ni 19.5±6.1µg/g; Cu 44.4±20.2µg/g; Zn 357.3±118.9µg/g. Our results show that our values are above what was reported in other studies around the world, except for Zinc. This suggests an extended exposition to pollution sources from human activities. This study constitutes the first step within a long-term health monitoring program in the VRS, and we plan to expand our assessment to potential dolphins' preys and seawater. Our ultimate goal is to provide relevant scientific information for environmental stakeholders in order to promote marine ecosystem conservation.

Population size and IUCN Red Listing of a threatened franciscana population

Sucunza, Federico[1]; Daniewicz, Daniel[2]; Zerbini, Alexandre[3]

The franciscana (*Pontoporia blainvillei*) is endemic of coastal waters from Brazil (18º25'S) to Argentina (42º10'S). The species is regarded as the most threatened small cetacean in the western South Atlantic Ocean due to high bycatch levels and habitat degradation. The franciscana is listed as Vulnerable in the IUCN Red List of Threatened Species. Recent analysis of mtDNA suggested that individuals found in the species' northern range (Brazilian State of Espírito Santo, ES) represent an isolated population. Three aerial surveys (December-January/2011, March/2018 and January-February/2019) following design-based line transect methods were conducted to assess distribution and estimate abundance of franciscanas off ES. A total of 324 transects were surveyed from the shore up to the 30m isobath between Itaúnas (18º25'S) and Presidente Kennedy (21º17'S), north and south ES boundaries. A total of 40 franciscana groups were seen (on-effort=27, average group size=2.5, SE=1.1) in coastal habitats (average distance from the shore=3.3km, SE=2.3km, range=0.4-8km). Abundance corrected for visibility and group size biases was estimated at 922 individuals (CV=0.35, 95% CI=470-1,810) combining data from 2018 and 2019. Results suggest that, at least during the summer, franciscanas in ES are distributed in very coastal habitats between Conceição da Barra (18º35'S) and Santa Cruz (19º56'S), within an area of only 2,400km^2. This is probably the smallest and the one presenting the most restricted range among all franciscana populations. The estimated abundance indicate that the ES population qualifies for listing as "Endangered" under the IUCN Red List criterion C2a(ii) because of the small size (less than 2,500 mature individuals) and because of an inferred decline in abundance as a consequence of bycatch and habitat degradation. Further research is needed to assess current mortality levels and to identify areas where conservation actions (e.g., establishment of no-take zones) can be implemented to minimize the extinction risk of this population.

Assessment of distribution and relative abundance of Guiana dolphins (Sotalia

guianensis) and common bottlenose dolphins (Tursiops truncatus) in an area severely impacted by an iron mining dam collapse in Brazil

Sucunza Perez, Martin[1]; Sucunza, Federico[2]; Berchieri, Natalia; Capello Neves, Mariana; Daniewicz, Daniel[3]

Guiana dolphins (GD) and common bottlenose dolphins (BD) occur along the coast of the Espírito Santo State (ES), southeastern Brazil, however information on their distribution patterns and abundance is scarce. In November 2015, after the Fundão iron mining dam collapse, the ES coastal area was impacted by the discharge of 39 million m^3 of toxic mud. Understanding the ecology of an impacted population is key to assess impact magnitude and to design monitoring plans. Here we present data about distribution and relative abundance of both species off the ES coast. Between January-February 2019, aerial surveys were carried out from Vitória (20°17'S/40°17'W) to Itaúnas (18°25'S/30°42'W). Design-based line transects (n=88, maximum transect length=20km) were placed perpendicular to the coast up to the 30m isobath. All groups of GD and BD were georeferenced and the relative abundance was estimated. A total of 59 groups of GD (mean group size=4.6; SD=7.4; range=1─50) and 17 of BD (mean group size=9; SD=18.6; range=1─80) were sighted throughout the survey area. GD groups were sighted from the coast up to the 30m isobath, with the highest encounter rate (ER) between 0-10m (7.2groups/100km). BD groups were sighted from 10m to 30m of depth, with the highest ER between 20-25m (2.3groups/100km). Relative abundance (uncorrected for visibility and group size biases) was estimated at 505 individuals (95%CI 282─906; Density=0.54; CV=0.30) of GD and 950 individuals (95%CI 280─3,221; Density=0.28; CV=0.66) of BD. The sediment plume discharged into the ocean showed a highly overlap with the distribution of GD and BD reported here, thus suggesting that these populations may have been directly impacted by the sediments. Although these are preliminary data on distribution and abundance of these species after the disaster, the results presented here can be used as a baseline to monitor long-term impacts of the mining dam disaster on these species.

Novel balloon census method for fusion of acoustic and visual census for the Ganges river dolphins ((Platanista gangetica)

A balloon census with the multiple compact video camera system (GoPro HERO) was developed and improved for supporting the fusion census of acoustic and visual census of the Ganges river dolphins to compensate the drawbacks of the visual census and increase the accuracy of the quantitative census data analysis and individual dolphin's information. In order to increase the surfacing dolphin's detection probability by the balloon camera system similar to that of a human observer, a visual field distance greater than 80m ahead of the census boat should be captured by the camera system with sufficient resolution. Therefore, we introduced a forward-looking compact video camera system with appropriate tilt angle along with the existing downward-looking video camera system. In addition, to maintain the visual field of the camera system for the field test in the river system, pitch angle of the both video camera systems can be tracked and controlled by the gyro sensors and via the software installed into a PC/tablet/smart phone through WiFi. Fusion census of both acoustic and visual census with the improved camera system on the balloon was conducted at the same experiment site in the Ganges river system for several days in February 2018 and 2019. The performance of the balloon camera system for supporting the fusion census was demonstrated well, even though the balloon census could be conducted only when the wind direction was aligned with the boat cruise direction. The balloon camera system could capture the individual dolphin's features such as migration behavior of the dolphin with a calf and the body length measurement of the small calf, and so on which will help the river dolphin's behavioral study.

Why Baja? An empirical model for estimating field metabolic rates and thermoregulatory costs

of gray whale calves (Eschrichtius robustus).
Sumich, James L.

Corresponding Author: jlsumich1@gmail.com

The purpose of this study is to develop a conceptual basis for comparing gray whale calf field metabolic rates to estimates of body heat losses and consequent required thermogenesis for body temperature maintenance from birth to weaning. The unavoidable minimum rate of body heat leakage is assessed and compared to the calves' metabolic activities.

I describe patterns and magnitudes of several morphometric, ventilatory and thermoregulatory characteristics of young gray whale calves, both free-ranging and captive, to quantify the metabolic activities and consequent energy requirements of individual gray whales in field situations.

Empirically derived equations (most scaled to body length) of four morphometric, seven ventilatory and nine thermoregulatory characteristics are developed to provide estimates of field metabolic rates and thermoregulatory costs to improve our understanding of the energetic demands that gray whale calves make on their lactating mothers, particularly in the face of disturbances that interfere with efficient and successful foraging. Where available, literature-reported CV values are assigned to random-normal functions to estimate variability of each derived equation.

Between birth and weaning, typical gray whale calves grow about 3m in length and increase body mass about 5x. Mean daily field metabolic rates (FMR) increase from 138 Mj at birth (2.4•BMR) to 264 Mj (1.5•BMR) at weaning.

Body surface and ventilatory heat fluxes were evaluated separately , then combined to estimate minimum total heat losses from birth to weaning at three ambient water temperature regimes; 18°C typical of winter natal lagoons, 2°C, typical of summer arctic conditions, and an intermediate value of 10°C typical of Oregon coastal waters during summer.

Comparisons between estimated minimum rates of heat loss and MR shown in Fig. 12 indicate that, for neonates, their required thermogenesis in 18°C winter lagoon water is substantially less than their estimated mean MR, and that no additional thermogenic activity over mean MR is required to maintain normal body temperature.

By the age of natal lagoon departure, calves in good body condition are capable of tolerating heat losses experienced in 2° C water without additional thermogenetic activities. It follows that little thermogenic advantage is achieved even by small calves by remaining in warmer waters along the migratory route during summer rather than returning to the Bering or Chukchi Seas.

Working with the lobster fishery to develop conservation measures for North Atlantic right whales in the Gulf of Maine, USA

The population of endangered North Atlantic right whales, *Eubalaena glacialis*, has been in decline since 2010, with mortalities outpacing a declining birth rate and increasing calving intervals. Most of these mortalities are related to anthropogenic causes, namely entanglement in fixed fishing gear. New regulatory measures to reduce the rate of serious injuries and mortalities due to entanglements, specifically in the American Lobster fishery, have been initiated in the US. However, there are information gaps regarding how the vertical lines of fixed gear are fished throughout the Gulf of Maine where the majority of this fishery exists. Additionally, little data exist on the functional needs of this industry for vertical line hauling strength spatially. We formed a collaborative with states, industry associations, and researchers to collect data on vertical line fishing practices in the region through an extensive outreach program. The program included a gear survey that resulted in 867 responses from fishermen on how and where they fish, 215 breaking strength tests of donated vertical lines, and documented hauling loads experienced by eleven fishermen fishing between 5-35 pot trawls in up to 400-meter depths throughout the region. These data are being used to build a model for use by managers to both describe the landscape of vertical line use and needs in the region, as well as assess proposed regulatory measures for conservation benefit to right whales and the impact of such measures on the fishing industry. We will present the outcomes of the outreach and research program, in addition to discussing how the collaborative worked within the regulated fishing

community to develop measures to protect North Atlantic right whales.

Changes in saliva steroid hormone levels of grey seal pups during lactation and post-weaning fast.

Surviliene, Vaida[1]; Moss, Simon[2]; Rukšėnas, Osvaldas[3]

Steroid hormones play a crucial role in modulating social and sexual behaviour of mammals. Steroid hormones affect and organize brain areas during early development leading to a future sex based behavioural differences. Disruptions in steroid hormone production and metabolism during critical early development stages might lead to certain behavioural failures in the future. Grey seals are large marine mammals, top predators and capital breeders. To understand how steroid hormones are likely to vary naturally in young grey seals, we collected saliva samples from grey seal pups during lactation period and post-weaning fast (up to 38 d postpartum) in 2012 and 2017 at the Isle of May (UK) breeding colony. Saliva was chosen for steroid estimation, since it measures unbound steroids that are considered to act directly on target cells. Synthetic swabs (Salimetrics) were used for obtaining saliva samples. Estradiol (E, N=57), testosterone (T, N=60) and cortisol (C, N=64) concentrations were measured with ELISA kits (IBL-International). Z-score normalization was applied to measures to avoid any differences in absolute concentration levels between years. No difference in E, T and C steroid concentration was found between sexes of grey seal pups (Mann-Whitney, $p > 0.05$). E and C levels reduced with pup`s age (Spearman's rho, E: $R = -0.489$, $p < 0.001$; C: $R = -0.339$, $p = 0.006$), while T levels did not change significantly with age. Means of concentrations of all steroids were 34.76% (E), 29.95% (T) and 42.09% (C) higher during lactation period then during post-weaning fast (Mann-Whitney, E: $p < 0.001$; C: $p = 0.001$; T: $p = 0.12$). However, highest steroid concentrations could be visible during mid and late lactation periods, and lowest - at the end of the postweaning fast (Kruskal-Wallis, E: $p < 0.01$; C: $p < 0.01$, T: $p = 0.27$).

Going with the flow or against the tide: Inspiring Marine Mammal Research and Conservation in Indian waters.

The intestinal microbiota is formed by the enormous number of bacteria and underpins the health and homeostasis of the host. Of these bacteria, core microbiota in the intestine is suggested to have co-evolved with the hosts and perform significant functional roles. We previously revealed that the differences of the composition of intestinal microbiota in captive bottlenose dolphins *Tursiops truncatus* at three aquaria, however, knowledge of core microbiota in the species have not been investigated. Here we represent core microbiota in the intestine of captive bottlenose dolphins. Fecal samples were collected from a total of 16 captive common bottlenose dolphins housed at Ocean Expo Park (Okinawa, Japan, $n = 4$), Enoshima Aquarium (Kanagawa, Japan, $n = 7$), and Tsukumi Dolphin Island (Oita, Japan, $n = 5$). All sampling was conducted as routine health check procedures. After extraction of bacterial DNA, the V3-V4 region of bacterial 16S rRNA was amplified. All resultant amplicons were subjected to pair-end sequencing protocol on Illumina Miseq platform. To identify the core taxa, the following criteria, a) present in all individuals at each aquarium and b) present at $\geq 0.1\%$ of total reads, were used. Total 10 bacterial phyla were detected from fecal samples of dolphins at three aquaria with Fusobacteria, Firmicutes, and Proteobacteria being the predominant phyla, and these three phyla were suggested as core phyla in dolphins. Total 470 bacterial genera were detected from fecal of dolphins, and 12 genera were identified as forming the core microbiota in captive dolphins. Of these core genera, *Enterococcus* and *Lactobacillus* were

regarded as probiotics in many animals. *Cetobacterium* was suggested as common members of intestinal microbiota in freshwater fishes and produce vitamin B_{12} at high efficiency. In this study, we revealed the main target bacteria to isolate and test their benefits to maintain health management of captive dolphins.

Tracing life history of immature Antarctic minke whales: Stable isotope oscillation in baleen revealed ontogenetic diet shifts and seasonal migration.

Understanding seasonal migration patterns in marine top predators are important to figure out how these predators affect each ecosystem. In Antarctic minke whales (AMW), *Balaenoptera bonaerensis*, winter breeding in warm ocean at lower latitude and summer feeding in cold and highly productive ocean at higher latitude are known for the mature individuals, however, migration patterns for immature individuals are unknown. Stable isotope analysis on carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$) has been applied to clarify where and what immature individuals fed to estimate their seasonal migration pattern. Baleen plates of seventeen immature whales, which were obtained by whales taken in the NEWREP-A: New Scientific Whale Research Program in the Antarctic Ocean during Austral summer from 2015 to 2017, were used in this study. Variations in isotopic values in $\delta^{15}N$ determined three types of age classifications; A) newborn, B) yearling, C) more than two years old. Constant values in $\delta^{15}N$ suggested the effect from lactation in Type A (with notch) and B (without notch), while periodic cycle in $\delta^{13}C$ and $\delta^{15}N$ indicated feeding mainly on Antarctic krill in the Antarctic Ocean and migration to lower latitude as same as mature individuals in type C. These results suggested that lactation timing is clear, and immature individuals have seasonal migration as same as mature individuals.

Antioxidant properties of dolphin serum albumin

[Purpose] Serum albumin (SA) is the most abundant protein in the blood. It functions as a carrier protein, contributes to osmoregulation, and acts as an antioxidant. Generally, SA exerts the antioxidative activity by scavenging reactive oxygen species. As marine mammals are superior divers, they are intermittently facing oxidative stress induced by reperfusion to ischemic tissues after dive. Previous studies reported on several antioxidants in marine mammals; however, no study focused on SA. We tried to reveal the antioxidative effects of dolphin SA by comparing those of other mammals' SA. [Methods] (1) The primary structures of SA proteins in cetaceans were characterized by multiple sequence alignment with other mammals sequences. (2) The degree of degradation of SA by hydrogen peroxide was tested by using SAs purified from sera in common bottlenose dolphin and other mammals. (3) The antioxidant effects of the SAs were examined by using dihydrorhodamine-123 (DHR) as the indicator. [Results] (1) The multiple sequence alignment revealed that several critical amino acids responsible for antioxidative functions were replaced to other amino acids in cetacean lineages. (2) Dolphin SA was degraded by hydrogen peroxide more than other mammals' SAs. (3) The antioxidative activity test with DHR suggested that dolphins SA may be relatively ineffective as antioxidant when compared to other mammals' SAs. These results suggest that dolphin SA may be less able in scavenging reactive oxygen species, even though cetaceans should cope with oxidative stress associated with dive.

Marine megafauna catch in Thai small-scale fisheries

Svarachorn, Thevarit[1]; Berggren, Per[2]
(1) Newcastle University, Newcastle upon Tyne, United Kingdom
(2) Newcastle University, School of Natural and Environmental Sciences
Corresponding Author: thevarit.svarachorn@gmail.com

Catch in small-scale fisheries is a conservation threat to marine megafauna. Yet, it is incognisant, poorly assessed and under-monitored in Thailand, where megafauna are common and small-scale fisheries abundant. This study represents the first catch assessment of five marine megafauna groups (rays, sharks, sea turtles, cetaceans and dugong) in Thai small-scale fisheries. Data on catch and fisheries effort across one year (2016 – 2017) were collected during questionnaire-based interviews with 535 fishermen in 17 provinces along the Gulf of Thailand and the Andaman Sea during September to December 2017. Catch per unit effort estimates were generated for each megafauna group by fishing gear type. Total catch per year for small-scale fisheries of each megafauna group was extrapolated using Thai official fisheries statistics. The results showed that the annual estimated catch was 4.02 million rays, 207,920 sharks, 1311 sea turtles, 652 cetaceans and 120 dugongs in Thai small-scale fisheries in 2016 – 2017. Crab gillnets was the biggest contributor to all marine megafauna catch with a high proportion of ray (49%), shark (32%), sea turtle (78%), cetacean (62%) and dugong (94%) catch. The total catches are considered underestimates as they were extrapolated based on fishing effort from 17 provinces representing 70% of the entire small-scale fisheries effort in Thai waters. Furthermore, a number of fishing gears reported by fishermen were excluded from the extrapolation since they did not occur in the official fisheries statistics. The results highlight the need for comprehensive assessment of marine megafauna catch in Thai small-scale fisheries to allow impact assessment of catch on respective marine megafauna species.

The power of passive acoustic monitoring – a powerful tool for detecting trends in harbour porpoise densities

The harbour porpoise (*Phocoena phocoena*) is strictly protected in the European Union and monitoring programmes that enable evaluation of trends in density or abundance are mandatory. Visual ship or aerial surveys are expensive and statistical variation is often high. Porpoise echolocation signals are an alternative measure of animal density which can be monitored by passive acoustic stations such as C-PODs. By assuming that the number of clicks detected is correlated with the density of porpoises, this method can inform on relative changes in porpoise densities. In Denmark, 6 Marine Protected Areas (MPAs) designated for porpoises have been monitored with C-PODs during 2012–2016. This study aimed to evaluate the statistical power to detect trends in such monitoring schemes. In each MPA, five C-POD stations collected data over two periods for 12–16 months each. Porpoise detections were parameterized as the average daily number of minutes with acoustic porpoise detections (Porpoise Positive Minutes) per month. For each station, differences in PPM between periods were compared using mixed-effects ANOVA. Power analysis showed that five stations recording for a full year was sufficient to detect a 5-20% change in animal density from one year to the next with 80% power and an alpha level of 0.2. Increasing the number of stations or monitoring months did not increased the power considerably. In five out of six MPAs, PPM increased significantly (by 19-32%) from the first year of deployment to the next. In the last MPA, no significant change was found and here, the power to detect a trend was much lower which may be due to lower detected levels of PPM in this MPA. Based on the current data, we conclude that passive acoustic monitoring using 5 stations for a full year provide sufficient power to monitor the long-term status of porpoises in MPAs.

Socio-economic models for marine conservation: The illegal wildlife trade in Caspian seal (Pusa caspica) products.

The illegal wildlife trade (IWT) in products from marine ecosystems is a global threat to biodiversity and is steadily escalating. Conservation biologists are now developing methods to investigate the volumes, scale and scope of such trade and how it influences the demography of exploited species. The population of Caspian seals has declined by around 90% in the last 100 years, primarily due to historic over-exploitation. Although organised commercial hunting ceased in the 1990s, the population is not recovering due to high levels of by-catch associated with illegal sturgeon fisheries. Seal fur, and blubber rendered to oil, originating

from by-caught and hunted seals form the basis of a substantial illegal commodity chain in the Caspian region. Here we show that a network modelling approach can be used to assess IWT impacts on the Caspian seal population, parameterised using data on by-catch rates and volumes of seal products traded through the IWT supply chain. Data on Caspian seal IWT were collected over 12 months (2018-19) in Dagestan, Russia, using interviews with fishers selected by probability sampling (n=120), and a full population survey with IWT actors, most notably, middlemen and seal product traders. Reported numbers of seals taken by Fishers in Dagestan, combined with data on traded product volumes, suggest a minimum of 3000-5000 animals entering the commodity chain per fishing season. Analysis of 191 trade partnerships show the trade is structured across a maximum of 7 levels in a network extending across Russia, involving the economic activity of tens of thousands of people. As well evaluating the demographic consequences for the seal population, this study can help understand the socio-economic drivers of the trade, and identify potential points of intervention or possibilities to incentivise alternative livelihoods. We suggest that this approach could be applied to studying small-boat fishery-marine mammal interactions worldwide.

Seeing the northern fur seals from the boulders: Developing an UAS approach for abundance assessments.

In 1963, NOAA Fisheries' Marine Mammal Laboratory (MML) began to use the mark-recapture method of shear-sampling northern fur seal pups to estimate pup abundance. Presently, these surveys are conducted biennually on St. Paul and St. George Island (Pribilof Islands, Alaska), requiring up to 22 people over the course of 2 and 3 weeks. The presence on rookeries poses potential safety risks to the scientists and creates disturbance of fur seals (authorized by a Federal permit NMFS/MMPA 14327 and IACUC ANW2013-3). MML began to use unoccupied aircraft system (UAS; i.e., drones) to augment Steller sea lion surveys in 2014 and have been working towards developing an UAS-based method for northern fur seal abundance surveys. The greatest challenge with our preliminary efforts was identifying fur seals from the background. In the summer of 2018, we collected spectral radiance measurements of northern fur seals and the background (rocks, grass, etc.) with an ASD FieldSpec 3 Spectroradiometer on St. George Island. These ground measurements were used in modeling and simulation to assess whether multi-spectral imaging (0.35 to 2.25 μm or visible to shortwave infrared spectral region) is feasible for better distinguishing fur seals. MML also used a heavy-lift hexacopter (APH-28) to conduct multiple UAS surveys of a small rookery with a FLIR DUO Pro R thermal sensor (with lower resolution visual imaging capabilities) and redundant surveys with an Olympus E-PM2 (25mm lens) mirrorless visual camera. UAS imagery counts (thermal-visual paired and high-resolution visual) will be compared to the traditional shear-sampling method. Preliminary data indicates that northern fur seals could be easily distinguished from the background using multi-spectral imagery. Assessing optimal imaging capabilities will guide sensor selection and then MML can explore which UAS platforms would be most effective for surveys to replace the traditional method.

Variation in ship noise perception by narwhal (Monodon monoceros), bowhead whale (Eubalaena glacialis) and ringed seal (Phoca hispida) along a shipping route in Northern Baffin Island, Canada.

Underwater noise created by ships can mask marine mammal communication and disrupt natural behaviour. Increasing shipping in the Arctic exposes marine mammals to higher levels of anthropogenic sound in a formerly pristine environment. Weighting functions adjust received noise levels across frequencies as they would be perceived by different groups of marine mammals. Weighting functions may indicate which species face higher exposure to ship noise. This study uses ship-based AIS data and applies weighting functions (Southall et al, 2019) for high and low frequency cetaceans (HF, LF), and phocids (PCW) to acoustic recordings along a shipping route near a sheltered Inlet in Northern Baffin

Island, Canada. The goal is to use the weighting functions to assess perceived broadband underwater noise levels from passing ore carriers. An Autonomous Multichannel Acoustic Recorder (AMAR) deployed from 4 August to 28 September, 2018 collected minute-by-minute levels in third octave bands with a continuous duty cycle. Broadband noise levels (10 Hz to 31.5 kHz) were calculated using linear and the three auditory weighting functions. Ship distances and orientation relative to the recorder were calculated to estimate the increase in noise level for each hearing group. All weighting functions showed reduced received levels from linear broadband when a ship was present. The highest LF, PCW and HF broadband levels were 7, 16 and 25 dB respectively lower than the linear levels. Received levels increased above ambient for HF when ships were 2.5-3 km away, and for PCW and LF, at 8-10 km. The highest noise levels occurred when the ore laden ships were facing away from the recorder. Noise levels increased above ambient for 25 minutes for HF and 80 minutes for the PCW and LF per ship transit. This study highlights the importance of accounting for the hearing abilities of different species in noise assessment studies.

An increase of harbour porpoises in Polish waters? A case study using passive acoustic monitoring.

Passive acoustic monitoring (PAM) is a suitable tool to detect the presence of cetaceans in a given study area and to investigate changes in occurrence of the target species over time. Between 2011 and 2013, a large scale PAM study was undertaken to investigate the occurrence of endangered harbor porpoises in the Baltic Sea (SAMBAH project). SAMBAH indicated a clear gradient in occurrence with higher porpoise detections in the Northwestern Baltic compared to the Southeastern part including Polish waters. The SAMBAH data indicated that in Polish waters porpoise abundance might be extremely low. Since the SAMBAH study was conducted over the period of only two years, it was not known how stable the documented distribution pattern are. In this study we investigated whether for Polish marine waters, the results obtained during the SAMBAH project could be validated for subsequent years and thus considered representative. The research was carried out in 2016-2018 in two subareas located in the Western and Eastern part of the Polish EEZ. A total of 10 automated porpoise click detectors (C-PODs, Chelonia Ltd.) were used for the data collection. The results showed that the spatial gradient of occurrence of the species which was found in the previous studies was preserved. However, the number of detections of harbour porpoises was much higher compared to the former investigation indicating a much higher number of animals present. Our study shows that presence of cetaceans can change dramatically between relatively short periods of time. This may be due to shifts in prey distribution. We conclude that PAM on harbor porpoises should be carried out over longer periods to get a better picture on the status of this endangered population in the Baltic.

Harbor porpoise sex life: Are lateralized and aerial mating behaviors characteristic throughout their range?

Harbor porpoises (*Phocoena phocoena*) have a reputation for being inconspicuous, and reports of aerial behavior are rare despite the species' common nearshore occurrence across a wide range in the northern hemisphere. Recent description of their mating habits in San Francisco Bay revealed that males often become fully or partially airborne as a consequence of their rapid sexual approaches to females (69% of mating attempts, $n = 85$) and that aerial behavior occurred only in a mating context. Furthermore, males always attempted to copulate by positioning their ventral side on the females' left side (100% of approaches, $n = 142$), typically perpendicular to her level position at the surface. Because these findings were limited to the non-migratory San Francisco-Russian River stock (a subpopulation of *P. p. vomerina*), our goal now is to determine whether this high-energy lateralized mating results in aerial behavior in other stocks and

subspecies of harbor porpoises. Preliminary results based on photographic records confirmed this same suite of behaviors from 10 other locations in the Pacific and Atlantic Oceans: Monterey Bay, California, USA; Burrows Pass, and Southern Puget Sound, Washington, USA; Prince Rupert, British Columbia, Canada; Cornwall, England; Devon, England; Shetland Islands, Scotland; Eastern Scheldt, Netherlands; Great Belt, Denmark; and The Kattegat, Sweden. We are seeking additional collaborative input on harbor porpoise behavior across the species' entire range. Researchers should be aware that aerial behavior may be a sign of mating activity, rather than foraging. Resource managers should factor observations of such behaviors into conservation and development decisions affecting potential breeding hotspots.

Drone videos: A new method for photogrammetry of fin whales (Balaenoptera physalus)?

Photogrammetry is a method that has been used to measure different characteristics of cetaceans. However, it is mostly based on the use of laser-metrics from vessels, or aerial photographs from aircrafts. We propose a non-invasive and coast-effective option, which can be used at sea, simultaneously with photo-identification techniques for fin whales (*Balaenoptera physalus*). We explored the usage of unmanned aerial vehicle (UAV, drone) images and videos to develop a new measurement method of individual fin whales off the Catalan coast. The drone-made videos enabled us to acquire a large amount of high-resolution vertical images of the head and the full body of the same individual and implement relative measurements. Due to the subsequent images, we were also able to account for measurement errors and the variability of these characteristics. In the present study, we obtained 427 videos over a 4 years period from 2015 to 2018. Due to the unique pattern of the chevron of fin whales, we were able to identify 84 animals, from which we selected a subset of 30 individuals for measurements, which had the best footage of the desired body axis. The relative measurements of the head and body were used to estimate full body length and the leanness with the size of the girth. We compared the relative values with the size of the boat, but also with other individuals, the data of the same individual within the year and between years, to see if there is growth and to examine the longevity of the characteristics. Such data are important, since it can provide information on the species. The acquired ratios can further be used to estimate body condition and nutritional status, and as such the health of the individual, which is crucial for our knowledge of the survival of the animal and the population.

Environmental DNA for assessing habitat use and genetic diversity of bowhead whales

One of the major obstacles in assessing the effects of climate change on Arctic ecosystem is the logistical and methodological challenges associated with data collection in remote, harsh environments. Thus information on the status and pressures affecting e.g. Arctic marine mammals is often restricted to certain species and/or geographical regions. Here we tested the applicability of environmental DNA (eDNA) as a simple, non-invasive and cost-effective tool for assessing the distribution, abundance and diversity of the spring aggregation of bowhead whales (*Balaena mysticetus*) in Disko Bay, Western Greenland. First, we extracted DNA from 150 water samples collected during May 2017 and 2018 from the "footprints" of diving whales or along random transects. Next, using novel bowhead whale qPCR probes we obtained an eDNA-based relative estimate of bowhead whale distribution, nicely correlating with the visually observed occurrence of whales. Moreover, we show that the genetic profiles obtained from footprints of individual whales match the profiles obtained from skin biopsies. Thus, by sequencing all water samples with presence of bowhead DNA we were able to reconstruct the mtDNA haplotype distribution and frequencies estimated through more than a decade of biopsy sampling and genetic profiling of bowhead whales in Western Greenland. As such, our study demonstrates the large potential for routine eDNA monitoring and population genetic inference of not just bowhead whales, but also other marine mammals.

Sequencing the mitochondrial genome of bowhead whales (Balaena mysticetus) from environmental DNA

Monitoring cetaceans with the use of environmental DNA (eDNA) is a novel approach in marine mammal research. Collecting water samples from the close vicinity of individuals is simple, inexpensive and nevertheless non-invasive, thus eDNA has a potential in complementing traditional survey methods.

In this study we tested if eDNA has the capacity to capture enough genetic material of cetaceans for sequencing full mitochondrial genomes.

Applying eDNA to answer questions related to population genomics of cetaceans is challenging. The quality of eDNA in seawater reduces with time and the majority of the extracted DNA from water belong to organisms that are the most abundant in seawater (eg. Bacteria). However, cetaceans often leave genetic material behind (eg. sloughed skin) while swimming through the water column. Water samples can be collected at the location of the final dive (footprint). Footprints can be easily detected visually and are likely to contain cellular material from the diving whale.

Surface water samples from footprints of individual bowhead whales were collected in Disko Bay, Western Greenland. The filtered eDNA samples were quantified with bowhead whale-specific qPCR probes. The eDNA samples that yielded high copy number of bowhead whale DNA were used to generate whole-genome shotgun sequences with Illumina HiSeq platform. Sequences were mapped to a reference bowhead whale mitogenome.

The results indicate that sequencing mitogenomes from eDNA samples can be a novel tool for population genomics and could provide a platform to monitor cetacean populations without the necessity of invasive techniques. Implementing eDNA to population genomics is not only beneficial for endangered species, where disturbance should be kept to a minimum, but also for rare and elusive species that are difficult to sample and monitor with conventional survey methods.

Use of social network analysis to understand disease transmission and its impacts on a Northeast Florida estuarine dolphin population

Szott, Emily[1]; Brightwell, Kristy[2]; Gibson, Quincy[3]

Corresponding Author: easzott@gmail.com

The St. Johns River (SJR) in Northeast Florida is an estuarine system inhabited by bottlenose dolphins (*Tursiops truncatus*). These dolphins live in complex, fission-fusion societies, associating with other individuals in groups often changing in size and composition. Between 2013 and 2015, SJR dolphins were impacted by an unusual mortality event (UME), caused by cetacean morbillivirus (CeMV), that was originally thought to be limited to coastal dolphin populations. This study analyzes how transmission of this disease may have been influenced by social interactions among dolphins within the SJR. Weekly photo-identification surveys were conducted between Nov. 2011-Oct. 2016 (n=189). Groups were defined using the 10m chain rule. Sighting histories were divided into three time periods: Pre-UME (Nov. 2011-Jun. 2013), During-UME (Jul. 2013-Feb. 2015), Post-UME (Mar. 2015-Oct. 2016). For each time period, half-weight indices of association (HWI) and several network measurements were calculated using SOCPROG v. 2.8. Mean HWI was significantly lower During-UME than the other two time periods (Pre-UME=0.048; During-UME=0.035; Post-UME=0.048; $p<0.017$). Weaker associations and decreased connectivity may have been a way for dolphins to avoid further spread of the contagion. However, maximum HWIs were sustained between Pre-UME (mean=0.515) and During-UME periods (mean=0.476; $p=0.158$), suggesting dolphins maintained preferential associations. Additionally, while reduced network measures and number of individuals present during the UME (Pre-UME: n=106, strength=5.01, reach=27.27, affinity=5.36; During-UME: n=90, strength=3.16, reach=11.68, affinity=3.49) may have been due to increased mortality, the Post-UME increase (n=130, strength=6.22, reach=42.28, affinity=6.71) suggests that dolphins may have moved out of the area during negative conditions. Centrality measures identified individuals with high likelihood of spreading CeMV throughout the network. Future research will use spatial analyses to determine the home ranges of dolphins during each time period, and analyze potential overlap of

CeMV+ stranded individuals to determine a possible path for disease transmission.

Bycatch reduction in Portuguese set nets

In mainland Portugal, interactions between fisheries and cetaceans occur in almost all fishing gears. Data gathered between 2010-2015 showed that set nets (used in the Portuguese polyvalent fleet) led to harbour porpoise, common dolphin and bottlenose dolphin mortality values well above their national populations' maximum annual acceptable mortality limit. To address this severe bycatch problem, a mitigation essay using pingers was carried out in Portuguese set nets. The essay covered 352 fishing trips corresponding to 733 control fishing events (nets without pingers) and 627 experimental fishing events (nets with pingers). During the essay, five cetacean species (Common dolphin, Bottlenose dolphin, Harbour porpoise, Pilot whale and Balaenoptera sp) interacted with fishing gear. Considering the number of cetaceans involved in interactions, interaction rates were 2,4256 in control nets and 1,0144 in nets with pingers. The difference indicates a 58,18% lower interaction rate in experimental nets in comparison to nets without pingers. With respect to the number of cetaceans involved in interactions that resulted in mortality, the bycatch mortality rate was 0,0491 in control nets and 0,0207 in experimental nets. The difference indicates a 57,84% lower mortality rate in nets with pingers in comparison to nets without pingers. In particular, nets equipped with pingers revealed a 51,62% reduction of the common dolphin mortality rate, and an 83,29% reduction of the harbour porpoise mortality rate, in comparison to nets without pingers. A large-scale implementation of pingers in set nets would be challenging, considering the large size of the Portuguese fleet and the costs associated with pingers and their long-term maintenance. Therefore, in Portugal the use of pingers should be combined with good practice manuals, robust and cost-effective bycatch monitoring tools and awareness campaigns, especially in Marine Protected Areas targeting cetacean conservation.

Evaluation on activities of radiocesium released by the Fukushima Dai-ichi Nuclear Power Plant(FNPP1) accident damaged by The Great East Japan Earthquake. – preliminary study using stranded odontoceti-

Radiocesium (^{134}Cs and ^{137}Cs) activity concentrations were measured to assess the radiocesium contamination in muscle tissues of stranded toothed whales (13 finless porpoises, one melon-headed whale, one sperm whale and one short-finned pilot whale) after the Fukushima Dai-ichi Nuclear Power Plant (FDNPP) accident caused by the Great East Japan Earthquake on 11 March 2011. Except for one new-born sperm whale (< detection limit: 0.16 Bq/kg-wet for ^{137}Cs), ^{137}Cs (half-life: 30.1 y) were detected from all 13 finless porpoises collected 31–2185 days after the FDNPP accident at 111–221 km far from the FDNPP. Of these, ^{134}Cs (half-life: 2.06 y) were detected from 8 individuals. One finless porpoise collected in December 2011 from Sammu City (210 km south from the FDNPP) showed a high radiocesium concentration of 1620 Bq/kg-wet, whereas other individuals presented lower values (1.03–72.1 Bq/kg-wet) less than the Japanese regulatory limit

for foodstuff (100 Bq/kg). In contrast, radiocesium was not detected from a finless porpoise and a melon-headed whale collected before the FDNPP accident. Electron-prove X-ray microanalysis was undertaken on the testes of 2 finless porpoises and 3 melon-headed whales. ^{137}Cs was not detected in all of the testes. Parasitic granulomatous pneumonia and parasitic hepatitis in some of examined finless porpoises, and suppurative pneumonia in some melon-headed whale were found respectively, although these findings was not related with Radiocesium (^{134}Cs and ^{137}Cs) activity concentrations directly. Our result demonstrated that radiocesium released from the FDNPP was accumulated in toothed whales, although almost all the values were under the Japanese food safety level.

A comparison of the diet composition derived from skin stable isotopes and stomach contents for two baleen whale species: Sei and Bryde's whales in the western North Pacific.

The common method for investigating diet of cetaceans is the identification of undigested prey items from the stomach contents. This method is believed to provide reliable information on the most recent prey prior to sampling. Recently stable isotope analyses have been developed and used to investigate diet composition in cetacean species. Using a Bayesian framework (SIAR), a stable carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$) isotope mixing model was used to assign diet composition to western North Pacific sei (*Balaenoptera borealis*) (n=180) and Bryde's (*B. edeni*) (n=50) whales (skin samples), and prey items: copepods (*Neocalanus spp.*), krills (*Euphausia spp.*), Japanese anchovy (*Engraulis japonicus*), Japanese sardine (*Sardinops melanostictus*), Pacific saury (*Cololabis saira*), mackerels (*Scomber spp.*) and North Pacific light fish (*Maurolicus japonicus*) in the western North Pacific during the summer of 2015 and 2016. Diet composition derived from the stable isotope and traditional stomach content analyses were compared. Both analyses suggested a larger diversity of preys in sei whale (six species) compared to Bryde's whale (three species; one accounting for over 95% of all contents). However, in the case of sei whale the diet composition differed between methods. The contribution of pelagic fish species was much higher in the stomach contents (about 85%) than in the stable isotope analysis (less than 20%). This result could be explained by: i) isotope analyses of skin provide information on the average composition of the diet weeks and even months prior to sampling, whereas the stomach content analyses give a snapshot of the whale's last meal (the simplicity in diet could explain the similarity of results in the case of the Bryde's whale); ii) possible seasonal/areal variation in the isotopic values of prey species, which was not examined in the present study.

Prey species of Indo-Pacific bottlenose dolphins (Tursiops aduncus) in a small oceanic island revealed by the analysis of foraging behaviors and stomach contents.

It is necessary to study the feeding ecology of animals for a better understanding of their life history and for their conservation. Previous studies have suggested that Indo-Pacific bottlenose dolphins (***Tursiops aduncus***) feed on a variety of species of fish and cephalopods, and that the prey species differ among populations. Therefore, it is important to list the prey species from each *T. aduncus* population. In Mikura Island, Japan, stranded and entangled dolphins, which usually provide the list of prey items, are rare because Mikura is a small oceanic island without beaches and intensive fisheries. Interviews with dolphin-swimming captains and guides, questionnaire surveys submitted via websites and SNS, and analysis of underwater footage for ID research of the 2015-2017 seasons were conducted to reveal the prey species of *T. aduncus* around Mikura Island. This evidence was then compared with the stomach contents of 10 individuals that were entangled mainly by gill nets around Mikura Island between 1996-2017. Dolphins around Mikura Island feed on a variety of prey species including 13 species of fish, 7 species of cephalopods and 1 species of crustaceans as prey species, and 9 species of fish and 1 species of crustacean as possible prey species. Octopus (***Octopodasp.***), flying fish (***Exocoetidae*sp.**) and

lizardfish (***Prionurus scalprum***) were the three dominant prey species which were observed during daytime underwater observations. Yellow striped butterfish (***Labracoglossa argenteiventris***) were found from the stomach contents of 40% of the entangled dolphins in the gill nets despite rarely being identified as prey species during daytime underwater observations, suggesting that entangled dolphins had taken the fish out of the gill nets before entanglement. Most dolphins observed feeding during the day were female (93% of 43 individuals). It was thought that nutrition demands might be different between male and females.

Behavioral responses of common bottlenose dolphins (Tursiops truncatus) to changes in salinity within the Barataria Basin in Louisiana

More than 3,000 common bottlenose dolphins (*Tursiops truncatus*) are estimated to inhabit Barataria Basin (BB), Louisiana, USA, a highly productive estuary characterized by variable salinity driven by natural and man-made processes. It is unclear whether BB dolphins move in response to fluctuating salinity, which can at times decline to 0 parts per thousand (ppt) in portions of the basin. We temporarily caught and attached satellite-linked tags to 17 BB dolphins (10 females; 7 males) to evaluate fine-scale movements relative to modeled salinity trends. Wildlife Computer (N = 11) and Sirtrack (N = 6) satellite tags transmitted for a mean 144 $\pm$ 36 S.D. days and 101 $\pm$ 67 S.D. days, respectively, and provided on average 2.4 $\pm$ 1.0 S.D. and 0.2 $\pm$ 0.2 S.D. quality locations (3, 2, or 1) per day. We compared the dolphin locations to mean daily salinity estimates provided by the Water Institute of the Gulf from a Delft3D model. Despite extremely low-salinity conditions, most dolphins maintained a limited range (averaging 3.4 km net movement per day within 10–20 km of their capture locations). One dolphin spent 49 consecutive days in waters estimated to be under 7.5 ppt salinity. Two dolphins had unusually broad movement patterns (averaging 7.6 km net movement per day), with one traversing the east-west and north-south extremes of BB. However, despite the broad ranges, their movements were not associated with salinity gradient. Across our analyses, we found no evidence that any of the dolphins moved in response to salinity changes. Due to loss of wetlands in BB, sediment diversions from the Mississippi River are being planned and could bring extreme decreases in salinity across the BB. This study provides information on potential behavioral responses of dolphins and can inform study designs to monitor associated health impacts from the planned diversions.

Geographical and genetic origin of marine mammals strandings in the Yucatan Peninsula through the use of two biophysical modeling approach.

Strandings are excellent sources of information since they allow scientific access to organisms that are very difficult to see in the wild. Several studies in the fields of pathology and population genetics, among others, have arisen from information gathered at these phenomena. However, population interpretations based on strandings lack certainty regarding the origin of the organisms, since, in some cases, organisms have been dragged hundreds of kilometers by currents, giving erroneous information about local populations. The present study aims to contribute to the knowledge of the population structure of marine mammals in Campeche, Yucatan, Quintana Roo and Belize. We determined the origin of strandings in the localities mentioned above using both, molecular markers and Lagrangian drift model. The genetic characterization of the recorded species was performed, comparing these with the information provided by databases to determine the

mitochondrial lineages present. To find the spatial origin of the stranding we used two ocean models: the Regional Ocean Modelling System (ROMS) and the Global Hybrid Coordinate Ocean Model (HYCOM). These models use several parameters like oceanic currents, date and geographic position of the stranding. To find the effect of the wind on the carcasses, we implemented a photogrammetry analysis. These models started from the point where the stranding occurred all the way to the probable geographic origin of death. To our knowledge, this type of research has not been done previously, we determined the trajectory of the carcasses, which in some cases exceeded 40 km, identifying recurring regions from which the strandings originate, even independently of the year or the climatic regime. These areas are generally coastal and close to urban centers, therefore related to high maritime traffic or intense fishing gear use. This suggests that strandings may be related to anthropic factors.

Long-term cetacean population presence and abundance in relation to moon cycles off Pico Island (Azores)

Taylor, Emily[1]; Martin, Saskia Cathrin[2]; Hartman, Karin[3]; Rotondi, Claudio[1]; Mészáros, Nóra[1]

Off Pico island (Azores), a long-term study has been focusing on monitoring cetacean species presence in the Bay of Ribeiras (230 km²). Data were collected through standardized land surveys from a fixed look-out post (using Steiner 20x80 binoculars) at 45m altitude. Surveys (average 20 mins. per survey) were conducted on a daily basis covering all tidal cycles with 2-hour intervals to avoid double counting. Next to standard environmental information, data was collected after Mann's (1999) point sampling method and the period analyzed included the years 2011 to 2018. During 964 days, covering 926 hours, 2613 dedicated surveys were conducted. A total of 19 species (3905 single sightings) were observed and clustered in 8 subcategories for further analysis: Balaenopteridae (n=5), Hyperoodon (n=1), Ziphiidae (n=3), Physeter (n=1), Globicephala (n=2), Grampus (n=1), Tursiops (n=1), Small Oceanic Delphinids (n=3). The effect of lunar cycles on cetacean species' presence and numbers were investigated running a Poisson regression model. To correct for the observation time, the number of sightings per moon phase were divided by the total hours observed. Grampus were present in almost 30% of all surveys, followed by Delphinids (27%) and Physeter (11%). A significant positive association between the lunar cycle and most cetacean species presence was detected during new moon, and after full moon (waxing crescent). Around full moon, cetacean species were less sighted and recorded in lower numbers. The relationship between lunar cycles and daytime cetacean presence may be linked to higher prey availability during different moon phases. Full moonlight is known to reduce organisms' vertical migration, with effects that trickle through the food web. This pattern concerns especially known night-foraging species such as Grampus and Globicephala, while most generalized (Tursiops) or deep-sea (Ziphiidae, Physeter) predators showed non-significant variation, suggesting that other environmental variables determine their presence.

Skin lesion prevalence of estuarine bottlenose dolphins (Tursiops truncatus) in the outer banks of North Carolina, with comparisons to other East coast study sites.

Bottlenose dolphins are sentinels of environmental health. Skin lesions may indicate disease or contaminant exposure, and can be used to infer population health. We estimated skin lesion prevalence and identified major lesion types on estuarine bottlenose dolphins, *Tursiops truncatus*, in Roanoke Sound, North Carolina over a three-year period using photo-identification. Boat-based transect surveys were conducted from April 2012 through October 2014. Data were processed using FinBase. High quality images of distinctive fins were examined for the presence of any skin lesion (n=169; P= 0.51; 95% CI = 0.43-0.58). Prevalence estimates of nine lesion types were calculated. Roanoke Sound estimates were compared between years and seasons, as well as to dolphins photographed at three southern study sites. Overall Roanoke Sound lesion prevalence varied little between years and did not differ significantly from southern site estimates ($p>0.05$). In Roanoke Sound, most lesions were observed in the spring (P=0.79; 95% CI: 0.63-0.95). Pale lesions were most common (P=0.38; 95% CI: 0.28-0.49), occurring at a higher prevalence than southern sites ($p<0.05$). Skin lesions occurring on Roanoke

Sound dolphins are similar in type to those observed in southern sites, yet vary in prevalence. Future studies should correlate lesions with environmental variables and use stranded dolphins to predict lesion etiology.

The increasing role of citizen science in UK marine mammal policy and management.

Taylor, Nikki
, United Kingdom
Corresponding Author: nikki.taylor@jncc.gov.uk

'Citizen science' historically had a reputation to many as amateur science which lacked quality control and yielded poor quality data with limited application to wider uses. With a myriad of organisations using a variety of data-collection protocols and volunteers with a broad scale of training, the data were generally only used by the organisations collecting them to promote their own messages. Since citizen science has gained impetus in recent years, these disparities are being addressed within e.g. the marine mammal community, making significant progress in improving the data-collection process. Volumes of marine mammal data are collected by UK citizen scientists, which is increasingly being used by the scientific community and contributing to policy decisions.

Marine data can be costly to collect; therefore, evidence collected through the national budget is often reactive to a specific need, or spatially/temporally limited. The resource that is available through citizen science data collection in the UK alone is vast. The value of such data is exemplified by the UK's Joint Cetacean Protocol which collated datasets amounting to over a million km of survey effort, much of which was citizen science data. This was analysed to investigate spatial and temporal trends in the abundance and distribution of cetaceans and more recently used to support the designation of MPAs for harbour porpoise. Predicted cetacean density from this resource are used routinely by industry for impact assessments, and statutory bodies in their advice for Regulators. These data also contribute to national reporting such as the EU Habitat's Directive assessment of conservation status.

The value of these citizen science initiatives has been demonstrated in the UK and there's a further need to build on this and ensure protocols, training, data storage and access are synthesised to make the most of this resource in contributing to the conservation and management of marine mammals.

Persistent organic pollutants in two declining Australian pinniped populations.

Persistent organic pollutants (POPs) are contaminants that cause immunosuppression, immunomodulation, endocrine dysfunction and neoplasia. Little is known of marine mammal exposure to POPs in the Southern Hemisphere. For the endangered Australian sea lion (*Neophoca cinerea*), the investigation of anthropogenic pollution is identified as a key *knowledge gap* and area of research *critical* to the species' recovery plan.

The aim of this study was to determine the concentrations of polychlorinated biphenyls (PCBs), dioxin/furans, polybrominated diphenyl ethers (PBDEs) and, per- and poly-fluoroalkyl substances (PFAS) in sample matrices from two pinniped populations with declining pup production. *N. cinerea* pups were sampled at Seal Bay, Kangaroo Island; Australian fur seal (*Arctocephalus pusillus doriferus)* pups were sampled at Seal Rocks, Victoria. In addition, POPs concentrations were determined in *A.p. doriferus* stranded along the Victorian coast.

High resolution gas chromatograph-mass spectrometry (HRMS) and liquid chromatograph-mass spectrometry (LCMS) detected POPs in all tissue matrices analysed; highest concentrations were detected in blubber. In *N. cinerea* pups, liver PFAS (ΣPFAS = 14488 ± 6657pg/g ww) and blubber dioxin-like PCB (Σdl-PCB = 3585 ± 2883pg/g ww) concentrations were lower than reported concentrations for pinnipeds in the Northern Hemisphere. In *A. p. doriferus* pups, the concentration of dl-PCBs in fur were Σdl-PCB = 646 ± 423pg/g ww, while significantly higher concentrations were detected in the blubber of stranded individuals (Σdl-PCB = 5,615,786 ± 2,606,393pg/g ww).

This study has key conservation and management outcomes for two declining populations highlighting maternal transfer of POPs and the utility of fur as a novel, minimally invasive sample for POPs analysis. While the role of anthropogenic toxicants in reduced pup production is unclear, associations with stranding and detection of these compounds in endangered and declining

populations demonstrates the ubiquitous nature of these toxicants in the marine ecosystem.

High harbour porpoise echolocation activity close to oil and gas platforms indicates a strong artificial reef attraction

The harbour porpoise, is the most common marine mammal in the central North Sea where offshore oil and gas installations are concentrated. Porpoises have been reported to show avoidance or altered behaviour in response to noise emitted during offshore activities such as shipping, seismic, drilling, wind farms and pile driving. Less well understood are responses of porpoises to sounds emitted from oil and gas platforms during routine operations, which may represent a permanent disturbance leading to possible habitat exclusion. However, offshore constructions may also act as artificial reefs with increased biodiversity and prey abundance leading to habitat attraction. To investigate the presence and feeding behaviour of harbour porpoises around a large production platform, we deployed autonomous acoustic loggers, recording continuously for two years, at 18 stations between 0 and 26 km from the platform. Click detectors recorded porpoise echolocation activity at all stations while broadband loggers recorded underwater noise at five stations. Harbour porpoises were detected at all distances, year-round in both years, however, two distinct seasonal activity patterns were found. During July-January, porpoises were attracted to the platform with high echolocation and feeding activity within 800 m of the platform, lower activity at 3-10 km, and again increased activity at 13 km and beyond. During February-June, porpoises were deterred from the immediate vicinity of the platform, while stations from 200 m to 26 km recorded uniformly, and lower, porpoise activity compared to July-January. Noise levels were elevated by up to 25 dB (at 5 kHz) closest to the platform and decreased to background levels at 13 km. These results indicate that offshore oil and gas platforms can act as artificial reefs attracting harbour porpoises in search of prey despite increased noise level. Offshore industrial structures may be important for ecosystems in an overexploited environment by acting as artificial reefs.

Trophic niche comparison among sympatric coastal dolphins off Southwest Atlantic Ocean

Sympatric species are expected to minimize potential competition by specializing on distinct resources or exhibiting differences in when or where resources are exploited. Therefore, a comparison of ecological niches can be important to evaluate underlying mechanisms of coexistence and eventually predict community responses to ecosystem changes. Here, we assess the trophic relationships among three sympatric dolphin species from Santa Catarina State - southern Brazil: the franciscana dolphin (*Pontoporia blainvillei*), the Guiana dolphin (*Sotalia guianensis*), and the coastal ecotype of bottlenose dolphin (*Tursiops truncatus gephyreus*). We evaluate the temporal variation of $\delta^{13}C$ and $\delta^{15}N$ stable isotopes in bone collagen to test dietary shifts and estimate the degree of niche overlap among these species using ellipses area (SEAc) through SIBER (Stable Isotope Bayesian Ellipses in R). In addition, we evaluate the contribution of potential prey to their diet using Bayesian mixing models. The $\delta^{15}N$ values were consistent across years, while $\delta^{13}C$ values decreased for bottlenose dolphin, suggesting variation in feeding areas through time. The franciscana dolphin showed the narrowest niche width and occupied the highest trophic level, whereas the bottlenose dolphin occupied the lowest trophic level with the broadest niche width. The trophic niche of Guiana dolphin was fully contained within the trophic niche of bottlenose dolphin, reflecting the high contribution of demersal prey species in both species' diets. In contrast, the franciscana diet is mainly composed by pelagic prey species, resulting in a lower niche

overlap with Guiana and bottlenose dolphins. To the best of our knowledge, this is the first study to evaluate resource use and niche overlap within the unique area were these three dolphin species coexist. Further compound-specific stable isotope analysis of amino acids is being processed and will generate additional data about resource use and habitat preferences of these coastal species in the study area.

Osteological descriptions of Steno bredanensis in the Canary Islands

In the Canary archipelago, 30 species of cetaceans have been recorded in its waters, 27 of which have one or some stranding records since the 1980s to date. One of these, the "rough-toothed dolphin" *Steno bredanensis*, is globally poorly known and there are few data on the osteology of this species from a few regions. Here we present the first osteological study of *Steno bredanensis* from the Canary Islands to increase the knowledge about the taxonomy and adaptations of the species. We carried out osteological analyses of different bones of 27 specimens stranded in the Canary Islands, including 17 complete skeletons. The results were compared within each other and by sex, as well as with other cetacean species, mainly Delphinidae species present in the archipelago. The skeletal ontogeny was analyzed in specimens with a total length between 82cm and 236cm., contrasting the fusion degree of the various cranial sutures and the synostosis of the vertebral complex, the sternum, the hyoid and the proximal pectoral region. An adult female was studied separately as it presented a different axial skeleton to the rest of the analyzed specimens as well as to the published data from other regions, highlighting a significantly higher number of vertebrae, and a sternum resembling other delphinids. The results of the studied specimens suggest the presence in the Canary Islands of two forms, one smaller, as well as sexual dimorphism identified in some metric variables of the skull. All studied animals presented dental furrows characteristic of the species, regardless the stage of development. This study contributes to implement the current knowledge of *Steno bredanensis*.

Impacts on odontocete occurrence from offshore construction using a novel anchoring system

Temple, Andrew[1]; Potlock, Kelsey[2]; Berggren, Per[3]

Continued global development of the offshore wind energy sector for the provision of clean, renewable energy is a pillar of the fight against human-induced climate change. Yet, the potential for unintended long and short-term environmental consequences of their construction is well established, albeit spatially inconsistent and species specific. Pile-driving is perhaps the most commonly cited element of the construction process with regard to negative environmental impacts, with a need for alternative anchoring methods often proposed. A novel gravity-base foundation, used by EDF Energy at its newly installed five turbine facility in a testing site off of Northumberland in the United Kingdom, is one such alternative.

The study presented here represents a unique opportunity to monitor and assess the occurrence of odontocetes pre, during and post construction in this testing site. Thus, allowing for initial inferences on the potential impacts of this novel anchoring alternative on locally occurring odontocetes. The area is frequented year round by three commonly occurring species with sensitivity to environmental disturbance (*Phocoena phocoena*, *Lagenorhynchus albirostris*, and *Tursiops truncatus*). Data were collected using passive acoustic monitoring (C-PODs) from June 2015 until October 2018, across nine sampling locations at varying distances from the installation site. Data analyses were carried out using generalised additive mixed models. The results reveal previously unknown spatio-temporal patterns in the occurrence of porpoise and delphinids, and indicate likely area exclusion of porpoises resulting from inter-specific competition. Further, the analyses indicate substantial effects of a range of environmental and anthropogenic variables on the occurrence of these species. With these effects accounted for specific note is made of the apparent short and long-term impacts of gravity-based foundation wind farm construction and the spatial nature and degree of apparent impacts are

discussed in the context of future technological development in this sector.

The next decade is expected to see significant expansion of anthropogenic activities in the North Sea. The need to understand and quantify the impact of these on marine mammal populations is critical in order to design and assess effective mitigation and population management. Harbour porpoises are the most abundant cetacean species in this area. Highly mobile and elusive, they are notoriously difficult to monitor, but the coastline provides a powerful vantage from which to conduct surveillance, particularly on biological and health parameters. Information on stranded individuals are recorded on a national level, yet for this study, data from all the five national stranding networks bordering the North Sea were combined.

This work demonstrates the first assessment of the North Sea population as one ecological unit. Data from 1990-2017 were used to investigate spatiotemporal trends and assess biological characteristics of the stranded population. A total of 16,247 individual strandings were recorded. Stranding numbers increased annually in all regions, with a sharp increase in the southern North Sea after 2004. A Generalised Additive Mixed Model framework revealed a region-specific seasonal pattern, enabling detection of periods of unusual mortality. There was heterogeneity in age-specific sex ratio, with particularly high presence of juvenile males in the southern North Sea, possibly suggesting a population sink. The majority of neonate strandings occurred along the northern Dutch, German, and Danish coastlines, potentially suggestive of areas of importance for calving. The study provided unique high-resolution insight into region-specific population parameters of North Sea harbour porpoises. This new knowledge comes as a valuable addition to live animal survey data. Combined, these data sources can inform planning consent decisions and mitigation of impacts of offshore anthropogenic activities. This work demonstrates the value of a transboundary approach to data analysis for deriving effective conservation and management strategies of highly mobile marine species.

Ontogeny of muscle physiology in arctic seals

Marine mammals must store and efficiently use oxygen while diving. Although oxygen is distributed across lung, blood, and muscle reservoirs, skeletal muscles play a substantial role in defining diving capacities. In general, locomotor muscles of marine mammals have large oxygen reserves to fuel aerobic metabolism at depth, but must also be capable of managing the buildup of anaerobic byproducts. Further, pups are not born with the same physiological capacities as adults, with aerobic and anaerobic abilities typically developing at the onset of independent foraging. Knowledge of species- and age-specific skeletal muscle physiology can inform understanding of diving constraints and behavioral flexibility. We examined myoglobin content ([Mb]) and non-bicarbonate buffering capacity (β) of a major locomotor muscle, the longissimus dorsi, in three Arctic seal species. Samples were obtained from ringed (*Pusa hispida*; n=11), bearded (*Erignathus barbatus*; n=37), and spotted (*Phoca largha*; n=12) seals in collaboration with native Alaskan subsistence hunters. We found adult ringed seal

muscle [Mb] to be 6.4±0.5 g Mb 100 g wet tissue^{-1}, while adult spotted seal muscle [Mb] was 5.5±0.5 g Mb 100 g wet tissue^{-1}. These data agree with previously reported values for other phocid species. In contrast, adult bearded seals had much lower muscle [Mb] (4.6±0.4 g Mb 100 g wet tissue^{-1}), making their muscle physiology more similar to benthically foraging walruses than to other phocids. Overall, we documented increasing ontogenetic trends in [Mb] and β for all three species; however, bearded seals exhibited more subtle developmental patterns. Our data suggest a strong link between muscle physiology, life-history strategies, and foraging behavior, and provide insight into the ontogeny of diving capacities and limitations in data-deficient species.

Kinematic detection of prey capture reveals sex reversals in foraging behavior between two populations of fish-eating killer whales

Obtaining sufficient prey to meet energetic requirements is critical for survival and reproduction. For cetaceans that feed cooperatively or share prey, sex can be an important factor determining foraging behavior. Interference from human activities, however, can potentially alter social structure and foraging behavior, and consequently foraging outcomes, which may impact population status. Identifying foraging outcomes has been limited by the challenges of detecting successful subsurface prey capture events. We sought to quantify population differences in foraging outcomes between two partially-sympatric populations of fish-eating killer whales residing in the coastal waters of the northeastern Pacific ocean, which have exhibited opposite trends in growth and recruitment over the past two decades. Specifically, we tested the hypotheses that (1) foraging outcomes are related to population status, and (2) sex patterns in foraging behavior differ based on population status. Using sound and movement data from suction cup-attached Dtags concurrently deployed on 52 individuals from both populations, we detected acoustic and kinematic signatures of searching and prey capture, respectively, to quantify foraging events, and computed foraging metrics including foraging rate, prey capture failure rate and searching effort. We constructed mixed effects models to determine the importance of population, sex, deployment duration, deployment ID, and year on our foraging metrics, and iteratively dropped non-significant terms to arrive at the best models. We found that foraging and failure rates as well as searching effort were affected by an interaction between population and sex: whereas females from the endangered Southern Resident killer whale population exhibited less foraging activity than their male counterparts, the converse was true for Northern Resident killer whales. We discuss these results in the context of differing levels of human disturbance, unbalanced demographic structure and different population growth trajectories between populations, and the implications of sex-based foraging differences on population recovery.

Social structure of indo-pacific humpback dolphin (Sousa chinensis) in the matang important marine mammal area in Perak, Malaysia

Social structure is the product of adaptive behaviour strategies in response to different ecological pressures to maximize individual fitness. As highly complex social animals, cetaceans exhibit various behaviours and have great diversity in their social structure throughout their global range. In this study, the social structure of the Indo-Pacific humpback dolphin (*Sousa chinensis*) in the Matang Important Marine Mammal Area (IMMA)

was investigated between 2013 and 2016. The association patterns were assessed using photo-identification techniques and measured by Half Weight Index (HWI) in SOCPROG program. A total of 105 group sightings across 14 boat-based survey over 125 days were included in the association analysis. Out of the 377 marked dolphin individuals, 41 were identified in at least 5 sampling periods. These individuals yielded a mean HWI of 0.15 ± 0.06 and social differentiation of 0.51, indicating well differentiated societies with weak associations between pairs. The distribution of maximum HWI association levels observed for each individual suggested that most individuals (80.5%, n=41) were not associated with any particular companion any more than expected if all individuals associated at random. However, the average-linkage cluster analysis showed that 15 individuals form relatively stronger association with each other (HWI ≥ 0.5). The stronger association observed among the 15 individuals suggested the influence of ranging patterns of the dolphins, whereby they were mostly found occurring within the estuary that restrict them to a smaller ranging area. This resulted in similar ranging patterns and increased their likelihood of association, as contrary to the dolphins that were sighted further from the coast and have a wider ranging area. Such research is important as it provides insights on the factors shaping the sociality in this species and can contribute towards the protection of the species through informed decision-making for the conservation of its habitats in the Matang IMMA.

Fin whale trends in the Mediterranean sea from the FLT MED MonNet long-term monitoring program

The "Vulnerable" Mediterranean fin whale has been identified as a key species for the definition of Good Environmental Status for the Mediterranean Region within the MSFD (Directive 2008/56/EC). The assessment of species distribution, population trends and relative abundance are then a priority for member states. National monitoring programs have been carried out with little international agreement on methods and temporal-spatial coverage. We use data collected within a long term monitoring program from 2007 to 2017 to identify trends within 2 consecutive periods 2007-2012 and 2013-2017 as well as changes in species distribution within the Mediterranean region and 4 sub regions. Further analysis at smaller spatial scales (i.e. national EEZs) have been conducted to inspect intra-regional differences. Data have been collected by 8 research groups, embarking dedicated observers from June to September on board of ferries crossing the Mediterranean Basins. 10 Fixed transects lying in territorial waters of Italy, France, Spain, Tunisia and Greece have been surveyed on a bi-weekly or weekly basis, for a total of 1221 surveys accounting for 1709 fin whale sightings. Ferries used varied in size, with heights of observation platforms ranging from 15 to 29m. Distance Sampling analysis has been used to assess Effective Width Strip for different vessels. Relative Abundance Index for each survey has then been computed at 3 spatial scales (regional-SubRegional-EEZs) on a yearly basis and then analyzed according to the above mentioned periods. Dataset collected represent a unique opportunity to obtain reliable estimates of population trends over a decade and highlight the effectiveness of long term monitoring program for MSFD objectives.

Occurrence and characteristics of signature whistles in wild bottlenose dolphins from the Ligurian Sea (Italy)

Bottlenose dolphins (*Tursiops truncatus*) make extensive use of narrowband whistles for intraspecific communication. Among the whistle types, each individual develops a unique whistle modulation pattern that broadcast its identity: the signature whistle. Although signature whistles have been extensively studied over the last 50 years in captive dolphins, studies on wild dolphins are rare because of the difficulties involved in recording unrestrained individuals. In our study, we investigated the acoustic structure and contextual use of the signature whistles of the bottlenose dolphins inhabiting the western Ligurian coast (Italy), within the Pelagos Sanctuary (NW Mediterranean Sea). This demographic unit is composed of nearly 250 individuals and has been studied since 2001. Surveys were conducted from July to October 2018, resulting in 25 encounters with the target species (average groups size 13.4 ± 9.14). Photo-ID data were collected with a digital reflex camera Nikon 7000 equipped with a zoom Nikon 70-200. Acoustic recordings were collected using an HTI-96-MIN hydrophone connected to a Zoom H5 Handy recorder (sampling rate 96 kHz). The visual inspection of spectrograms allowed us to identify 936 whistles. Among these, using the SIGnature IDentification (SIGID) method, 504 whistles were identified as signature whistles and grouped into 17 different categories of frequency modulation. Hence, for each whistle, we extracted the frequency contour using the Beluga toolbox for MATLAB and we measured eight acoustic parameters. The 17 signature whistle types were then statistically validated using a stepwise leave-one-out Discriminant Function Analysis (DFA). Photo-ID data were visually analysed and 83 individuals were positively identified. Finally, we investigated the relationships between signature whistles occurrence and the context as well as the presence of photo-ID individuals in the pod. Our results provide the first insight into the characteristics and contextual use of signature whistles in this population of wild bottlenose dolphins.

Conservation of Irrawaddy dolphins in Bago City and Municipality of Pulupandan, Philippines: A multi-sectoral approach.
Teruel, Romeo Gotera[1]; de la Paz, Manuel Eduardo[2]; Pacalioga, Jessica[1]; Aguilar, Virgilio[1]; Pillo, Maribeth[1]; Pandan, Mary Ann[1]; Canal, Mercedez[1]; Banes, Rowena[1]

A Multidisciplinary research project was conducted in support of the efforts to conserve the Irrawaddy dolphins in the coastal waters of Bago City and Pulupandan, Philippines through the establishment of Marine Protected Areas (MPAs). Phase 1 of the project focused on the drafting of policies and management plan necessary in the setting up of MPA anchored on data on the updated dolphin population estimates, inventory of fishes, socio-economic profile, stakeholders' awareness and perceptions on Irrawaddy dolphins and MPAs in the locality. Phase 2 is a continuation of dolphin and fish monitoring with additional studies on water quality, tourism potential, livelihood, and project assessment. Phase 2 was done to formulate integrative strategies to ascertain the sustainability of the MPAs. The research project used the Multi-Sectoral Approach (MSA) involving local stakeholders in the project and in the post-project activities to include information and education campaign and drafting and approval of MPA management plan and ordinances. The more pronounced challenges encountered using the MSA include the i) difficulty of engaging community members in the project because of economic reasons, and ii) diminishing support of local government due to changing local priorities as affected by the programs initiated by national government. Overall, it is imperative to sustain the current conservation efforts through exploring more innovative partnerships given the following evidence-based local realities: i) declining population of endangered Irrawaddy dolphins in the locality, ii) community members are living below the poverty line, and iii) a significant number of community members are not aware of the presence of the Irrawaddy dolphins in their locality. More importantly, the current efforts should also take cognizance from the recent re-categorization that has raised the status of Irrawaddy dolphins in Guimaras Strait from ***vulnerable*** to ***critically endangered*** by International Union of Conservation for Nature.

Short-term effects of airgun pulses on narwhals.

The narwhal (*Monodon monoceros*) is a high Arctic species inhabiting areas that are now experiencing marked changes due to climate change and an associated increase in anthropogenic activities. The sensitivity of narwhals to seismic exploration was studied in two integrative experiments in August 2017 and 2018 in East Greenland. The study exposed narwhals (n = 9) instrumented with satellite transmitters and behavioral-physiological-acoustic sensors to airgun pulses. The whales were caught in nets and released after instrumentation. We compared data for periods with and without sound disturbance, and with different distances to the sound source.

Our analyses demonstrated a decrease in feeding rate, changes in diving depth profiles, and a paradoxical decrease in heart rate while stroking rate increased during escape. Two general behavioral responses to noise disturbance were identified. One reaction was to "freeze" and remain at the upper part of the water column and significantly reduce the vocalization activity compared to the undisturbed situation. The second reaction was a flight response where the whale increased its swim speed and stroking rate while remaining near the water surface. Here the narwhal altered its vocal activity to only include calls, which were increased significantly.

These behavioral results integrated together with direct measurements of physiological responses enable quantification of the energetic costs related to sound disturbances. In the most extreme case, energetic cost based on changes in stroke frequency for a 100-200 m dive increased three-fold during escape compared to periods without sound disturbance. Together, these results can be used to assess both short-term and long-term effects of seismic activity on narwhals representing individual to population scale effects. Ultimately, these results provide important insights about narwhal vulnerability to anthropogenic noise that can be used to mitigate the effects of human activities in the Arctic.

The Growing Important Marine Mammal Areas (IMMAs) Network: An update on the global process for informing the management practices of marine mammal place-based conservation.

Important Marine Mammal Areas (IMMAs) are a place-based conservation tool identifying discrete portions of habitat, important for one or more marine mammal species, that have the potential to be delineated and managed for conservation. The IUCN Joint SSC/WCPA Marine Mammal Protected Areas Task Force (MMPATF) is working to identify a global IMMA Network, through a series of regional expert workshops. During 2016-2019, six expert workshops were held investigating portions of the Pacific, Indian, Atlantic, and Southern Oceans, as well as adjoining South Asian, Mediterranean, and Arabian Seas. Over 100 IMMAs have been identified as a result of these expert workshops, engaging over 200 experts worldwide, assessing candidate IMMAs for over 40 species of marine mammal including cetaceans, pinnipeds and sirenians. Two further workshops are planned for the waters of Australia and New Zealand, and the Eastern and Southeast Temperate and Tropical Pacific. Each regional workshop follows a pre-defined process, in consultation with the marine mammal science and conservation community, developing a range of knowledge products for use by marine researchers, managers, and decision makers. These include a spatially explicit IMMA layer displayed in a web-accessible IMMA e-Atlas and region-specific best practice examples in area-based conservation and management, associated with pilot implementation projects. The products of these workshops are being utilised by regional Task Force groups, part of the legacy of the IMMA workshops, helping ensure the effective use and future evaluation of IMMAs. Examples of IMMA use include those by international conservation and management initiatives, such as the Convention on Migratory Species, Convention on Biological Diversity, and the International Whaling Commission. New case studies are in development for the use of IMMAs to enhance the consideration of marine mammals in protected area networks and to assist with marine spatial planning.

Review of current underwater sound propagation modeling methods

The understanding of anthropogenic effects on marine life continues to improve. However, the ability to predict an effect will always be limited by the ability to predict the sound field. The goal of the study was to identify the best combination of underwater acoustic models for use by the Exploration and Production (E&P) industry for environmental evaluation and marine animal disturbance mitigation. This goal has been accomplished by providing comprehensive critical and objective analysis of 28 of the currently available underwater acoustic propagation models, application models, and the required supporting data (marine physical and marine animal databases). An important result of achieving this goal is the ability to identify gaps and weaknesses in propagation modeling, databases and exposure modeling.

A brief theoretical summary of the standard numerical models (Wavenumber integration, Normal Modes, Ray Solutions, Marching Solutions, Energy Flux, Hybrid, and Gridded) has been developed. Each of these classes of models is evaluated with respect to differing environmental conditions and model capabilities. Finally, model prediction uncertainties have been analyzed with identification of limiting fidelity factors such as limited oceanographic and seabed knowledge.

Using nonlinear signal processing to identify North Pacific Right Whale sounds and measure calling depths in the Bering Sea

North Pacific right whales (NPRW) are a highly endangered species that resides in the Bering Sea during summer months, but their winter distribution remains relatively unknown. Substantial amounts of passive acoustic data recorded over the past decade in the Bering Sea have demonstrated the ability to detect the presence of NPRW via two types of calls: a frequency-modulated 'upcall' and an impulsive 'gunshot'. Unfortunately, the structure of these calls can be similar to the calls of much more common species, such as gunshots of bowhead whales and frequency-modulated sweeps of humpback whales, which makes identifying NPRW presence in certain regions difficult during certain times of year. Here we use recently-developed nonlinear signal processing techniques to demonstrate how single-hydrophone recordings of sounds in the Bering embed information that can be used to estimate the range and depth of calls. We investigate whether the depth distribution of calls differs between species, providing a potential cue for species identification. 12 NPRW 'upcalls' and 20 'gunshots', recorded in critical NPRW habitat, were processed to isolate individual normal mode arrivals from each call. The relative modal arrival times permitted range estimates between 1 and 40 km, while the relative modal amplitudes permitted call depth estimates, provided that environmental inversions were obtained from high signal-to-noise ratio calls. Gunshot sounds were generally only produced at a few meters depth, while upcall depths clustered between 10 and 25 m, depth ranges significantly different from gunshots (Wilcoxon rank sum test $p=2.9\text{x}10^{-5}$) and consistent with previously published bioacoustic tagging results from North Atlantic right whales. Bowhead whale gunshot sounds are generated at depths of 20 meters or greater, providing support for the idea that measuring relative calling depths of calls (measuring the relative amplitudes of first and second mode arrivals) may help classify species from otherwise ambiguous frequency-modulated calls. (Work sponsored by the North Pacific Research Board).

Can we help you with your distance sampling survey design or analysis?

Distance sampling is a widely-used suite of survey methods for estimating population size or

density. For marine mammals, the most common variant is a visual line transect survey, either from an aeroplane or a boat; however, new survey platforms are starting to emerge including aerial photography and video, towed and fixed passive acoustic arrays. Obtaining reliable estimates can be tricky: survey design, field methods and analysis all need to ensure the important assumptions are met as well as possible, and an adequate sample size of lines and of observations are required. Sometimes more complex survey and analysis methods can be used where assumptions of the more basic methods are not met – for example a double-observer protocol can be followed where animals on the trackline are not detected with certainty. The purpose of this poster is twofold. First, we will give an overview of the methods, tools and training available both for the basic approaches and for more complex and recent variants. We will cover recent developments in density surface modelling, estimation of trackline detection probability and incorporation of animal movement. We will showcase recent software for checking survey designs through simulation. Second, we will provide free consultancy to anyone who has questions about surveys they are planning or have already undertaken. Please come see us at the poster, or contact any of us by email (len.thomas, tiago.marques or cso2 @st-andrews.ac.uk; rocio.prieto.gonzalez@gmail.com) to set up a meeting.

Eliminating risk of entanglement in fishing pot lines for large whales: Update on efforts to develop and test "ropeless" gear.

Thomas, Peter[1]; Heinemann, Dennis[1]; Werner, Timothy[2]
(1) Marine Mammal Commission, Bethesda
(2) Anderson Cabot Center for Ocean Life, New England Aquarium
Corresponding Author: pthomas@mmc.gov

In the United States and Canada, the entanglement of large whales in buoy lines used in trap/pot fisheries has become a serious problem for several marine mammals and fisheries. In the case of the North Atlantic right whale (*Eubalaena glacialis*) entanglement is the most immediate threat to its persistence. Whales unable to escape entanglement drown or eventually succumb to injuries caused by the lines cutting into and through their tissues, or loss of energy and condition due to drag and/or impaired feeding. Even if they are able to eventually shed the gear, the loss of body condition may impair reproduction for several years. While dozens of mitigation measures have been proposed, many tested, and some implemented over the years, most do not offer a complete or in some cases even a partial solution to the problem. Removing buoy lines from the water is the only approach with the potential to largely eliminate entanglement risk. One such approach entails using so-called "ropeless" gear. Some prototype ropeless gear is designed to bring pots to the surface using inflatable bags, while most have a float or floats that can release a hauling line using a digital timer, galvanic release, or acoustic release so that the traps/pots can be retrieved. This presentation will review the devices currently used and under development, describe the systems necessary to put them into widespread practice, and discuss the hurdles that need to be cleared if this technology is to become operational.

A fine-scale and longitudinal assessment of energy requirements for Arctic seals

Thometz, Nicole[1]; Reichmuth, Colleen[2]; Russell, Brandon[3]; Hermann-Sorensen, Holly[4]; Rosen, David[5]

Ice-dependent Arctic seals use sea ice as a substrate for various critical functions including rest, pupping, molting, and predator avoidance. These activities may become disrupted or more energetically costly in the absence of sea ice. For example, during the annual molt seals shed several layers of epidermis and fur, and regenerate a new coat. To facilitate this process, seals haul out for extended periods, increase blood flow to the skin, and maintain elevated skin temperatures. Molting is energetically costly, and associated costs are predicted to increase if appropriate haul-out substrate is unavailable. Similarly, energetic costs may increase if haul out platforms and foraging areas are spatially separated. Measures of resting metabolism can be used to evaluate the potential impact of environmental changes on seasonal energy requirements. Working with eight highly trained Arctic seals, encompassing three species [bearded (*Erignathus barbatus*), ringed (*Pusa hispida*), and spotted (*Phoca largha*) seals], we used open-flow respirometry to track fine-scale changes in the resting metabolic rate (RMR) of individual seals for up to three years. Further, we examined the relative importance of key variables such as air and water temperature, photoperiod, age, body condition, and physiological state on documented changes in RMR. Our data reveal clear seasonal patterns in energy demands that relate to the molting strategies of each species. For species

that molt over a relatively short interval (spotted: 36±4.6 days, ringed: 29±2.5 days), RMR increased sharply (range: 26-47%) across the molt. In contrast, molting over a longer interval (bearded: 107±14.8 days) appeared to limit energetic costs as indicated by a more stable annual RMR. Our findings reveal a previously unknown relationship between molting strategy and seasonal energy requirements and provide quantitative data that can be used to predict how sea ice loss and associated environmental changes may alter energetic balance in Arctic seals.

The status of harbour seals (Phoca vitulina) in the United Kingdom: Regional trends and potential drivers.

Thompson, Dave[1]; Duck, Callan[2]; Morris, Chris[2]; Russell, Deborah[3]
(1) Sea Mammal Research Unit, St Andrews, United Kingdom
(2) University of St Andrews, St Andrews, United Kingdom
(3) Sea Mammal Research Unit, University of St Andrews, St Andrews, Scotland
Corresponding Author: dt2@st-and.ac.uk

UK harbour seals share their shallow, marine habitat with increasing levels of industrial activity and rapidly changing populations of competing species such as grey seals (Halichoerus grypus). Intensity of these pressures varies regionally and understanding how harbour seal populations have responded to them, at appropriate spatial and temporal scales, is essential for developing effective conservation/management strategies.

Aerial survey counts of seals hauled-out during their annual moult were used to estimate population sizes and trends at national (UK), regional (Seal Management Unit; SMU) and local (Special Area of Conservation; SAC) scales.

The current UK harbour seal population estimate is similar to estimates from the 1990s, but some sub-populations have declined significantly while others have increased. Fitted trends suggest that UK harbour seal populations are divided into three geographically coherent groups: Southeast populations (Northeast & Southeast English SMUs) showed continuous increases punctuated by PDV epidemics in 1988 and 2002; Northeast populations (East-Scotland, Moray-Firth, Orkney, Shetland SMUs) have declined dramatically since the late 1990s; Northwest populations (West-Scotland, Western-Isles, Southwest-Scotland SMUs) have remained stable or increased. This geographical population substructure is matched by recent population genetics results.

Trends within SACs generally match SMU trends since the 2002 PDV epidemic. Of nine harbour seal SACs, four declined (in East-Scotland, Moray-Firth and Orkney SMUs), four remained stable (in Shetland and West-Scotland SMUs), and one increased (in Southeast England SMU).

Differences in regional trends have resulted in large changes in relative abundance: e.g. in 1996-1997 West-Scotland and Orkney each held c.27% of the UK population but now hold c.50% and c.4% respectively; in 1980, the Southeast England population was c50% that of the Wadden Sea but by 2016 was <20%. Regional grey seal trends are presented and grey seal competition and/or predation are discussed as potential drivers of regional harbour seal dynamics.

Beyond hormones: Gaining the most physiological data from blow sampling using shotgun proteomics.

Thompson, Laura[1]; Neely, Benjamin[2]; Romano, Tracy[3]

(3) Mystic Aquarium, Mystic
Corresponding Author: lthompson@mysticaquarium.org

Collection of blow (exhaled breath condensate) has become a promising alternative to blood for obtaining biological information such as hormones, microbiome and genetics from free ranging cetaceans. Additional information may also be gained from other proteins expired in the breath. Qubit protein analysis of 72 blow samples from 10 belugas (*Delphinapterus leucas*) suggests variable concentrations ranging from <100 to >7,000 µg/ml. Identification and quantification of the blow proteome may be useful in determining lung health, as well as physiological status. This project aims to investigate the application of blow for this purpose by evaluating how the protein profile in beluga blow samples correlates with matched blood samples, and identifying changes in the proteome that may be associated with dive physiology. Three sets of matched blood and blow samples were collected from two belugas (1 male, 1 female) at Mystic Aquarium. In addition, matched blood and blow samples were collected from a single whale following completion of either active or stationary dives (2 replicates). Blow samples were also collected immediately prior to and 1 hour following these dive behaviors, demonstrating the usefulness of blow as a non-invasive tool for repeated sampling. While results of this work are forthcoming, a mid-level protein profile analysis was carried out on a single pooled blow sample

submitted to MS Bioworks. Only 10 µg of protein was needed, and over 482 proteins were identified. Among the most abundant proteins were serum albumin, mucin, cytokeratins and several complement proteins, important mediators of inflammatory responses. It is expected that blood and blow protein profiles will be similar though not exact due to perfusion and protein transport processes. We aim to identify specific proteins with altered abundance following breath-hold (dives) with and without activity, which can be further used to understand the health status of free ranging whales.

Simulating humpback whales response to airgun sounds using agent based models

Thomsen, Frank[1]; Mortensen, Lars[2]; Mortensen, Jonas; Theophilus, Teo Zhi En[3]; Dunlop, Rebecca; van Berkel, Joshua Jon[4]

The behavioral response of marine mammals to high intensity sounds such as airguns can occur at relatively large ranges. Yet, it has been a challenge to understand the population level consequences of these effects. Predictive modelling is often the only available approach for quantifying movement patterns in response to pressures such as noise to inform population studies. The use of models rests on the assumption that they are able to replicate natural conditions, which has not been proven sufficiently. Here, we investigated the ability of Agent Based Models (ABM) to imitate the movement of migrating humpback whales (*Megaptera novaengliae*). The agents were released into a simulated domain, where their decisions were generated stochastically (i.e. within predefined probabilities) based on coded traits and established external forcings such as temperature and noise. The input data for the ABM came from the BRAHSS study (Behavioral Response of Australian Humpback whales to Seismic Surveys). The model was run for baseline and sound exposure scenarios. Various output measures were compared between the BRAHSS and the ABM data. Swimming speed, course changes and deviations from course were all simulated in a way that did not show any significant differences to the observations during BRAHSS. Only for diving time, our model showed differences to observations. This can be explained by the lack of model calibration for this factor. Our study confirms the potential of ABM to replicate movements of marine mammals in both natural and sound impacted circumstances. We found the ABM successfully imitate key migratory behaviors observed during the BRAHSS experiments as well as changes in these behaviors when agents were exposed to a moving airgun sound source. While the ABM of migrating humpback whales does reflect most humpback behaviors observed in the BRAHSS study, knowledge gaps call for further dedicated research related to ABM modelling.

Identifying diel variation in Northern Resident killer whale vocal activity, call type and temporal frequency of echolocation using digital acoustic recordings from DTAGs.

Thornton, Sheila[1]; Gavrilchuk, Katherine[2]; Towers, Jared[2]; DeRoos, Mike[3]

The fish-eating Northern Resident killer whale (NRKW) population frequents waters from southern Alaska to northern Washington state, with seasonal movements throughout the Pacific Canadian waters that correspond to the presence of their primary prey species, which include Chinook and other large salmonids. Bouts of fast repetitive clicks with short inter-click intervals (termed "buzzes") employed during the terminal phase of prey pursuit are strongly associated with prey capture attempts. Use of echolocation to identify and secure prey is a vital component of the life history of this ecotype and communication between individuals during foraging contributes to prey sharing success. Reduction in foraging efficiency may occur when animals are exposed to anthropogenic noise from vessel traffic, which masks communication or echolocation signals. Suction cup digital acoustic recording tags (DTAGs) were deployed on NRKW in Johnstone Strait to evaluate night time foraging behaviour and guide mitigation of impacts from vessel traffic on killer whale foraging and catch success. In August of 2018 (year one of a three year study), 18 individual whales were tagged, resulting in 35 hours of day and 35 hours of night time data. Vocal activity, call type and echolocation use were quantified and compared from day to night. NRKW also engage in a behaviour called "beach rubbing", where they rub their bodies on stones in the shallow waters of beaches. Contact with the pebbles results in a distinctive sound signature and provides an opportunity to examine the diel pattern of rubbing beach use. These analyses contribute

important information on NRKW behaviour and we discuss the results with respect to diel differences in shipping traffic and how the potential impacts of vessel noise differ between day and night.

Diversity of endogenous carbon monoxide (CO) in the blood of 24 air-breathing diving vertebrates

Carbon monoxide (CO) is considered by many to be strictly a toxic gas. However, CO is naturally produced in bacteria, plants, and animals from the natural breakdown of heme, a common component of many heme-proteins used for oxygen transport and storage. We recently discovered that an animal with extremely high heme stores, the northern elephant seal, have concentrations of CO in their blood that resemble the levels seen in chronic cigarette smokers. We hypothesize that the elevated CO seen in the blood of elephant seals is directly related to their heme protein store concentration, and not solely attributable to the fact they are an air-breathing diver. To test this, we have measured the concentrations of CO in the blood of 24 air-breathing vertebrate divers (pinnipeds, cetaceans, mustelids, penguins, and sea turtles) with a wide variation in their heme protein stores. We find that heme stores alone do not predict the magnitude of CO seen in the blood of animals, as we measured higher levels of CO in species with the highest heme protein stores (e.g., elephant seals) as well as in the species with the lowest heme proteins stores (e.g., sea turtles). We suggest the variability in endogenous CO seen between the taxa could better be reflected by the rate of red blood cell turnover, or average breath-hold duration.

Using fine-scale variation in habitat features and environmental productivity to estimate local carrying capacity and range-wide recovery potential for Southern sea otters

For many depleted marine mammal species, managers face challenging questions about recovery potential: for example, what habitats can support sustainable populations, and how to set recovery targets given uncertainty about future abundance? One approach used to answer these questions is to extrapolate densities from existing populations that have already reached equilibrium; however, for species that have been severely depleted and are still recovering there may be few such populations to work with. Moreover, habitat characteristics of still-unoccupied areas may differ from the few areas in which populations have fully recovered. We present a multi-scale analytical framework for circumventing both challenges, simultaneously answering questions of habitat suitability and population recovery potential. We use Bayesian State-Space methods to fit a density-dependent process model to 35-years of spatially-explicit survey data from recovering southern sea otter populations. Localized carrying capacity (K) is computed at the scale of a 100m spatial grid as a multivariate function of both abiotic (bathymetry, benthic substrate type and distance from shore) and biotic (kelp abundance, nearshore primary productivity) habitat features. The process model also incorporates population spatial structure, environmental stochasticity and key sources of density-independent mortality (the latter were fit to cause-of-death data from beach-cast carcasses). Our approach allows estimation of K from survey time series even in areas still below equilibrium abundance and provides realistic estimates of K across the full range of variation in habitat characteristics, with associated precision estimates accounting for both process error and parameter uncertainty. We next apply posterior predictive distributions from the fitted model to estimate recovery potential in currently unoccupied areas of the historical range in California. We use our results to identify important habitat areas for future

colonization and recovery, and to provide a robust estimate of range-wide recovery potential that can be used by managers to determine the Optimum Sustainable Population (OSP) target abundance for southern sea otters.

Differences in humpback whale food preferences during two summer seasons in Senyavin Strait, Chukotka: Behavioral evidence.

Humpback whales are known to feed on a wide variety of prey, with their spatial distribution strongly dependent on abundance and density of prey aggregations during the feeding season. Various methods, some more invasive than others, are used to identify the prey — parallel fish trawling, isotope analysis, stomach studies. It is important to develop methods to identify prey which could be used in critical habitats without disturbing the whales. Here we suggest a method to determine the predominant prey by whale behavior and supplementary observations with control by stable isotope analysis. Small-boat surveys were conducted during August-September 2017 and 2018 in Senyavin Strait, Chukotka, to collect humpback whale behavioral data, tissue samples and photo-identification. A total of 34 days at sea resulted in identification of 143 individual whales. The spatial distribution of feeding humpbacks changed dramatically between seasons. In 2017 whales foraged over depths of 20-60 m with more activity in daytime and often accompanied by seabirds. In 2018 all the whales moved north to a deeper bay, where they were mostly resting in daytime and foraging in the evenings with no birds around. In addition, the faeces samples taken opportunistically in 2018 revealed the presence of krill (Euphausiacea) mandibles. The stable isotope analysis showed a higher trophic level for 2017 ($p<0.05$). Thus we conclude that, in general, humpback whales switched their diet from schooling fish in 2017 to krill in 2018. Our data provide an idea not only about the feeding ecology of a humpback whale aggregation, but also about the underlying prey distribution and ecosystem processes. The study was supported by the Russian Foundation for Basic Research, grant 18-04-00462.

Assessment of ship strike risk for sperm whales, using prey-informed distribution models and shipping intensity from AIS

Mortality or serious injuries to whales from ship strikes have been reported worldwide, and currently are one of the major threats to some whale populations. In the Azores, sperm whale injury and mortality rate from ship strikes is unknown, but several episodes were recorded over the years, calling for a better understanding of the risk posed by this threat to the whales.

To address that question, we modelled sperm whale distribution in the Azores for the spring, summer and autumn, using static and dynamic environmental predictors. Predictors included prey (micronekton) distributions simulated with the Spatial Ecosystem and Population Dynamics Model (SEAPODYM), as previous studies have shown that prey information can greatly improve model performance. Whale sightings were recorded by observers from the Azores Fisheries Observer Program (POPA), between 2001-2015. Shipping intensity was calculated from data collected between 2012-2015 using the automatic identification system (AIS), on-board most commercial, fishing and passenger vessels. Areas of greater risk of ship strikes were identified by intersecting predicted whale distribution and shipping routes.

Several shipping routes were identified, corresponding chiefly to passenger and cargo lines between the islands, large cargo ships and tankers crossing the region, and routes between the main fishing ports and fishing grounds.

Mean predicted relative sperm whale density varied among seasons, although some areas consistently had some of the highest values within a season. Accordingly, areas of greater ship strike risk also varied seasonally. In all seasons there was an overlap between areas with higher predicted relative sperm whale densities and intense shipping routes. However, the risk of ship strikes appears to be greater during the spring, when the highest predicted whale density values were calculated. These results will be instrumental to develop management tools to decrease ship strike risk to sperm whales in the region.

Advancing anthropogenic noise risk and noise mitigation assessments for endangered Southern Resident Killer Whales

Endangered Southern Resident Killer Whales (SRKW) number only 75 individuals. Synergistic threats of lowered prey availability, noise disturbance from whale watching boats and large ships, and high-levels of contaminants all have been documented to hinder recovery. Unprecedented levels of concern about the population's future has led to multiple research collaborations; here we focus on new approaches that aim to quantify risk from anthropogenic noise and report key findings of four interlinked studies. Firstly, an effort-corrected fine-scale habitat density model (monthly and by pod) using a variety of sightings data sets from 10+ years was developed. Secondly, multiple years of acoustic recordings in Haro Strait using calibrated, cabled, broadband (10Hz-100kHz) hydrophones have provided a better understanding of natural and anthropogenic noise contributors (especially commercial ships), as well as SRKW behaviour. New noise effect metrics that combined disturbance dose-response curves with high-frequency masking in a probabilistic spatiotemporal simulation model have been used to quantify the potential effects of noise disturbance on SRKW foraging. Acoustic sound pressure level analysis using cumulative probability distributions functions and GAMMs and this bespoke SRKW-noise overlap simulation model have been standardized tools used to assess the efficacy of regional mitigation actions, such as 61-day (2017) and 111-day (2018) voluntary commercial vessel slowdown initiatives in Haro Strait, a core area of SRKW Critical Habitat. A better understanding of key foraging areas is vital for population recovery, especially in offshore areas where habitat use may be changing, as well as for defining marine protected areas. While challenges remain, political will has intensified trans-boundary stakeholders to advance a suite of mitigation actions, to enhance eduction and fill key data gaps. The studies reported here assist in defining where, when and what mitigation actions managers should consider in protecting SRKW, as well as highlighting steps needed to improve future noise risk assessments.

Auto-detection of gray whales (Eschrichtius robustus) off Sakhalin Island, Russia using shore-based infrared

In 2017, a 28 km^2 section of the gray whale (*Eschrichtius robustus)* Sakhalin nearshore feeding area at the mouth of Piltun Bay, Russia, was monitored for more than three months using a shore-based infrared, automated whale detection system (WDS). The WDS was comprised of nine thermal cameras that covered a 90° field of view (FOV) and displayed whale blows on screen for real-time viewing during the day or night. Long-wave infrared (LWIR) video data were collected 24 hours/day, 7 days a week for a total of 98 days (May 28-Sept 3), resulting in 54,493 whale blows detected by the LWIR WDS. Effective detection distance for the WDS was up to 6km from the platform, and the average whale distance was 1.66km. Detections occurred at all hours of the day and night, and on average, 30-70 blows were detected hourly over the period. The average hourly number of blows were lowest from late morning to midday (0900-1300) and peaked late afternoon to early morning (1600-0200). As expected from historical distribution studies of the area, the maximum number of detections occurred in July when mothers return to the area with their calves. Dense fog prevented detections, but whale blows

were detected by the WDS during some periods of light fog, rain and high sea state (

Visual assessments of skin lesions on free-ranging bottlenose dolphins (Tursiops truncatus); Reliability and utility of quantitative tools.

Skin lesion prevalence in a cetacean population can serve as an indicator of population health. Photo analyses offer a simple, non-invasive approach to characterizing and quantifying skin lesions in cetaceans. In many cases, photos may be the only data available from which to gain insight on health concerns for a given wild population. However, there are limitations to using photos and there's subjectivity in classifying skin lesion types and/or quantifying measures of skin lesion prevalence and extent. One needs to ensure that measures used are reliable (*i.e.*, that there is consistency in the results of a measure) otherwise the validity of results is questionable and may mislead interpretation. This is a commonly overlooked concern in the literature, where scoring photo data is commonly executed by a single person and not tested for reliability.

We used data from photo-identification studies of common bottlenose dolphins (*Tursiops truncatus*) in the U.S. Northern Gulf of Mexico to: (1) test the reliability of a skin lesion classification system, (2) compare methods of quantifying skin lesion extent, and (3) determine the validity of using the dorsal fin as a proxy for assessing skin lesions on the entire visible dorsal/lateral surface. Good to strong levels of reliability were achieved for seven of 17 defined lesion types (categorized by appearance and/or known etiology) and reliability was high for the two tested measures of extent of skin coverage (tracing tool vs. rating approach). Skin lesion extent estimated from the dorsal fin alone over- or under- represented the visible dorsal/lateral surface by as much as 43%, suggesting that this is an unreliable proxy for the entire animal. This study provides a much-needed context analysis of tools used for quantifying skin lesions in dolphins. We discuss the pros and cons of the methods tested and provide recommendations for future studies.

Genetic investigation on Cuvier's beaked whale, Ziphius cavirostris on the coast of Turkey and Northern Cyprus, based on mtDNA sequences.

The beaked whales are the least known cetacean taxa in the world and mostly known through stranding records in the world oceans. Cuvier's beaked whale *Ziphius cavirostris* is the only beaked whale species commonly found in the Mediterranean Sea, but their distribution is cosmopolitan the northern hemisphere. They are known to be sensitive to noise pollution, indicated by stranding cases due to seisimic surveys or naval operations using mid-frequency sonar. Their genetic structure has little been studied due to the lack of samples. Five strandings of Cuvier's beaked whale were reported along the coast of Turkey and northern Cyprus in June 2016 and March, November 2017. In this first genetic study on the Cuvier's beaked whales from the Aegean Sea and the Levantine Sea, undertaken with these stranded samples, mitochondrial DNA control region (444 bp) and cytochrome b (424 bp) sequences revealed two haplotypes (four out of five individuals had a single haplotype). Control region haplotypes were identical to two previously identified ones from the Ionian (Greece) and Adriatic (Croatia) Seas, the only areas previously investigated within the Mediterranean basin. The isolated eastern Mediterranean subpopulation was highly differentiated based upon the presence of two unique haplotypes, which were not found outside of the Mediterranean. More samples from the Mediterranean Sea (especially the western basin) need to be sequenced with the same mtDNA markers for a better understanding of the genetic population structure of this species, which can be used to elaborate more concrete conservation measures for this species.

Prey echoes reveal long range biosonar behaviour in sperm whales.

Sperm whales use their hypertrophied nasal complex to produce the most energetic sounds in the animal kingdom supposedly to echolocate deep-sea prey at long ranges. However, direct tests of this long-standing hypothesis are lacking, and little is known about how sperm whales use this high-powered biosonar system to forage. To test how their self-generated, large scale acoustic scenes guide their foraging and biosonar behavior, we deployed sound and movement tags (DTAG4) on the anterior part of the nose of three sperm whales. For all three whales, we recorded bottom and surface echoes, and for one of them, we were able to record individual prey echoes out to ranges of 100 meters during 22 foraging dives. That whale encountered between 79 and 473 echoic objects per foraging dive of which less than 10% were targeted for capture, as inferred by the presence of a buzz, suggesting echo-informed prey selection. Echoes from some of the targeted prey could be detected throughout the transition from regular clicking to the buzz phase, revealing a hand off distance to this fast tracking mode of echolocation of some 25 meters, surprisingly long compared to other toothed whales. None of the three, tagged sperm whales consistently reduced interclick interval or click intensity leading up to buzzes as would be expected if tracking a single target. Rather, acoustic gaze changes appeared to be driven by echo returns from the sea floor and possibly the large-scale auditory scene of the deep scattering layer. In conclusion, we provide direct evidence that their powerful sound generating nose equips sperm whales to echolocate prey resources over long ranges and as a consequence acoustic gaze changes may be driven primarily by the large scale acoustic scene rather than by the spatio-temporal relationship with individual prey.

Evolutionary consequences of the structure-function relationship of the pinniped ankle during secondary adaptation to life in water.
Tonomori, Wataru

Corresponding Author: twono081@gmail.com

To reveal morphological changes in the structure-function relationship of the pinniped ankle bones during secondary adaptation to life in water, I traced the character change of the pinniped astragalus and calcaneum.

The results reveal that the otariid astragalus and calcaneum possess the greatest number of primitive characters in the crown pinnipeds. Due to their swimming locomotion using only forelimbs, the primitive ankle joint remains in the crown pinnipeds because their ankle joints have no functional requirement from swimming locomotion. The Odobeninae (Odobenidae) and *Allodesmus* spp. (Desmatophocidae) share many characters in their ankle bones, which suggests that the function of their ankle joints also is similar. Previous studies based on axial morphology suggested that *Odobenus rosmarus* (Odobeninae) and *Allodesmus* spp. shared the same swimming style, and my study supports this suggestion. Some previous studies indicated the correlation between the prosperity of the crown odobenids (i.e., Dusignathinae + Odobeninae) and the decline of *Allodesmus* spp. during Tortonian (mid to late Miocene). The results of my study suggest a possibility of the correlation between the replacement of their niche and an inferred similarity of their ankle joints. The phocids possess a specialized ankle joint. Some unique characters indicate the ankle joint of the phocids is twisted laterally, and allowing flexibility and strong plantar flexion. Because of the "twisted" ankle, in the phocids, the hindlimb did not contribute to movement on land. On the other hand, this ankle is adaptive for their swimming: lateral pelvic oscillation. This is the functional trade-off for dual locomotion: walking and swimming. Moreover, in the pinnipeds with a swimming style defined by lateral pelvic oscillation, the phocids achieved the greatest species diversity, geographic distribution, and feeding diversity. Therefore, I suggest that phocid's acquisition of the specialized ankle led to their divergence in the pinnipeds of the same swimming style.

Calving during migration: Recovering humpback whales giving birth in unprotected waters.

Humpback whales (*Megaptera novaeangliae*) migrate to find suitable calving habitat, which includes warm (19-28°C), shallow, and sheltered waters. East Australian humpback whales (E1) are thought to breed within the vast Great Barrier Reef Region (16°S to 24°S).

Here, we investigated the presence of newborn calves occurring in Gold Coast Bay (i.e. south of the primary breeding grounds) from 2013 and 2016 using platforms of opportunity and a citizen science approach. More specifically, we examined (1) initial location at which newborn calves were observed, (2) depth (m) and SST (°C) associated with these sightings, (3) relative age classification of newborns, and (4) newborn swimming direction via GPS tracking.

A total of 74 newborn calves were observed with photographs and GPS locations recorded. Sightings occurred primarily in July (51.4%), August (41.9%), but also in June (4.1%), and September (2.1%). Based on diagnostic morphological features, newborn calves were categorized as Age Class 1 (n = 30) or Age Class 2 (n = 44).

Results indicated that 1) E1 humpback whales are giving birth during their northern migration, at least 1,000 km south of the primary recognised calving grounds; and that 2) the Gold Coast Bay provides suitable calving habitat (i.e. warm (19.6 to 22.8 C) and shallow (17.2 to 50.8 m)) waters for pregnant humpback whales; and that 3) the majority of newborn Age Class 1 or 2 calves travelled in a northward direction.

We conclude that newborn humpback whale calves are present in the Gold Coast Bay from June until September. Our findings may signify that this population is expanding its calving range to the south, in waters that have no legislative protection or designation as calving areas. Conservation managers and tourism operators should plan appropriate conservation measures to ensure cows with newborn calves can utilise these waters without being affected by anthropogenic activities.

Sounds of stress: Evaluating the relationships between variable soundscapes and gray whale stress hormones.

Cetaceans live in a sound-filled environment full of acoustic cues to aid foraging, communication and navigation. Human activities often fill the ocean with sounds from vessel traffic and industrial activities, with potential consequences to cetacean ecology and health. Cetaceans may be able to tolerate some degree of added sound, but when does sound become noise? And, when does noise cause stress? We address this knowledge gap through measurement of the soundscape in coastal Oregon, USA waters with spatially and temporally concurrent fecal sample collection from gray whales for hormone analysis. Between June and October 2017 and 2018 we used hydrophones to record 2088 hr of acoustic data at two study sites with contrasting anthropogenic use. To characterize the soundscapes, two bands of acoustic data within the likely hearing range of gray whales were chosen for analysis: a low-frequency (100-150 Hz) band reflected sound associated with larger vessel activity, and a higher-frequency band (2 kHz) reflected smaller vessels and wind generated noise. Median low frequency sound levels were similar at the two sites, yet median higher frequency band levels were up to 7 dB higher at the site with heavy anthropogenic use. Simultaneously, 82 fecal samples were collected and glucocorticoid concentrations were determined after assay validation. Cortisol levels were used as an indicator of physiological stress, and ranged from 0.08 to 68.16 ng/g (mean = 16.36, SD = 12.65). Recognizing that cortisol levels may be affected by intrinsic and extrinsic factors, we used a long-term photo-id dataset, drone body condition assessment, and reproductive hormone levels to control for variation in cortisol levels relative to demographic unit, health, and reproductive status. We then examine the complicated relationships between ocean noise intensity and gray whale stress. This work represents a longitudinal effort to quantify the effect of ocean noise on a wild cetacean.

Chronic exposure to glucocorticoids increases the expression of atrophy-related genes in elephant seal muscle fibers.

Sustained elevations in circulating glucocorticoids due to chronic or repeated stress can have deleterious consequences for animal health. To study the effects of chronic glucocorticoid exposure on muscle atrophy in elephant seals, we isolated muscle progenitor cells (myoblasts) from three northern elephant seal pups during their molting fast. Elephant seal myoblasts stained positive for the skeletal muscle marker desmin and were fully capable of differentiating into skeletal muscle fibers (myotubes) in primary culture. Differentiation was accompanied by marked increases in the mRNA expression of the myogenic genes *mrf4*, *myogenin*, *myod*, *myh1*, *myh8*, and *tnnt1*. Exposure to increasing concentrations (1-100 μM) of the synthetic glucocorticoid dexamethasone (DEX) for 48h decreased the expression of glucocorticoid receptors *gr1* and *gr2* in a dose-dependent manner, suggesting that prolonged DEX exposure promotes a compensatory response to increased glucocorticoid receptor signaling. Exposure to 1-10 μM DEX increased the expression of myogenic genes (*myogenin* and *myrf4*) and atrogene *murf1* whereas exposure to 100 μM DEX had the opposite effect. Unexpectedly, exposure to DEX had no effect on *mtor* or *pcna* expression suggesting that even when exposed to high doses to glucocorticoids, protein synthesis is not impaired in primary elephant seal myotubes. Conversely, DEX exposure increased the expression of the myostatin regulator *cebpd* and atrogenes *foxo3* and *ddit4* in a dose-dependent manner, suggesting that prolonged exposure to high concentrations of glucocorticoids might promote muscle atrophy in elephant seals despite their extraordinary capacity to tolerate stress.

Presence of fin whale (Balaenoptera physalus) related with coastal influence and oceanographic conditions in Garraf feeding ground

The fin whale (*Balaenoptera physalus*) moves every spring season through the Catalan coast and the Catalano-Balearic Sea. Since 2014, from March to May, visual maritime surveys consisting of random transects have been conducted and sightings data has been recorded. The study area is a coastal zone of more than 1300 km^2 and extends until 15 miles offshore. The presence and distribution of fin whales in the area has been studied; differences between seasons have been observed in number of animals and their spatial and time distribution. In addition, behavioral data has been collected, having recorded mainly foraging and feeding behavior. For this reason, we aimed to analyze the influence of the coast on the fin whale presence. A comparative study has been done considering the next variables: presence and distribution of fin whales, chlorophyll-a concentration, sea surface temperature (SST) and salinity (SAL), as well as rainfall inputs on land (in a 50 km radius from study area). For the analysis, 8 day and monthly resolution data of oceanographic variables and monthly rainfall inputs have been used. *The rainfall has been related with and increment of phytoplankton; satellite chlorophyll has been used as a proxy of phytoplankton biomass. There is a positive Pearson correlation between rainfall and chlorophyll-a concentration. And a positive non-significant correlation between rainfall and fin whale sightings with an offset of one month. An offset of 2-3 weeks has been found between chlorophyll concentration and whale sightings. Moreover, crosscorrelations show a relationship between the presence of fin whales and the oceanographic variables chlorophyll-a, SST and SAL, and rainfall. Thus, the coastal inputs in this area have a high impact in the presence of fin whales, since less rainfall on land in the previous weeks cause a decrease of the fin whales observed. Enforcing it as a feeding ground.*

Seasonal and geographical occurrence of blue whale stereotyped and non-stereotyped calls in the Southern Indian Ocean.

The Southern Indian Ocean is a seasonal habitat for the Antarctic blue whale as well as for Madagascan and Australian pygmy blue whale populations. Their presence has been demonstrated by analysing continuous acoustic records from the OHASISBIO hydrophone network. This array, deployed since 2010, comprises 5 to 9 fixed mooring sites spread over a region from 24° to 56° South and from 52°

to 83° East. Antarctic blue whale acoustic occurrence has been well described within this territory, based on a systematic detection of its stereotyped Z-calls. However, pygmy blue whale distribution has mainly been inferred from broad-scale acoustic power spectral density estimations that lack precision. In addition, D-calls, which are non-stereotyped calls produced by males and females of every population while foraging, have never been monitored in detail in the area. To study temporal and geographical occurrence of these four sound types in the OHASISBIO hydroacoustic data, we applied an automated detection algorithm based on dictionary learning and sparse representation of the signal. The systematic detection of stereotyped calls confirms the distribution pattern described for Antarctic blue whales and improves that of pygmy blue whale acoustic populations. Madagascan pygmy blue whale calls are mainly detected west of the network, whereas Australian pygmy blue whales are mostly recorded at the eastern sites. Both populations share a common seasonality, with a detection peak during austral autumn. Overall, these patterns provide a better understanding of blue whale sympatric areas, where multiple sub-species or populations seasonally gather. D-calls are detected all over the hydrophone network, with a variable number of detections depending on the site, year and season. Eventually, the comparison of the detection patterns of stereotyped calls and D-calls in this 9-year-long dataset provides insights on how blue whale populations use and share the Southern Indian Ocean as habitat.

The effect of anthropogenic noise on foraging buzz activity of bottlenose dolphins (Tursiops truncatus) in the New York Bight

Vessel noise has been shown to interfere with odontocete echolocation. When foraging, bottlenose dolphins produce shorter, faster clicks with shorter inter-click intervals (ICI<16ms), called *foraging buzzes.* Previous studies demonstrate that in heavily trafficked waterways, high vessel noise significantly reduced prey capture attempts in small cetaceans. Bottlenose dolphins are present in New York waters from spring to fall, migrating south during winter. Their more recent and extended presence suggests that the coast of New York provides important foraging habitat. Presently, little is known about the foraging behavior of these dolphins and the potential impact from feeding around the busy New York Harbor. We used passive acoustic monitoring to evaluate dolphin foraging behavior, indicated by foraging buzzes, in high-level and low-level (>96 & <96dB re 1µPa, respectively) anthropogenic noise conditions. Recordings were analyzed from six acoustic recorders deployed over one year in the New York Harbor. A click detector was used to identify all foraging buzzes, and only those with a signal-to-noise ratio of at least 10dB were included in the final analysis. Foraging buzzes were measured by the number of buzz sequences and total duration within each 1-minute segment where these buzzes were detected. A two-sample permutation test was used to test for a significant difference in foraging rates between noise conditions. Foraging activity tended to decrease under high-level noise conditions, even after taking into account masking effects. These results demonstrate a negative relationship likely attributed to anthropogenic noise on the foraging activity of dolphins. Interruption of foraging activity may impact the overall energetic budgets of these dolphins, possibly leading to decreased fitness or other consequences. Further research into the health, diet, and behavior of these dolphins is required to understand the extent to which anthropogenic noise is disrupting foraging and the long-term effects of such disruptions on population dynamics.

Monitoring odontocetes via their clicks: Surprising strengths and weaknesses of high-resoution time-domain data analysis.

Tregenza, Nick
Chelonia Limited, Mousehole, Cornwall , United Kingdom
Corresponding Author:
nick.tregenza@chelonia.co.uk

Valuable numerical assessment of the Vaquita and the Baltic Sea Harbor Porpoise (SAMBAH) has been achieved using click loggers. The detections in these studies were based on finding 'coherent' trains of similar clicks in C-POD data. This greatly reduces the false positive rates of click-by-click classifiers but has had a high false negative rate for dolphins.

To improve this 12 different time domain features of each click are recorded by the C-POD-F logger. Multiple descriptors of train coherence are then derived from these time-domain click features, plus click time and measures of click reverberation. Some of these descriptors are then used to choose between alternative possible trains, and others are 'reserved' to avoid the 'overfitting' hazard of using

the same criteria to find trains and to measure their coherence.

To explore and assess the discriminatory power the distributions of these train descriptor values in different types of cetacean-free noise were compared with their values in data dominated by true trains from porpoises, dolphins, boat sonars, or weak unknown train sources (WUTS). The data came from C-POD-F click records, C-POD-F raw data capture, or sound sampled at 586kHz.

The results showed that (1) useful levels of discriminatory power come from time-domain descriptors, (2) this usually varies across noise regimes, (3) recording at high time resolution increases power, (4) reverberation metrics are valuable, (5) power in train coherence assessment is not generally closely related to power in determining the species, (6) post-processing of time-domain data is very fast, but both (7) real time determination of click starts and ends, and (8) useful real-time extraction of very weak broadband clicks are problematic, and (9) that automated population trend monitoring could be improved using this approach.

Geographic variation in Blainville's beaked whale (Mesoplodon densirostris) echolocation signal.

Blainville's beaked whales (*Mesoplodon densirostris*) have a cosmopolitan distribution from temperate to tropical waters, but are classified as "Data Deficient" under the IUCN Red List. We investigated geographic differences in Blainville's beaked whale frequency-modulated (FM) echolocation pulses from recording sites across the North Pacific, Gulf of Mexico, and NW Atlantic as a potential tool for population-level discrimination. Blainville's beaked whale FM pulses have been described as species-specific, with a steep energy onset at around 25 kHz, a small energy peak at 22 kHz, a peak frequency of 30 to 34 kHz, and an inter-click interval of 280 ms. Quantification of the variability in spectral shapes and inter-click intervals measured within and between encounters was achieved through weighted network clustering. Spectral averages obtained from the primary clusters identified at each site exhibited frequency shifts of up to +/- 6 kHz relative to the previously described Blainville's FM pulse type. We observed differences in spectral structure between ocean basins and also identified a latitudinal cline, with higher peak frequencies occurring in lower latitudes. While geographic variation in click characteristics has been documented for several species of odontocetes, such variation had not been documented previously in beaked whales. The observed variability may have several possible origins, potentially related to differences in body size or prey size. These findings provide insight into the geographic distribution of a rarely observed species, and also suggest that this variability in echolocation signal frequency may be a first indication of acoustic delineation between population-level boundaries of Blainville's beaked whales that have not been identified previously.

Simple models to predict daily prey consumption by marine mammals as a function of their costs of living

Trites, Andrew W.
UBC Marine Mammal Research Unit, Vancouver, British Columbia
Corresponding Author: trites@zoology.ubc.ca

In general, smaller species of marine mammals have higher mass-specific energy requirements than bigger species (e.g., 4-5% for dolphins and 2-3% for large whales). However, closer inspection of energetic requirements of different sized species reveals that many consume significantly more or less than predicted by generalized models of consumption. This implies that the simple models currently used to determine daily rations are ineffective to estimate the food requirements of marine mammals, and that new means are required to yield better estimates of prey consumption. I used well-supported estimates of energy requirements for 28 species of marine mammals to derive three generalized equations that predict the energy requirements of all pinnipeds and cetaceans as a function of body mass and their cost of living (high, medium and low). The relationship between cost of living and food requirements likely reflects

differences in evolutionary pathways that shaped predator-prey interactions. These new equations that incorporate cost of living are superior to existing generalized equations that have been used in the past to estimate energetic needs, and can be used to derive estimates of prey consumption for species of marine mammal with unknown energy requirements.

The trophic interactions among cetaceans in the southwestern Atlantic Ocean inferred through stable isotopes

The offshore waters in the western South Atlantic sustain large abundances of cetacean species. Yet, due to their occurrence at long distances from the coast hampering the study of their feeding habits, little is known about their intra and inter-specific trophic ecology and level of interactions. We measured carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$) stable isotopes in skin biopsies of odontocetes to assess the spatiotemporal variation in their area of isotopic niche and overlap in resource use. The study area in the outer continental shelf and slope off Brazil (~23°S to ~34°S) was divided into southeast and south areas, according to their oceanographic characteristics. $\delta^{13}C$ and $\delta^{15}N$ showed some persistent seasonal (austral autumn vs. spring) and latitudinal patterns, consistent with variations at the base of the local food-web. The rough-toothed (*Steno bredanensis*) and common dolphins (*Delphinus delphis*) had the highest mean $\delta^{15}N$ values, indicating high trophic positions in the food webs of the outer continental shelf and shelf break of the southern region. Bottlenose (*Tursiops truncatus*) and Atlantic spotted dolphins (*Stenella frontalis*), frequently reported forming mixed-species associations in the region, showed large isotopic niche overlap in both seasons and areas. Atlantic spotted and common dolphins showed significantly large core isotopic niche overlap in the South, mainly in spring. Spinner dolphins (*S. longirostris*) showed consistently low $\delta^{15}N$ values, and an overlap in its isotopic niche with the pantropical spotted dolphin (*S. attenuata*) in the southeast region. Killer whales (*Orcinus orca*) and a single pilot whale (*Globicephala melas*) had very similar $\delta^{13}C$ and $\delta^{15}N$ values, consistent with feeding in offshore waters. $\delta^{13}C$ and $\delta^{15}N$ in sperm whales (*Physeter macrocephalus*) suggest individuals feed on similar trophic levels, but throughout a wide spatial range. The data presented here provides a first insight into the trophic interactions and ecological niche of cetaceans in these oceanic waters.

The dynamic time waveforms of Amazon River dolphins (Inia geoffrensis) and other acoustic emanations: Comparisons of free-ranging dolphins in the Peruvian Amazon with a dolphin in human care.

Documentation of Amazon River dolphin (*Inia geoffrensis*) activity is difficult due to the opaque water in which they commonly inhabit in conjunction with their morphology and shallow-surfacing behavior. Furthermore, obtaining quality audio recordings of these animals is also challenging given their preference for shallow habitats characterized by currents carrying copious quantities of debris, changing bottom topography, and dynamic hydrologic cycles. Recently the IUCN changed the Amazon River dolphin status from data deficient to endangered due to unsustainable fishing practices. However, the quantity of animals found in the wild is still unknown. The goal of this research is to develop methods to acoustically count Amazon River dolphins in their natural habitat. An understanding of the dynamic time waveform is needed to accomplish this goal. To this end, an Amazon River dolphin housed at the Duisburg Zoo in Germany was recorded in March of 2018. This setting allowed investigators to document the location and position of the dolphin in relation to the hydrophone array. This information allowed for the determination of various time waveforms

associated with both on-axis and off-axis clicks. Additionally, comparisons were made between the vocal emanations of the Duisburg Zoo dolphin with those produced by free-ranging dolphins from the Peruvian Amazon. Click peak frequencies obtained from the zoo recordings were lower than those found from Peruvian Amazon recordings. Finally, both zoo dolphin and Peruvian Amazon recordings contained frequency-modulated "whistles", high-amplitude pulses possibly used to stun prey, and suspected Twin Inverted Pulsed Sonar (TWIPS). This work supports the theme of the opening plenary presentation by Roger Payne at the SMM 21st Biennial Conference, illustrating that studies of marine mammals in human care strengthen field studies. Further investigation into the unique high-amplitude pulses is warranted.

Photo identification of marine cetaceans using convolutional neural networks

Modelling cetacean population dynamics and behaviour is paramount to effective population management and conservation. Cetaceans also make prime candidates for modelling ecosystem change under the ecosystem sentinel concept as they reflect the current state of the environment, responding to changes across different spatial-temporal scales. Methodologies of cetacean research include photo-identification (photo-id) - collecting photographic data and identifying individuals based on unique markings. Manual photo-id can however be costly and time consuming due to the number of person-hours required for identification, as well as the potential for misclassification due to issues such as observer fatigue. Current image analysis software like DARWIN and Wildbook do not employ state-of-the-art deep learning techniques whilst requiring a large amount of manual user input to provide possible matches.

With progressively more data being collected during fieldwork due to an increasing use of technology, there is an urgent need for an automatic system to quickly perform photo-id with reduced error rates. Thus, a novel approach to cetacean photo-id through the utilisation of deep learning networks (specifically Convolutional Neural Networks, CNNs), has been developed and implemented on high-powered GPUs by bringing together an interdisciplinary team of computing scientists, marine biologists, and engineers. This new approach provides a powerful platform for solving fine grain computer vision tasks such as individual animal photo-id.

Images taken during fieldwork are uploaded to the system, which is currently pre-trained to segment *L. albirostris* fins from large panoramic above-water images. The detected fins are passed to a second component for photo-id. Users are then presented with a list of most-likely identifications along with confidence scores, greatly reducing the set of fins a human observer needs to review when matching fins to fin catalogues. This system will significantly aid marine biologists by increasing the accuracy and speed of the identification process.

Assessing the wintering range of Southern Hemisphere humpback whales (Megaptera novaeangliae) using satellite telemetry.

Satellite tagging provides a wealth of information on movements and habitat use of migratory species, such as baleen whales. Humpback whales typically occur in warm low-latitude waters during winter. Current knowledge suggests that movement (transiting, localized, and migratory) and distribution (clustered or broadly distributed) patterns differ across these wintering grounds; however this has not yet been comprehensively tested. We compare the temporal and spatial low-latitude behavior of humpback whales using a unique tracking dataset of 461 individuals from 2002-2018, representing all three Southern Hemisphere major ocean basins and seven discrete wintering grounds. We applied a switching-state-space model to Argos locations to identify changes in behavioral patterns (i.e. likelihood of exhibiting localized movements). The character of restricted movements differed between regions, with broadly-distributed areas of localized movement along the shelves of continental wintering areas associated with coastal habitat (i.e. eastern and western South Atlantic, eastern Indian Ocean, and eastern South Pacific and Madagascar), contrasted with smaller constrained areas of localized movements near both oceanic islands and offshore shallow bathymetric features (i.e. Oceania and western Indian Ocean islands). Males exhibited localized movement in core areas during the peak of the season in the Western Atlantic and in the Eastern Pacific, as well as in offshore corridors during the southern migration in eastern Indian Ocean. Localized movements of females with calves were observed in different sites across all wintering grounds over the season, which can be used for resting or nursing. Although whales widely disperse across wintering areas, the localized movements revealed a smaller range size of high-use areas. Overall, this comprehensive tracking dataset of Southern Hemisphere humpback whales provides an improved and comparative understanding of their circumglobal wintering behavior and distribution, and also higher resolution information to inform future management measures.

The Amazon and Orinoco dolphins face a large number of threats, which is reflected in the new categorization of the IUCN as EN. It is critical to determine which are the key (core) areas for these species, the displacements or seasonal migrations, the effect of connectivity loss in several rivers due to dams, and how the dolphins are using protected areas. To evaluate this, a total of 31 dolphins of the genus *Inia* were tagged between 2017 and 2019 in the rivers Tapajós (Brazil), Amazon, Orinoco and Guayabero (Colombia), San Martín (Bolivia) and Marañón (Peru) with Argos-linked Spot 299A satellite transmitters. This study is the first to identify movement patterns and habitat use of *I.g. geoffrensis, I.g. humboldtiana* and *I. boliviensis* using this type of technology in the Amazon and Orinoco. The results show that the largest displacements were performed by *I. boliviensis*, where a male individual moved 333.7 km between

the rivers San Martín and Iténez in Bolivia, followed by an *I.g. geoffrensis* male tagged in the Tapajós River, an *I.g. geoffrensis* female tagged in the Colombian Amazon and finally an *I.g. humboldtiana* (48.8 km). Tagged males were more mobile than females; the latter generally remained in the same areas, with shorter movements between tributaries, lagoons and main rivers. Results show long differential transboundary movements as a result of spatial heterogeneity, water types, system productivity, biomass, and a differential use of habitats. Finally, the importance of the confluences, small tributaries and wetland complexes within the protected areas such as the national and departmental natural parks Juruena (Brazil), Iténez (Bolivia), Pacaya-Samiria (Peru) and Amacayacú and the Tarapoto Ramsar site (Colombia) is highlighted.

An instrument-based aerial survey of ice-associated seals in the Chukchi and East Siberian seas in Russia, spring 2016.

In the spring of 2016, an instrument-based, multispectral aerial survey was carried out in the Russian part of the Chukchi Sea and eastern part of the East Siberian Sea to estimate the abundance and distribution of ringed and bearded seals on the spring ice. As the distance to the mainland was increasing, the density of both species of seals was statistically significantly declining. According to the statistical modelling results, the highest numbers of ringed seal were expected in the areas located along the coast, where the ice break-up was observed the earliest. Taking into account the correction of the obtained estimates of the abundance of seals on ice to the proportion of animals being disturbed by the aircraft engine noise (30,2% of ringed and 5,9% of bearded seals), and also keeping in mind that up to 32% of the animals could have been in the water during the survey, we expect the population size of the bearded seal in the Russian part of the Chukchi and eastern parts of the East Siberian Sea to exceed 7 000, and the ringed seal - 21 000 individuals. The underestimation can also be attributed to the ringed seal snow lairs being partially untouched in April. This was the first seal instrument-based aerial survey in the region and it provided more verifiable data and robust estimates than previous visual sighting surveys and our analyses took into account more sources of uncertainty, as well. The work was supported by National Marine Fisheries Service, NOAA and NPRB.

Reconstruction of amino acids' carbon and nitrogen stable isotopes profiles in baleen whales earplug

Phytoplankton plays an important role in marine ecosystems by supporting the marine food web through carbon transfer to higher trophic levels. However, climate change can alter ecological and biogeochemical functions by supporting changes in phytoplankton and species composition. Using carbon and nitrogen stable isotope composition of consumers in higher trophic levels can reveal variation at the base of the food web. Significant advancement in instrumentation and analytical technique offers a powerful tool for tracking the sources of stable isotope variation in consumers and the biochemical pathways. Analysis of compound-specific stable isotope of individual amino acids (CSIA-AAs) using gas chromatography combustion isotope ratio mass spectrometry (GC/C/IRMS) provides more insight into baseline and trophic variability on the consumer. Baleen whale earplug, traditionally used to provide age estimates and lifespan, has the capability of recording and archiving the life history of individual whales. This novel technique of combining age estimation with reconstructed bulk stable isotope and AAs of earwax can assess changes in marine ecosystems structure and productivity in global scale at decadal time scales. This approach is based on enrichment of stable isotope values of some AAs in organisms in comparison to the food source (trophic and non-essential AAs), and other AAs with similar stable isotopes value to the baseline (source and essential

AAs). Reconstruction of multi-decadal bulk stable isotopes along with amino acids stable isotopes in long-lived migratory animals like baleen whales can provide temporal and spatial variation in the structure of marine ecosystem food webs in response to climate changes.

"Click, click. Who's there?" A quantitative description of long-finned pilot whale echolocation clicks from the North Atlantic.

The long-finned pilot whale (*Globicephala melas*) is a large member of the ocean dolphin family (*Delphinidae*), distributed through the temperate North Atlantic. Much remains unknown regarding the population dynamics and movement of these whales throughout their home ranges. As an abundant, vocally active cetacean species that produce a variety of acoustic signals, pilot whales are good candidates for passive acoustic monitoring (PAM). However, their echolocation clicks are hard to distinguish from those of other delphinid species due to similarities in spectral content, particularly in the absence of accompanying tonal signals. To address this, we used passive acoustic monitoring to establish detailed quantitative descriptions of pilot whale echolocation clicks, including variations in spectral content as a result of receiver depth. Acoustic encounters were recorded with autonomous instruments deployed at various depths in coastal waters off Cape Breton Island, Nova Scotia (n = 29 recordings), as well as offshore on the Scotian Shelf (n = 25 recordings), the Gully Marine Protected Area (n = 2 recordings), and off the coast of Ireland (n = 1 recording). We found that spectral click parameters (peak and centroid frequencies) decreased with increasing receiver depth, while click duration increased. Overall, click spectra got wider and lost high-frequency inputs at greater depths. These differences are important to take in to consideration during PAM monitoring projects, and may be explained by different sound propagation conditions at the surface versus at depth. It is also possible that pilot whales adjust their clicks based on the surrounding environment or behavioral function. The results of this study, combined with prior published work on the classification of tonal calls, will allow for the development of more accurate pilot whale automated click detectors for PAM, leading to better long-term monitoring, with the goal of understanding this species' acoustic behaviour, habitat use, and population structures.

Emerging interactive digital technologies in cetacean and marine conservation
Tsui, Henry Chun Lok; Kot, Brian Chin Wing
City University of Hong Kong, Hong Kong, Hong Kong S.A.R., China
Corresponding Author: cltsui9@cityu.edu.hk

Education on cetacean and marine conservation is challenging, as most of the ocean are invisible to the human eye, and marine species and processes are spread over large temporal and spatial scales. Interactive digital technologies have the potential to support learning about the ocean, as, virtually, they can take the learners into the depth of the ocean and help them visualise complex interactions between different marine species over time and space.

In 2014, a 10.8-metre long Omura's whale (*Balaenoptera omurai*) stranded in the Hong Kong waters, with evidence of fishery entanglement. Delegates from the Jockey Club College of Veterinary Medicine and Life Sciences and students from various departments of the City University of Hong Kong (CityU) had taken the lead to deflesh the whole skeleton and preserve it into a specimen. Together with the cooperation with the pioneer cetacean virtopsy project, aiming to provide supplementary or complementary information to conventional necropsy for the biological health and profile investigation of stranded cetaceans, CityU is one of the first institutions worldwide to apply interactive digital technology to create various multimedia products in cetacean and marine conservation, namely virtopsy, 3D surface scanning, photogrammetry and 3D printing, motion graphic, immersive virtual reality, and mobile application.

These technologies require different levels of knowledge, manpower and production time. The use of these technologies in cetacean and marine conservation can make the invisible visible, allowing engagement with and manipulation of the abstract features of the ocean, as well as human interactions and threats to marine species. These technologies provide a field of action where users can experiment, make mistakes, get feedback and try again in ways that are different from paper-based learning activities, and would be demonstrated and displayed in various outreach visits and exhibitions, to increase public empathy for nature and arouse public awareness in conservation and nature.

Diel variation in humpback whale singing activity off Chichi-jima Island, Ogasawara,

Male humpback whales (*Megaptera novaeangliae*) sing complex songs in their breeding season. To investigate the diel and tidal effects on the behavior of humpback whale singers, we conducted passive acoustic monitoring in the Ogasawara Islands, Japan. The waters of the Ogasawara Islands are one of the breeding grounds for humpback whales of the western North Pacific stock. Two automatic underwater sound monitoring systems (AUSOMS-mini stereo, AquaSound Inc., Japan) were deployed at two stations off the west side of Chichi-jima Island during winter 2016–2018 to monitor phonating whales. 24-hour recordings were continuously conducted for 1–3 months per year. The number of singing whales was acoustically counted every hour by using time difference of arrival of each song at both recorders. The mean number of detected singers in each time of day was calculated and compared with the tidal cycle. In total, 5,015 hours recording data were collected. 0–9 singers per hour were detected (mean ± SD = 3.5 ± 1.5 singers/hour), and they appeared throughout the day. The acoustic occurrence of singing whales was peaked in the early morning and dusk and decreased during the daytime when we used all data; however, the peak time was shifted in connection with the tide type. The mean number of detected singers was less during spring tide periods than during the other periods, and that was more during neap tide periods than during the other periods. Additionally, during spring tide periods, more singers were detected in the high tide time than in the low tide time. Our results suggest that the singing activity of humpback whale singers is influenced by the diel and tidal cycles, or they moved offshore where is outside of the detection range of our recorders during the daytime.

Passive acoustic monitoring shows diurnal and seasonal patterns for Irrawaddy dolphins (Orcaella brevirostris) in Kep, Cambodia.

(1) Marine Conservation Cambodia
(2) Marine Conservation Cambodia, Kep, Cambodia
Corresponding Author: sarahtubbs123@gmail.com

Irrawaddy dolphins (*Orcaella brevirostris*) are considered Endangered on the IUCN's Red List of Threatened Species, with marine populations being the subject of relatively little research focus in comparison to their freshwater counterparts. In Cambodia's Kep Archipelago, the species faces threats from a high intensity of Illegal, Unreported and Unregulated (IUU) fishing activities, which leads to bycatch, habitat degradation, and prey depletion. As part of The Cambodian Marine Mammal Conservation Project's activities to support the conservation of this population, innovative Passive Acoustic Monitoring (PAM) techniques were employed to collect baseline data on the population's diel and seasonal activity patterns. A C-POD (Continuous POrpoise Detector) was deployed east of Koh Ach Seh (10°21'31" N, 104°19'22" E) on 23 June 2018, to continuously recorded cetacean clicks between 20 and 160 kHz, produced within a 1km range of the device. A Generalised Linear Model was used to examine the initial six-months of data recordings. Significantly more Detection Positive Minutes (DPM – the minutes within each hour with positive recordings of cetaceans) were recorded in non-daylight hours compared to daylight hours, with the fewest DPM recorded between 08:00 – 15:59. September had the highest number of DPM, compared to any other month, followed by October and November. The diurnal and seasonal activity patterns observed could be explained by prey movements, freshwater inputs or monsoon seasonality. This study is the first of its kind, using long-term PAM techniques to study Irrawaddy dolphins. Results reveal crucial information on the population's temporal and seasonal activity patterns. As local IUU fishing predominantly occurs during non-daylight hours, the study also highlights a vital cause for conservation concern, regarding overlapping spatial and temporal use of the Kep Archipelago by both dolphins and IUU fishing vessels at night. Future research to determine population distribution and ranges, to shape future regional conservation strategies are suggested.

Comparison of salmon predation by harbour seals in estuary and non-estuary habitats in British Columbia, Canada

In British Columbia (B.C.), harbour seals are thought by some to have caused the decline of Chinook salmon, in turn contributing to the decline of Southern Resident killer whales. Recent harbor seal diet data has been restricted to a few years and has come primarily from scats sampled in estuary habitats near salmon bearing rivers. There is emerging evidence suggesting that only a subset of the total population consumes salmon, and that rates of salmon consumption vary considerably with sampling location, season and year. We sampled ~2000 scats collected at an estuary (Cowichan Bay) and 7 non-estuary sites from spring to fall in the Strait of Georgia. Using a combination of hard part and high-throughput DNA techniques, we determined seals consumed a wide range of prey, with gadids (primarily hake) and forage fish (primarily herring) dominating diets in both habitats (typically >75% of diet). Juvenile salmonids, chinook, and to a lesser extent coho and chum, collectively made up 1.4% (CI = 0.8–2.1%) of the spring diet at non-estuaries and 2.5% (CI = 1.4–3.9%) in Cowichan Bay. The difference is considerable when translated into number of salmon smolts consumed, and indicates smolt predation was 50% higher at the estuary site. Salmon consumption spiked in the fall (primarily returning adult chum salmon), and was higher in Cowichan Bay (35%, CI = 29–40%) than at non-estuary sites (9.1%, CI = 7.3–11.0%). In addition to being highly variable by site and season, rates of salmon consumption can vary significantly between years. Our findings highlight that estuaries should not be used as proxies for non-estuary sites when assessing predation on salmonids and that models estimating seal related mortality should consider differences in diets inside and outside of estuaries, over multiple years.

Using science and governance in establishing habitat conservation measures at the Saguenay–St. Lawrence Marine Park and surrounding waters to favor the recovery of the St. Lawrence beluga population.

The world's most southerly beluga whale (*Delphinaterus leucas*) population, the endangered St. Lawrence beluga, lives downstream of industrial North America. The main threats to the recovery of the population are exposure to contaminants and to disturbance by intensive navigational activities such as shipping and tourism. The Saguenay-St. Lawrence Marine Park, of which 77% of the territory is designated critical habitat for the beluga population and which also encompasses feeding grounds for a diversity of other whale species, is one of the areas used by marine mammals where marine traffic is most intensive in Canada. Under Parks Canada's Conservation and Restoration Program for species at risk, the marine park team is implementing a habitat conservation project (2017-2022) entitled *Sharing the waters with belugas*. The purpose of the project is to protect and restore the acoustic environment of important habitats for species at risk in the marine park, particularly the beluga, to contribute to their recovery while remaining one of the best places in Canada to observe mammals and to increase public support for marine conservation. To date, two habitats have had their level of protection enhanced: 1) The Baie Sainte-Marguerite (<1% of the marine park territory) where navigation was prohibited as of 2018 and 2) A significant portion of the upper St. Lawrence estuary (44% of the marine park territory) where whale watching activities have been excluded as of 2019. These two habitats are intensively used by female belugas and their young during the summer, and their protection is considered essential to favor the recovery of the population. This presentation will focus on the scientific and governance approach used, the challenges, the measures put in place and the first results of compliance to inspire other marine mammal protected areas in their conservation actions to enhance marine mammal habitat protection.

Managing cumulative effects of multiple stressors on marine mammals.

Tyack, Peter
University of St Andrews, St Andrews
Corresponding Author: plt@st-andrews.ac.uk

Assessing the cumulative effects of multiple stressors is a top priority problem in marine ecology. Environmental assessments of proposed actions often must consider the cumulative effect of the action when added to those of other human activities. Scientists view cumulative effects from the perspective of populations rather than activities, with effects accumulating when organisms are repeatedly exposed to the same or different stressors. Most marine mammals are protected from intentional hunting, but over the last century, global industrialization and population growth have created or increased stressors, including chemical and noise pollution, loss of habitat, and bycatch in fishing, which alone kills hundreds of thousands of marine mammals globally each year. Significant

progress has been made in understanding how marine mammals respond to specific dosages of stressors such as toxins or noise, and these dose-response relationships can be used to predict the impact of stressors on individuals. In some cases, especially where we understand the mechanism of action, we can predict the aggregate impact of repeated exposure to the same kind of stressor. However, we cannot predict how stressors will interact to affect individuals and populations of marine mammals. A 2017 US National Academy of Sciences report defines an interaction between stressors to occur if the dose-response function of one stressor changes when the dosage of another stressor is changed. Interaction between stressors can be investigated by estimating dose-response functions of one stressor at several different dosages of a second stressor which cover the expected range in the future environment. To decide how best to reduce the effects of activities that threaten marine mammals, we need to develop methods to assess how changes in a combination of stressors can best bring populations to a healthy resilient state.

Post-release monitoring of a stranded and rehabilitated short-finned pilot whale (Globicephala macrorhynchus)

Little is known about the movements and behaviors of pilot whales, due to the expense and logistical challenges of studying these pelagic, deep-diving odontocetes. Stranded whales offer unique opportunities to learn about these species, particularly if they are able to be released. A subadult female short-finned pilot whale (*Globicephala macrorhynchus*) stranded on the NE Gulf of Mexico Florida coast in June 2017, was rehabilitated for 38 days and released off the West Florida Shelf. Post-release monitoring of the individual, "Gale," lasted 32 days using a satellite-linked tag that provided data on location, dive depth, and dive duration. Gale appeared to use ocean currents to facilitate a SE movement around Florida, and then a northward movement along the continental shelf break to the waters off Cape Hatteras, North Carolina. During her travels, Gale received a net positive assistance from ocean currents, especially east of Florida where 57% of her travel distance was congruent with the surface speed and direction of the Gulf Stream. The current-assisted travel contributed in-part to our observation of Gale traveling further (4,152 km) and faster (130 km·day^{-1}) than previously reported for *Globicephala spp.* Gale's dive behavior was typical of other pilot whales, with average dive depths (243 ± 136 m) and durations (7.9 ± 2.2 min) within the range of reported values for *Globicephala spp.* Gale also occupied habitats commonly used by pilot whales, such as the continental shelf break and submarine canyons. Thus, it is likely that Gale was using her natural abilities and skills effectively, and that her movements and behaviors could be considered representative of short-finned pilot whales in the Gulf of Mexico and northwestern Atlantic Ocean. The information presented here contributes to a better understanding of pilot whales, their movements between ocean basins, and to the assessment of rehabilitation and release protocols.

The respiratory physiology of the harp seal (Pagophilus groenlandicus): Total lung capacity, anatomical dead space, and ventilatory response to exercise.

Size and proportional makeup of the marine mammalian respiratory system are important determinants of lung compression at depth, ventilatory airflow, and effective ventilation. Data on phocid total lung capacity (TLC) and dead space (V_D) are sparse, as are quantitative studies of gas exchange in unrestrained seals. In the harp seal (*Pagophilus groenlandicus*), an abundant pinniped in the northern hemisphere, we have a) determined and modeled TLC and V_D, and b) investigated ventilatory responses to exercise. Sixteen individuals (West-Ice stock; both sexes, newborn–adult, euthanized for unrelated research purposes with permits from Greenland authorities) were used for air and water volumetry of excised lungs ($n_{animals}$=10, $n_{measurements}$=132) and conducting airways, from nose to bronchi ($n_{animals}$=16, $n_{measurements}$=147). The TLC was determined with pressure–volume curves, it was 70 [60–88] mL/kg at 40 cmH_2O transpulmonary pressure. It scaled isometrically with total body mass (slope 1.006; r^2=0.99, log–log linear regression); V_D scaled

slightly allometrically (slope 1.129; r^2=0.97). Total adult V_D (3.1 mL/kg, estimate) was partitioned into 9% nasal, 55% tracheal, and 36% bronchial volume. One juvenile female (59 kg) was trained for voluntary spirometry on land/in water at rest and after standardized physical exercise of varying effort levels. Ventilation (n_{trials}=60, $n_{breaths}$=500+) was substrate-specific; minute volume ($\dot{V}_E$) at rest on land was half that in water. Here, average tidal volume (V_T) at rest was high (26% of $TLC_{predicted}$), but it still doubled after heavy exercise (45–60% of $TLC_{predicted}$), as did $\dot{V}_E$. Respiratory frequency was high (31 min^{-1}) and did not change much with physical activity. The maximum V_T (79% of $TLC_{predicted}$) was comparable to human vital capacity (75–80% of TLC). Conclusions: The proportionally small nasal and large tracheal V_D potentially facilitate pressure equalization and lung collapse at depth, respectively; thus, reducing risks of barotrauma and decompression sickness. Increased ventilation after exercise resulted almost solely from an increase in V_T.

DNA barcoding based identification of fish species in the diet of cetaceans at the South-Western coast of the Black Sea.

Three small cetacean species: the bottlenose dolphin (*Tursiops truncatus*), the short-beaked common dolphin (*Delphis delphius*), the harbor porpoise (*Phocoena phocoena*) inhabit the waters of the Black Sea. All three are under enormous human-induced pressure: direct hunting until 1983, present day by-catch, over-exploitation of the food base, pollution, habitat modification and disturbance by heavy marine traffic. Although the distribution and movements of dolphins are closely related to their feeding habits, only few researchers on the Turkish coastline conducted studies on the diet of cetaceans. We carried a pilot study on DNA barcoding based analysis of the stomach content of two cetacean species stranded to the coast of south-western region of the Black Sea (Zonguldak, Turkey) in spring 2018. DNA metabarcoding as a high throughput sequencing approach has been proven useful in identification of undigested remains in dolphin stomachs, and is more reliable than traditional diet analysis using morphological identification. We used complete homogenized stomach contents of the short-beaked common dolphins and the harbor porpoises. After DNA extraction, the taxon-specific fragments were amplified and sequenced using universal primers for teleost fishes and invertebrates. The most abundant fish species in the diet of the short-beaked common dolphin, as well as of the harbor porpoise, was the horse mackerel. Our research is the first to provide taxonomic identification of prey species of the Black Sea cetaceans using DNA barcoding.

Molecular biomarkers of stress and immune system function in beluga blow

Corresponding Author: eunal@mysticaquarium.org

Using non-invasive sampling techniques is critical especially for cetaceans as a part of a global concern for marine mammal health, and to support conservation efforts of threatened/endangered species in a changing marine environment. Belugas (*Delphinapterus leucas*), such as those in Cook Inlet, AK are critically endangered and others are on the decline. Analysis of exhaled breath condensate (blow) has been established as a non-invasive method for studying the composition of airway lining fluid with potential to identify immune/inflammation related biomarkers (e.g. cytokines, chemokines, and toll-like receptors). This study investigated molecular biomarkers of health using quantitative PCR (qPCR) on cells recovered from beluga blow for assessment of respiratory and systemic immune function. The feasibility of carrying out sex determination and gene expression measurements in the same blow sample was also investigated. Blow samples were collected into 50ml conical tubes twice weekly before, during and after various stressor events (i.e., hydraulic beluga lift construction, whale transport) and the DNA and RNA were simultaneously extracted. To date, validation of qPCR protocols were successfully carried out for inflammatory markers including cyclooxygenase-2 (COX2), C-C-Motif-Chemokine-Ligand-5 (CCL5), interleukin-8 (IL8); regulatory markers including transforming-growth-factor-beta (TGFb), glucocorticoid-receptor (Nr3c1), and a reference gene (GAPDH). The results demonstrate that both DNA (4-25ng/µl) and RNA (5-350ng/µl) can reliably be obtained, and sex determination and gene expression measurements of 4-7 genes can successfully be carried out in the same blow sample depending on yield. Moreover, pre- and post-blow samples taken during acclimation of the whales to a hydraulic lift resulted in significant increase of COX2 and Nr3c1 genes ($p<0.05$). Since gene expression studies can capture perturbations at the cellular level before clinical symptoms develop, the

proposed method can be utilized as an additional diagnostic and health monitoring tool for belugas under professional care as well as for health assessment studies of wild/free-ranging whales.

Gray whale migratory movements between the western and eastern North Pacific

Gray whales have traditionally been considered to consist of two populations, one in the western North Pacific (WNP) and the other in the eastern North Pacific (ENP). The ENP population ranges from wintering areas off Baja California, Mexico, to summer feeding areas in the Bering, Beaufort, and Chukchi Seas. The WNP population feeds off Sakhalin Island and southeast Kamchatka, Russia. Historical evidence indicates that the South China Sea may have been used as a wintering ground in the WNP. Genetic, telemetry and photo-identification comparisons between the ENP and the WNP show some degree of population mixing during the winter. Here we present a multinational effort to evaluate trans-Pacific movements of gray whales photo-identified in both the ENP and WNP. Images of 379 whales identified on the summer feeding grounds off Russia (316 from Sakhalin; 150 from Kamchatka), were compared to 10,685 individuals photo-identified in the wintering lagoons of Baja California, Mexico (1,590 from Laguna Ojo de Liebre; 7,151 from Laguna San Ignacio; and 1,994 from Bahia Magdalena). A total of 42 matches were found, including 13 Sakhalin-Kamchatka-Mexico, 25 Sakhalin-Mexico, and 4 Kamchatka-Mexico. These matches consist of 21 females, 13 males, and 8 whales of unknown sex. Thirteen whales were observed making round trips (summer-winter-summer), 11 with winter in Mexico and the following summer in Russia, and 6 with summer in Russia and the following winter in Mexico. The others were matched in non-sequential years. These 42 matches, in combination with 12 previous matches, result in 54 gray whales being linked between Russia and Mexico. Movements between the WNP and ENP for at least 25% of the gray whales identified off Sakhalin Island and Kamchatka highlight the conservation and management importance of further examining gray whale population structure in the North Pacific.

Combining an unmanned aerial vehicle and computer vision to monitor and automate abundance counts of northern fur seals (Callorhinus ursinus)

Visual counts of northern fur seals (NFS) have traditionally been collected by observers during the breeding season. However, NFS form dense aggregations on rugged coasts making visual surveys laborious and difficult to verify. We tested the utility of using an un-manned aerial vehicle (UAV), (Phantom 4 PRO) to collect aerial photos of NFS on a rookery to use for abundance counts. We flew the UAV at ~25 m altitude on transects overlapping by 50-75%. A single flight of an entire rookery produced about 1,000 photographs. Stitching and manually counting images proved laborious and time consuming but verified that visual head counts on images were accurate and replicable. To improve image processing, we used Photoscan software to stitch images into a high-resolution geo-referenced

orthophotoplan (OPP), eliminating the need to identify a border between distinct images when counting is performed on separate images. However manual counts of one survey on a single OPP still required up to 50 hours of observer time (e.g. one complete survey was approximately 26,000 fur seals). To reduce analysis time and optimize the aerial count method we evaluated the ability of a deep learning neural network known as U-Net to automate counts. This convolutional neural network was developed for biomedical image segmentation. We trained the U-Net to recognize and count individual seals on images by masking an area to be detected. In a preliminary test we created about 1,500 image-mask pairs and had the U-Net count an entire OPP map. Compared model count results was with at least 97.5% accuracy. This novel survey method substantially reduced survey cost and analysis time while producing highly accurate, reproducible, and verifiable results. These methods could easily be applied to the survey methods for other species found in high-density aggregations, for example at rookeries, haulouts or even migrating herds.

Plugging into marine mammal science: The power of the earplug.

To understand the cumulative effects of multiple stressors on large baleen whales, it is imperative to quantify and understand both the types of stress (*e.g.*, intrinsic, extrinsic and ecological drivers) and their relative contributions. Therefore, the long-term goals of this project are to reconstruct lifetime (i.e. birth to death, ~6-month resolution) stress and stressors profiles in baleen whales using their earplugs. Reconstructed chemical and elemental profiles were derived by combining markers of stress (i.e. cortisol) and stressors profiles with age and date estimates derived from the earplug. Specifically, markers of reproduction, aging (DNA), foraging (i.e. bulk carbon and nitrogen stable isotopes), community structural shifts (i.e. compound-specific amino acid stable isotopes), and pollution were assessed. Lifetime hormone profiles, which resembles repeat sampling, were baseline corrected and provided an opportunity to combine profiles from different individuals, species, and generations. Stress and stressor profiles were reconstructed from blue, humpback, fin, gray, and Minke whales. Here, we present 150 years of stress data and examine historical relationships between cumulative stress and industrial whaling as well as current trends in baleen whales. Additionally, we highlight the utility of this matrix to assess pregnancy rates, climate change, contamination, community structure, and the long-term health impacts of stress. The results of this study will contribute to improving mitigation strategies through improved assessments of the potential impacts of anthropogenic activity.

Cultural geography of Eastern Caribbean sperm whales.

Cetaceans have complex oceanic distributions that relate to their social structures. In the sperm whale (Physeter macrocephalus), a nomadic deep-diving species, females live in stable matrilineal social units which are themselves members of larger cultural clan defined by vocal dialects. Most of what we know of Caribbean sperm whale social dynamics comes from a long-term study off Dominica where over 20 social units have been monitored since 2005 and two vocal clans have been identified. It was expected that social units encountered in Dominica ranged throughout the Eastern Caribbean with, perhaps, differences in distribution between the two vocal clans, since studies in the South Pacific found sperm whales to have home ranges spanning around 2200km. To test these hypotheses, from February to April 2019, we surveyed the Lesser Antilles (between Grenada and St Kitts, spanning 550km) from a sailing vessel. When encountered, sperm whale groups were tracked from hours to days, while acoustic and photo identification data were collected. We had 38 encounters with female groups: 15 solely acoustic and 23 from which we obtained photo-identification data. All female encounters were leeward of the islands and only males were heard windward. Groups from both the EC1 clan (10 groups) and EC2 clan (7 groups) were identified throughout most of the survey routes. However, none of the previously identified EC1 social units were found outside of Dominica and Guadeloupe. Instead, 14 new sperm whale groups (4 probably EC1, 6 probably EC2, 4 unknown) were encountered around the other islands. In contrast,

one EC2 unit from Dominica was re-identified 170km away, off St. Lucia. These results suggest that sperm whale societies might be organized at a smaller scale than expected in the Eastern Caribbean and that the clans have distinctive ranging patterns.

First abundance estimate of the white whale (Delphinapterus leucas) stock in Svalbard, Norway.

The Svalbard Archipelago in the Norwegian High Arctic is experiencing rapid declines in the seasonal duration and extent of sea-ice cover, and local tidewater glaciers are melting and retracting onto land. These changes represent a serious threat to all of the resident ice-associated species, including white whales (*Delphinapterus leucas*). White whale feeding in the past in this region was concentrated in front of tidewater glaciers and at edges and under annually formed land-fast ice. Despite extensive hunting in the past, no assessments of abundance have been conducted for white whales in this region, so neither the stock size, nor the stock trend, are known. The first ever aerial survey of the Svalbard white whale stock was conducted during the late summer in 2018. This survey covered: (i) coastline of all major islands in Svalbard (ii) major fjords and (iii) transects into the open ocean. A total of 265 individuals (in 22 groups) were detected along 4965 km of coastline transects. No white whales were observed along the 1481 km of fjord transects or along the 535 km of open ocean transects. After correcting for surface availability, using tracking data from the same stock in previous summer seasons, the Svalbard white whale stock was estimated to number 549 (95% CI 436− 723) individuals. This estimate is surprisingly low considering that this species is one of the most commonly observed Arctic cetacean in the area, but it does confirm suspicions based on challenges encountered in finding animals when operating tagging programmes. This first stock size estimate is important in the context of the rapid environmental change that is taking place in the region, providing an important baseline for comparison with future abundance estimates. It also represents an essential step in the local conservation and management of this species.

Marine mammal science and ethical dilemmas: The case of dolphin drive hunts.

The dolphin drive hunts that occur annually in Taiji, Japan have received global condemnation on both welfare and sustainability grounds. The considerable ethical and political controversy surrounding these and other small cetacean hunts serves as just one example of a contemporary issue challenging experts in the field of marine mammal science. The ethical dilemmas facing the organizations active in marine mammal research and conservation, including the Society for Marine Mammalogy (SMM) and the European Cetacean Society (ECS), may become more pronounced as public and member interest in the protection of marine mammals grows through heightened awareness and exposure through social media. We present a historical timeline of the SMM's response to the dolphin drive hunt issue to illustrate the intersection of science and policy, while exploring the human dimensions that often drive conservation and welfare policy. We evaluate the challenges associated with integrating prevailing scientific knowledge with ethical, social and cultural dimensions of controversial marine mammal issues and examine the roles, boundaries and potential for international marine mammal societies in responding as a collective to policy issues and debates that are often compelled by scientific and public interest. We examine existing ethical guidelines within the SMM and ECS to explore the intersection of science and policy to assist in navigating increasingly complex threats to marine mammals. As professional marine mammal societies, should we develop policy positions on high profile marine mammal issues? What are the barriers to translational science and related advocacy within the marine mammal scientific community? A rapidly changing natural environment will only exacerbate the ever-changing social, political and cultural landscapes researchers face in disseminating and applying scientific data within management and policy arenas.

Effect of mussel farms on endemic endangered Hector's dolphins, Cephalorhynchus hectori hectori, at Banks Peninsula, New Zealand: An ecosystem perspective.

valma163@student.otago.ac.nz

With a growing human population, demand for food has steadily increased, as has pressure on marine resources. Over the last two decades, aquaculture production has increased dramatically, including in New Zealand, where the culture of green-lipped mussels (*Perna canaliculus*) has experienced rapid expansion. Nine mussel farms have been established at Banks Peninsula, home to a resident population of Hector's dolphins. In 1988 a marine mammal sanctuary created new restrictions on fishing, but did not affect aquaculture. Here we aim to assess the effects of mussel farms on Hector's dolphins from an ecosystem perspective. Therefore, their effect on the environment and the dolphins' habitat use was analysed in three bays with mussel farms (treatments) and three without (controls). The effect on water was measured via analysis of dissolved nutrients, and on sediment via analysis of organic matter. Habitat use by the dolphins was quantified through passive acoustic monitoring. Results showed significant differences (ANOVA, $p < 0.005$) in the dissolved nutrient content in the water and organic matter (%OM) in the sediment between bays and seasons. Sediment results indicated higher %OM in bays with mussel farms through all sampling seasons. Additionally, the %OM values were positively correlated with the farm's size ($r^2 = 0.42$, $p < 0.005$) and inversely correlated with distance from the farm. Acoustic data showed dolphin detections in all bays on >75% of days sampled. There were significant differences in detections between bays, but no consistent effect of mussel farms. In bays with farms, there were lower rates of detections adjacent to farms, compared with monitoring sites on the opposite side of the bay, suggesting small-scale displacement. This study suggests that mussel farms have significant impacts on the environment of Hector's dolphins. Their effects should therefore be carefully considered in future management of the habitat of this endangered species.

Where and when are you going? Unravelling distribution patterns of baleen whales through a bibliographic review.

Macaronesia, an oceanic area located in the Northeast Atlantic, exhibits a high topographic and oceanographic complexity that enables a rich biodiversity. Among cetaceans, seven species of baleen whales have been recorded in the area. These are migratory animals that travel long distances between feeding grounds at high latitudes in summer and tropical areas for mating and breeding in winter. Being such mobile animals, the conservation and management of baleen whales' habitat is highly challenging. Hence, knowing and understanding the patterns of their distribution is fundamental. Despite the many records of baleen whales in Macaronesia, heterogeneity in research effort has resulted in scattered occurrence data that leads to an incomplete picture of their distribution in the area.

With that in mind, the aim of this study was to increase knowledge of distribution patterns of baleen whales and identify research effort gaps in Macaronesia.

From a total of 14 peer-reviewed publications, four public reports, two poster presentations, and four databases, we gathered 1798 records in Macaronesia since 1990 for four species of baleen whales: minke whale (*Balaenoptera acutorostrata*), fin whale (*Balaenoptera physalus*), blue whale (*Balaenoptera musculus*)and humpback whale (*Megaptera novaeangliae*). Spatio-temporal descriptive analyses and modelling were carried out in order to understand occurrence patterns.

The results show a big lack of research effort and occurrence data in offshore areas and in some coastal waters, namely off the West African coast. Moreover, blue, fin, and humpback whales are sighted mainly in spring in the north of Macaronesia, while minke whale distribution is clearly different, with a stronger presence in summer. This study highlights areas in urgent need of research effort in order to inform decision-makers and support effective measures for the protection and conservation of baleen whales in Macaronesia, an area crossed by the migratory corridors of these whales.

Skeletons in the closet: Investigating body size change in California sea lions over 60 years.

Body size is a fundamental trait influencing the ecology and physiology of marine mammals. Several studies have suggested a size reduction in some pinnipeds species over the last few decades is a consequence of density-dependent intraspecific competition and indirect competition with commercial fisheries and/or of climatic variability. California sea lions (*Zalophus californianus*; CSL) present a unique opportunity to investigate the relationship between body size and population density. Population density has steadily increased since the 1970s after centuries of commercial sealing and now may be approaching carrying capacity. We hypothesize that CSL have reduced in size over the last decades with population recovery. To assess this hypothesis, we measured the standard (SL) and condylobasal (CBL) lengths of 296 adult male CSL skulls that stranded along the coast of northern California over the last 60 years. We grouped specimens by decade (<1970, 1971-1979, 1980-1989, 1990-1999, or >2000) and performed one-way ANOVA and Tukey's multiple comparison tests. Mean SL differed significantly among decades ($p < 0.001$), with significant differences between those smaller specimens from the 1960s and 1970s and the larger specimens from later decades ($p < 0.001$). The CBL was more stable over time; however, we found significant variation in the mean among decades ($p < 0.001$). Again, specimens from the 1970s and 1980s had smaller mean CBL than specimens from some later decades ($p < 0.05$). Overall, these results contrast with studies performed on other pinniped species, suggesting that local factors other than population density such as changes in primary production, prey composition, or interspecific competition are affecting body size in these animals. Further work is being conducted to explore these other mechanisms and the ecological consequences of these shifts in body size.

Cetacean Morbillivirus infection in a Guiana dolphin (Sotalia guianensis) off the coast of Sao Paulo, Brazil: A case report.

By-catch is a major threat to cetaceans worldwide. Factors predisposing to by-catch may not be apparent in many instances; however, systemic infectious diseases could play a role. *Cetacean Morbillivirus* (CeMV) is a highly contagious pathogen that may cause significant morbidity and mortality in various odontocete and mysticete species. Hereby we provide pathologic evidence of CeMV infection in a Guiana dolphin (*Sotalia guianensis*) representing the first case confirmed in south-central coast of Sao Paulo state, Brazil. A 28 kg, female, juvenile (2-yo according to dental analysis) Guiana dolphin stranded dead in Praia Grande, São Paulo (-24.075061; -46.5761138), in September 10th, 2018. The animal was collected during the Santos Basin Beach Monitoring Project (*Projeto de Monitoramento de Praias da Bacia de Santos* - PMP-BS), one of the monitoring programs required by Brazil's Federal Environmental Agency, IBAMA, for licensing process of the oil production and transport by Petrobras at the Santos Basin pre-salt province. The carcass was fresh at necropsy. Grossly, linear erosions and lacerations compatible with by-catch were observed in the rostrum, peduncle and pectoral and caudal fins. Additional findings included: pulmonary edema and hemorrhage; verminous pneumonia (*Halocercus brasiliensis*); middle ear trematodiasis (*Nasitrema attenuate*). Microscopically, the main lesions were: marked pulmonary edema; bronchointerstitial pneumonia with necrotizing bronchiolitis and intracytoplasmic and intranuclear inclusion bodies; eosinophilic and lymphoplasmatic and proliferative pleuritis with intralesional *H. brasiliensis*; and cerebral lymphocytic meningitis. PCR analysis for *CeMV* was positive in lung and lymph nodes. To our knowledge, this is the first report of CeMV in a Guiana dolphin from the south-central coast of São Paulo state, Brazil. These results have implications for CeMV dynamics and geographic range. In the present case, the cause of death was ascribed to by-catch. Nonetheless, the severity and extent of concurrent CeMV infection and endoparasitism might have played a role predisposing to by-catch.

Behavioral contexts change the social connectedness of individual dolphins specialized in foraging with fishermen

joao.vallepereira@gmail.com

Social interactions among animals are diverse and dynamic, forming heterogeneous social environments within which some individuals are more connected than others. This heterogeneity can stem from multiple factors—from the ecological environment to individual traits. While individual behavioural specialisations has been shown to structure animal population, how they modulate sociality at the individual level is much less clear. Here we investigated whether a specialized foraging tactic can influence individual social connectedness. In southern Brazil, a population of bottlenose dolphin (*Tursiops truncatus*) forages with net-casting fishermen. Not all dolphins use this tactic with the same frequency, which shapes the population into distinct social modules—those that often and those that rarely forage with fishermen. We tested if the frequency of foraging with fishermen influences the number of social associations dolphins maintain during two behavioural contexts—foraging and not foraging. We found that dolphin that frequently forage with fishermen tend to have a higher number of associations when foraging (β=0.005, SE=0.001, Z=4.474, df=30, P<0.001), being more socially connected and central in the social network. However, this pattern reverses outside of the foraging context: dolphins that often interact with fishermen have fewer connections (β=-0.005, SE=0.001, Z=-3.812, df=30, P<0.001). Despite changes in network centrality, social modules were noticeable in both behavioral contexts. These results suggest that social preferences are context-dependent and illustrates how specialized behavior can influence social patterns at the individual and the population level.

Key-words: bottlenose dolphins; *Tursiops truncatus*; social networks

Does dental variation reflect the level of genotypic variation in ringed seals?

Valtonen, Mia; Kammonen, Juhana; Löytynoja, Ari; Auvinen, Petri; Jernvall, Jukka

Corresponding Author: mia.m.valtonen@helsinki.fi

Pinnipeds tend to exhibit higher dental variability than mammals in general, usually attributed to the lack of tight occlusion. This suggests that selection in tooth shape is relaxed in seals. Moreover, their permanent teeth form and erupt already during prenatal development, which implies that tooth shape is predominantly determined during development and little affected by environment. Therefore, we hypothesize that phenotypic variation in seal teeth should reflect the level of genotypic variation in a given seal population. We examined ringed seals (*Pusa hispida*) by comparing four populations of different sizes: two marine populations, Arctic (*P. h. hispida*) and Baltic (*P. h. botnica*), and two isolated lake populations, Ladoga (*P. h. ladogensis*) and Saimaa (*P. h. saimensis*). The population sizes of the Arctic, Baltic, Ladoga, and Saimaa seals are >1,500,000, >11,000, >3,000 and ~400 seals, respectively. We assessed the level of phenotypic variation in lower postcanine teeth (P2-P5) by examining cusp number and size. We utilized museum collections and inspected >250 individuals from each population. In order to assess the level of genotypic variation, we sequenced genomes of ten seals from each population. As expected, the marine populations showed the highest phenotypic and genotypic diversity, whereas the smallest population, Saimaa, stood out with clearly the lowest phenotypic and genotypic variation. Our study suggests that even though mammalian dentitions are generally highly adaptive structures, in seals dental variation could be used as a proxy for the level of genotypic variation.

Estimating entanglement and vessel collision scarring rates in southeast Alaskan Humpback whales (Megaptera novaeangliae) using unoccupied aerial systems

As capital breeders, humpback whales (*Megaptera novaeangliae*; HBW) rely heavily on accumulated energy reserves to meet the costs of growth,

migration and reproduction. Fishing gear entanglements and vessel collisions impose significant demands on the energy budgets of large whales - the equivalent of an unnatural and taxing life-history stage. While previous studies have utilized boat-based photography to estimate scarring rates of rorqual species, these rates are likely underestimates because sub-surface scarring may not be detectable from research vessels. This study used Unoccupied Aerial Systems (UAS) to estimate the proportion of non-lethal entanglements and vessel strikes among HBW in southeast Alaska (SEAK). The dorsal surface of each whale was divided into five regions (pre-blowhole, post-blowhole, dorsal fin, peduncle and caudal flukes), with scarring codes assigned to each region based on the presence/absence of scarring deemed consistent with previous entanglement or vessel collision. From this, individual whales were assigned a likeliness code subsequently used to calculate minimal, conditional and maximal scarring percentages. Between July and August 2018, 90 UAS flights were conducted during 13 boat-based surveys. From a sample of 68 individually identified HBW, we report minimal, conditional and maximal scarring proportions of 35.1%, 43.1 % and 53.7%, respectively. Our results coincide with previous boat-based scarring analyses for HBW in SEAK (52–78%) and the Gulf of Maine (48–65%), but exceed rates estimated for HBW in Iceland (24.8%). We demonstrate how UAS provide a novel perspective from which to quantify scarring rates in a cost-effective and efficient manner. Since HBW in SEAK form part of the Hawaii distinct population segment, future analyses will expand to include HBW in Hawaii. An enhanced understanding of anthropogenic sources of HBW mortality is imperative, with vessel-related HBW mortality rates in US West Coast waters estimated to be twice the recommended potential biological removal limit.

Lessons from a decade of monitoring coastal dolphins in port areas in Brazil: Guidelines to improve and align monitoring actions.

Port areas are globally expanding and impacting the marine environment, particularly coastal dolphins, which are sentinels of the ecosystem health, quality and functioning. Therefore, their monitoring should be included in environmental management, planning and Environmental Impact Assessments (EIA). However, this integration poses a variety of challenges. Since 2007, our team has been monitoring Sotalia guianensis, a near threatened coastal dolphin, at one of the largest agricultural ports of South America, Paranaguá, which is located adjacent to a World Heritage Site. A variety of methodologies have been applied, such as occurrence, abundance and distribution estimates by photo-identification and line transect surveys, collection of stranding data, health assessments and acoustic monitoring. During this decade, many ways to improve monitoring of coastal dolphins in port areas have emerged. The most significant improvements to standard monitoring practices can be summarized in six general categories: **(1) Sampling design:** selecting adequate sampling days. **(2) Sampling methods:** categorizing anthropogenic activities (e.g. dredging, vessel traffic, pile driving); photo-identification recording group size and composition, habitat use, behaviour and skin diseases; recording bioacoustics to evaluate sound interferences; collecting stranded carcasses for histopathology and contamination levels. **(3) Data analysis:** improving health assessment; associating distribution with habitat quality and health scores; defining standard acoustic behaviour and evaluating potential masking impacts on dolphins' communication. **(4) Interpretation of the results:** assessing synergetic and cumulative impacts generated by different port activities. **(5) Communication of the results:** reducing the knowledge gap between the academic world and other port stakeholders. **(6) Implementation of results in environmental management and planning:** minimizing disparity between research and policy; improving feedback loops in management and planning cycles. These findings allowed the establishment of a set of guidelines to monitor dolphins in port areas, enhance EIAs with cetacean monitoring, and provide baseline support to align mitigation and conservation actions in port areas.

Oceanographic barriers, divergence, and admixture: Phylogeography and taxonomy of two putative subspecies of short-finned pilot whale.

In cetaceans, taxonomic uncertainty due to the difficulty of obtaining morphological data can hamper our understanding of the drivers of evolution in these species. We use genomic data to examine these forces in the short-finned pilot whale. While being recognized as a single global species, it includes at least two distinct morphological forms originally described in Japan: the 'Naisa' and 'Shiho' forms. We first examine phylogeographic patterns of divergence using mitogenomes (N=181 samples) and nuclear SNP loci (112 SNPs, 105 samples), and find evidence for three evolutionarily divergent types within the species. Next, we test taxonomic structure among those types using mtDNA control region sequences (345 bp) from 735 globally distributed samples, which indicate subspecies differentiation between two of the types, separated by the East Pacific Barrier: the Shiho subspecies (eastern Pacific Ocean and northern Japan) and the Naisa subspecies (Atlantic, Indian, and western/central Pacific Oceans). The third type, found only in the Atlantic Ocean, is a divergent population within the Naisa subspecies, separated from the western/central Pacific and Indian Oceans by the Benguela Barrier off South Africa. Finally, we sequence a representative nuclear genome from each of the three different types and a long-finned pilot whale to further examine their evolutionary relationships. Results from analyses of these full genomes suggest differences in ancestry shared with the long-finned pilot whales between the types of short-finned pilot whales, which could indicate incomplete lineage sorting or inter-specific introgression, with no significant mixing between the three types of short-finned pilot whale.

Linking climate and ocean productivity to the prevalence of southern right whales (Eubalaena australis) in South African waters

vandenberggideon@gmail.com

South African coastline surveys conducted since 1969 reveal fluctuations and a recent reversal in a long-running increasing trend in abundance of southern right whales (*Eubalaena australis*, hereafter SRWs), whose populations have been recovering from historic whaling. Furthermore, the surveys reveal that the typical three-year calving cycle of female SRWs has shifted to four- or five years, implying either additional resting years between successive calving events or calving failure. This study used wavelet analysis, an effective method of time series analyses on non-stationary data, to reveal significant synchrony in the cycles of SRW cow-calf pair counts and various climate indices (Oceanic Niño Index, September Antarctic sea ice extent and the Antarctic Oscillation) as well as ocean colour (January chlorophyll a concentrations in three putative SRW feeding grounds). In addition, autoregressive integrated moving average (ARIMA) models were used to investigate the potential role played by ocean colour and the various climate indices in the inter-annual fluctuations of cow-calf pair counts, as well as the recent reversal in their increasing trend of local abundance. The impacts of climate are thought to be mediated through the influence of physical oceanography on SRW prey (krill and copepod) availability, while chlorophyll a concentrations have been found to correlate with densities of SRW prey. These aspects ultimately impact feeding success and body condition of SRW, and consequently their reproductive

condition and migratory behaviour. ARIMA models analysing the inter-annual fluctuations in SRW cow-calf pair counts reveal significant model performance improvement through the inclusion of the Antarctic Oscillation and chlorophyll a concentrations from two of the three putative SRW feeding grounds. Results from this study indicate that annual fluctuations in SRW calf abundance in coastal South Africa appear closely influenced by feeding ground productivity and global climate indices, mirroring similar findings for South American and Australian SRW populations.

Generational cycling of PCBs in harbour porpoises of the southern North Sea

Polychlorinated Biphenyls (PCBs) may still negatively impact the harbour porpoise (*Phocoena phocoena*) population in the southern North Sea, even though bans on the use of these chemicals already started in the 1970s. This study focused on presenting an overview of PCB concentrations in age classes and sexes of harbour porpoises that beached along the Dutch coast (2006-2017). This provides information on different uptake routes of these contaminants in harbour porpoises during their life cycle and the influence of maternal off-loading to consecutive offspring. PCB concentrations were analysed in several sample types: blubber (all age classes: foetus, neonate, juvenile, adult), milk and placenta (adult females). Lowest PCB concentrations were found in blubber samples of foetuses. In males, PCB concentrations increased with increasing length, whereas in females concentrations decreased once animals reached the adult age class due to maternal offloading. Transfer of PCBs via lactation appeared to be a more important route than placental transfer, and was followed by uptake from food. Neonates, juveniles and adult (males) contained PCB concentrations up and above levels that may exert physiological or reproductive effects. This study further confirms that PCBs remain in the harbour porpoise population for a long time. Further insight into the role of PCBs and other contaminants effecting the health status of harbour porpoises is therefore needed.

Bottlenose dolphins in the Sound of Barra (western Scotland): A community with the potential to flourish, or one doomed to disappear?

Effective management of coastal developments requires accurate, up-to-date, and site-specific information on the spatio-temporal presence of local populations, and the underlying anthropogenic and natural drivers.

Using a combination of photo-identification (1995-2018) and acoustic C-POD data (2010-2013), this study collected information on population size, site fidelity, and life-history parameters (gender, calving rate, survival, inter-birth interval), and investigated year-round presence and relationships with environmental conditions, of a small bottlenose dolphin (*Tursiops truncatus*) community occupying the Sound of Barra (SoB) and surrounding waters off western Scotland.

Results showed that, based on >16,000 photographs, the community size has remained fairly stable at least since 2006 (limited efforts for earlier years prevented full assessment), consisting of ≤15 individuals annually, with a total of 19 dolphins identified. Summer site-fidelity of >20 years was observed for several individuals. Sex was determined for thirteen individuals, and a one-tailed binomial test on gender ratio confirmed that the community was female-dominated (three males and ten females). Results pertaining to the other biological parameters, although limited in available data, were comparable to those reported for other coastal populations.

Over 900 days of C-POD monitoring revealed a year-round presence of dolphins, with increased probability of detecting dolphins around sunset and sunrise. Despite close proximity between the two acoustic monitoring locations (<7 km), contrasting relationships with the tidal cycle were found, suggesting site-specific usage of these areas.

Although this community may represent an embryonic group with potential to grow, it is also plausible it represents a remnant of a previously larger group. As such, given the stochastic effects on small populations and potential Allee effects, the low numbers of reproducing females, in

combination with the community's geographic, and apparent social and genetic isolation from other dolphins, the future viability and existence of this community is of conservation concern.

Grey seal (Halichoerus grypus) predation on marine mammals in German waters – new tools and methods to determine predator identity.

Within the last years, scientific reports showed that grey seals throughout their European range utilise harbour porpoises, harbour seals as well as conspecifics besides their predominantly piscivorous diet. The present study gives a comprehensive overview of the current state of knowledge on the predation of marine mammals by grey seals in German waters. Outcomes of a retrospective analysis of necropsy results of suspicious harbour and grey seal (n = 417) and harbour porpoise (n = 1070) carcasses stranded on the coasts of Schleswig-Holstein throughout 27 years will be summarised focussing on pathological investigations of the retrieved carcasses along with behavioural observations. Occurring wound patterns are described and summarised in the form of assessment criteria and verified using two case reports. Suggested diagnostic parameters include lacerations with a linear, cut-like wound margin, large parts of detached epidermis and underlying tissue, as well as the loss of blubber tissue. Additionally, assessment criteria which aim to identify an interaction with predatory or scavenging foxes are suggested. Findings will be discussed in the context of observed predation behaviour, which can be regarded as largely consistent over time and between individuals. It is characterised by a prolonged phase of feeding during which mainly blubber tissue is removed by repeated teeth scraping over skin flaps. Whether this behaviour is part of a general specialised feeding strategy or rather related to an individuals' personality remains unclear. With regard to the presented findings, it must be assumed that this behaviour is at least regionally widespread. However, our understanding is not yet sufficient to conduct a comprehensive assessment of the ecological relevance and should therefore be a major focus of future research. Likewise, the use of standardised assessment criteria like the ones presented here, should be the common goal for future cross-national comparisons of recorded data.

Using passive acoustic data to explore spatio-temporal patterns in marine mammal community composition.

To date, the majority of studies investigating marine mammal distribution and behavior take a single-species perspective, which is often driven by the logistic difficulties of collecting appropriate data at sea. Passive acoustic monitoring tools, provided these exhibit sufficient bandwidth, have the potential to provide insights into community structure as devices operate autonomously simultaneously collecting data on baleen, pinniped and toothed whale acoustic presence. Data can provide information on local species diversity, residency times and patterns in species co-occurrence.

Using multi-year passive acoustic data from 6 sites in the Weddell Sea, Atlantic sector of the Southern Ocean, we here explore how local marine mammal community compositions develop over time.

We show that the effective number of species exhibited little variation over time, reflecting that species remain in Antarctic waters throughout austral winter. Community composition showed almost complete seasonal overturn, recognizing that species replace each other throughout the year. For all 6 sites, community dissimilarity increased with increasing temporal distance reflecting temporal trends in community composition beyond seasonality. Several species exhibited significant positive or negative co-occurrence patters over time, suggesting predator-prey relationships, competition for prey species as well as acoustic

interference between co-occurring species. These seasonal associations were consistent across and between all oceanic sites, but partly inversed at the Western Antarctic Peninsula recording site. This study shows that the application of biodiversity metrics to PAM data can foster insights to the timing of behaviors and community composition, which can boost the interpretation of responses in the light of ongoing environmental changes.

Numerical models to investigate North Atlantic right whale encounter rates with snow-crab gear in the Gulf of St. Lawrence.

Fishing-gear entanglements are a substantial source of injury and mortality among endangered North Atlantic right whales (NARW(s); *Eubalaena glacialis*). NARWs occupying the southern Gulf of St.Lawrence (sGSL) have been observed swimming and feeding near high densities of snow-crab fishing gear. The number of NARWs observed in the sGSL has increased since 2015; coincident with an increase in reported NARW entanglements in snow-crab and unidentified gear. The goal of this study was to use numerical models to estimate the frequency of NARW encounters with the snow-crab gear, as each encounter represents a potential entanglement. We combined the time and space gear distribution data (2015-2018) with empirically informed NARW movement models to estimate temporal and spatial variability in simulated whale encounter rates with the snow-crab gear. Due to the uncertainty in the timing and immigration rates of NARWs into the sGSL we present four models of immigration rate: constant, linear, and emigration rates from Cape Cod Bay, and the discovery curve of individuals in the sGSL; each used to populate movement models of individual whales. In 2017, there was an unusually high landings quota in the snow-crab fishery with ~45,500 traps reported and repeatedly deployed in the sGSL for a cumulative exposure of ~3.2 million trap-days. The trap-days were approximately half that level in 2015 and 2016 with ~36,000 traps and ~1.8 million trap-days reported in each year. Preliminary analyses indicate ~two-fold and ~four-fold increases in the average number of encounters between whales and gear when comparing 2015 and 2016, respectively, to 2017. Fisheries management measures in 2018 included static and dynamic area closures, and through the simulations we also examined the "fence effect" of these closures on encounter rates. We propose these models can inform fisheries management policy options and decision-making, and to assess the effectiveness of the conservation measures implemented.

Keep an eye on me: Using underwater photos and video from citizen science to evaluate prevalence of injury in pygmy killer whales (Feresa attenuata) in Hawai'i.

Assessing injuries and body condition of cetaceans has often been limited by what can be seen from the surface; while photos contributed from the public can help fill gaps in sighting histories, the recent increase in the use of inexpensive high-resolution underwater cameras allow better assessment of an animal's overall health. Underwater photos and video taken primarily from citizen science contributions off O'ahu and Hawai'i from 2006-2018 were used to examine the origin (anthropogenic or natural), type (using 10 predefined categories), and prevalence of external injuries in 55 individual pygmy killer whales known to be resident to the islands. Out of 39 encounters with 2,343 good quality underwater photos, 124 injuries were recorded and all individuals had at least one injury (mean=3.2, SD=1.2). Only 15.8% of injuries recorded underwater were completely visible in encounters with surface photos (n=33), revealing how many injuries may otherwise go undetected. Cookie-cutter shark (*Isistius* sp) bite scars (91% of individuals) and conspecific rake marks (85% of individuals) were most frequently observed. Both deep linear scars (55% of individuals) and mouthline scars (43%) were biased by sex. Adult males had much higher rates of both (81% with linear scars, 74% with mouthline scars) compared to adult females (19% and 26%). In addition to mouthline injuries that may reflect prior fishery

interactions, two individuals with bullet-shaped wounds not visible from the surface, and one with a propeller strike wound, provide evidence of interactions with humans. Only 8% of individuals in our photo-ID catalog were evaluated and thus underrepresent the number with likely anthropogenic injuries. Underwater citizen science contributions, particularly when combined with surface photos often necessary for identification, can increase documentation of injuries otherwise not visible. Obtaining additional underwater and surface imagery would allow for a better assessment of injuries from both natural and anthropogenic sources.

Acoustic monitoring targeting MSFD's good environmental status and cetacean conservation

The Marine Strategy Framework Directive's Good Environmental Status (GES) is being targeted by European Member States around the Mediterranean Sea by 2020. This should also improve conditions for cetacean survival in this region. Among the various anthropogenic pressures to monitor and regulate there is marine noise which falls under descriptor 11 of the MSFD. Investigating the often underestimated levels and impacts of marine sound pollution at a regional level is essential to effectively monitor and reduce this increasing environmental problem. Pilot projects in Western, Central and Eastern Mediterranean areas, undertaken as part of the QUIETMED project allowed critical investigation of the methods and strategies to achieve the requirements for Descriptor 11 in two '1/3-octave bands' (i.e. 63Hz and 125Hz) while also providing means for acoustic monitoring of cetaceans in these study sites. In the central Mediterranean, off the Maltese Islands, the deployment of two Passive Acoustic Monitoring Systems, using RTSys SDA14 recorders for monthly recordings, was first undertaken in 2018. This provided a vital investigation on the status of marine sounds in the two areas situated at different distances from the main vessel traffic paths, following MSFD requirements. The acoustic recordings in these two locations also contributed useful data on cetacean presence in the same spatiotemporal situations being analysed. Such monitoring strategies, that allow simultaneous monitoring of ambient sounds originating from anthropogenic activities and from natural sources including cetacean species, strengthen the effectiveness, rigour and implications of the extent to which GES for marine sound levels may be achieved. Elusive and vulnerable cetaceans are considered conservation flagship and umbrella species but also important indicator species, so local to regional acoustic studies reveal how their distribution also relates to sound variability in a heterogeneous Mediterranean marine environment.

Current flows cause variation in high frequency noise at a fine scale: Implications for passive acoustic studies of high frequency cetaceans.

Passive acoustic monitoring (PAM) studies are widely used to investigate cetacean encounter rates, distribution, and associations with local environmental variables. Many coastal and tidal regions experience fast currents, which in turn creates noise from sediment flow and in some cases additional noise created by turbulence passing PAM devices. As noise increases, the effective detection area is likely to be reduced. Therefore, a study that does not consider variable detection range may result in inaccurate findings. This study investigated relative detection range of harbour porpoise (*Phocoena phocoena*), a species commonly studied using PAM, using sea-bed recorders and demonstrates the implications for analyses. Seven SoundTraps were deployed approximately 500m apart at a coastal site that experiences moderate tidal range and current speeds. SoundTraps continuously recorded full-bandwidth noise and porpoise signals. Deployments were repeated shortly after, using a high frequency click detector to allow longer data collection of porpoise vocalizations to investigate associations with environmental variables. Each site experienced noise variation in the harbour porpoise bandwidth as a result of tidal current flow. During certain periods, sediment noise presented similar characteristics to porpoise echolocation clicks. Variation in click received level mirrored

trends in noise variation, suggesting first possible evidence of the Lombard effect in harbour porpoise, where animals compensate for high noise by vocalising at higher amplitudes. Porpoise detections were present during loudest periods suggesting that masking may not be present. Considerable noise variation was recorded between recorders less than 1km apart, suggesting implications for studies that compare between sites. Porpoise associations with predictor variables were revealed between sites when noise was not incorporated into analysis. Results suggest that it is key to measure fine-scale noise conditions in conjunction with spatio-temporal acoustic studies of cetaceans of distribution and behaviour.

Mom, can you hear me? Impacts of underwater noise on mother-calf contact calls in endangered belugas (Delphinapterus leucas).

Noise and anthropogenic disturbance from recreational and commercial vessel traffic were identified amongst the main threats to the recovery of the endangered St Lawrence Estuary (SLE) beluga population. The consequences of acoustic masking could be particularly adverse in the case of critical vocalizations that maintain contact between mothers and their dependent calves. Here, we modeled communication range of adult and newborn beluga broadband contact-calls under quiet and noisy conditions in Baie Sainte-Marguerite, an important summering area for this population. To do so, we used measurements of ambient noise obtained with a calibrated hydrophone in the presence and absence of boats (verified visually from an observation tower), a composite beluga audiogram based on thresholds pooled from all individuals tested with AEP and behavioural methods, and apparent source levels of adult and neonate contact-calls. Source levels were estimated from received levels of contact calls recorded from two wild populations (SLE and Eastern High Arctic) and from Oeanogràfic aquarium (two adults and a neonate) at known distances from a calibrated hydrophone, with propagation loss equations suited to each location, and from contact-calls recorded from five individuals carrying temporary Dtags (SLE). The modeled median distance at which the signal excess reached zero in all 1/12 octave bands analyzed (487 to 97162Hz center frequencies), considered the maximum communication range, was considerably reduced in noisy conditions, particularly for neonates, given that their calls had substantially lower source levels and peak frequencies than adult contact-calls. Thus, a neonate's call would suffer a 56% reduction in range to a median distance of 190m in noisy conditions. The estimates in our study are the first approximations of source levels and active space of beluga calls with a known function, and show that masking of these calls by noise may be particularly problematic for the underdeveloped contact-calls of neonates.

Effects of boat activity on bottlenose dolphin foraging behaviour

In many parts of the world, impacts of recreational activities have focused on cetaceans' displacement. Nonetheless, changes in behavioural patterns of cetaceans that do not flee may also pose a threat. In Cardigan Bay, UK, two Special Areas of Conservation have been established to protect bottlenose dolphins (*Tursiops truncatus*). However, over the past decade, human pressures have increased markedly. Careful management is needed to conserve this population whilst safeguarding its socio-economic value. This study aimed to evaluate possible effects of boat disturbance on bottlenose dolphin presence and foraging activity in the southern SAC, where a long-standing code of conduct with good compliance is found. Acoustic detections recorded with acoustic data loggers (T-PODs) from 2005 to 2008 during the summer season were obtained from ten different sites within Cardigan Bay SAC to evaluate how boat disturbance affected bottlenose dolphin foraging activity. Generalised linear models (GLM) were used to test bottlenose dolphin presence and stages of foraging behaviour (recorded as buzz occurrence) and the effect of noise level at different moments of a boat encounter at different sites. Results show an increase in bottlenose dolphin presence and in foraging activity when boats are around. In addition, foraging activity seemed to stop when boats were leaving the area at

all sites but particularly at those where boat activity was lower. We conclude that dolphins maintain occupancy despite vessel presence but alter their behaviour during a boat encounter. Therefore, dolphins may increase feeding because they cannot socialise or rest in the presence of boats, or because the cetaceans have habituated to the boats and do not see the motorised vessels as a threat, linked to their code of conduct compliance. Results highlight the value of enforcing regulations, contributing to an area-based management scheme that promotes species conservation alongside a sustainable ecotourism-industry.

New subspecies of bottlenose dolphin (Tursiops truncatus gephyreus) classifies as Vulnerable under IUCN criteria

A recent reassessment of the world-wide taxonomy of *Tursiops* confirmed the validity of the subspecies Lahille's bottlenose dolphin (*Tursiops truncatus gephyreus*; Lahille 1908). These dolphins are distributed in the coastal waters of the southwest Atlantic Ocean, between the state of Parana (southern Brazil) and the province of Chubut (Argentina). They occur in two genetically and geographically isolated "subpopulations" under the IUCN definition: one ranging along the coast of southern Brazil and Uruguay, composed by at least five management units and operating as a metapopulation, and a second ranging along the coast of Argentina.

The abundance of Lahille's bottlenose dolphins has been estimated for most parts of the subspecies' range. The sum of available estimates suggests a maximum total population size of 600 individuals. With an estimated 60% of mature individuals, the total number of mature individuals in the subspecies can be estimated at 360, well below the threshold to classify as Vulnerable under Criterion D. Due to their low numbers, high site fidelity and restricted coastal distribution, Lahille's bottlenose dolphins are particularly sensitive to local anthropogenic impacts.

The genetic variability of Lahille's bottlenose dolphins is low at both nuclear and mtDNA markers, and there is evidence that the subspecies is declining in at least part of its range due to bycatch in fisheries and other unknown factors. Of particular conservation concern is the Argentina subpopulation, due to its low and likely declining abundance (of at most 140 mature individuals), genetic isolation from the rest of the subspecies and its low genetic variability. However, robust data are still lacking to quantify the population declines, and the possible consequences for the subspecies' conservation status. It is therefore a priority to obtain improved estimates of population dynamics and life history parameters for each subpopulation, for which continuous dedicated research efforts are crucial.

Are Tursiops truncatus modulating the whistles parameters during mixed groups contexts?

Cetaceans depend highly on acoustic signals to communicate, navigate and find food. Mixed groups contexts, characterized by temporary and opportunistic encounters between different species, may play an important role on the acoustic dynamics of the species involved. Considering the communicative function of whistles, we used these sounds to investigate the acoustic relationships between *Tursiops truncatus* when involved on mixed groups contexts versus when not involved. Acoustic recordings of interspecific associations of *T. truncatus* with *Globicephala melas* and with *Grampus griseus* were collected and compared with recordings of *T. truncatus* in a single species context. Both type of the recordings were performed with omnidirectional hydrophone array coupled to a digital recorder (sampling frequency of at least 96 kHz/24 bits) on the western South Atlantic Ocean. A total of 1267 whistles were analyzed and the following acoustical parameters were extracted: minimum, maximum, center, delta, beginning and ending frequencies, first and third quartile frequencies, first and third quartile of

duration, inter-quartiles range of duration and frequency, frequency at 95% and 5% and whistle duration. In order to verify if whistles of single species groups of *T. truncatus* were different from the interspecies associations, a Support Vector Machine (SVM) model - a machine learning method useful to detect patterns among groups of different classes - was implemented. SVM analysis showed a clear separation of whistles, with an error rate of 9,5% for both analyzes (between the contexts: single species versus the mixed group with *G. melas* and between the single species versus the mixed group with *G. griseus*). The results show that interspecific associations between dolphins may influence whistle structure and highlights that *T. truncatus* whistles can be modified during interspecific interactions. Multi-species associations of odontocetes remain poorly understood; thereby these findings can be useful to elucidate the possible driving factors behind these interactions.

Male humpback whale song behaviour: Singing while on the move.

Male humpback whales, *Megaptera novaeangliae,* are known for producing complex song while on the breeding grounds. Their song is seemingly part of a vocally mediated mating sexual display to either attract females and/or deter other males. Thus, a large acoustic active space of song could be of importance to the fitness of males. Previous studies which investigated the behavior of singing males have been limited by observational platforms. A better understanding of how males move geographically and distribute song in a breeding area, could help understand the potential impact of anthropogenic disturbances and noise. We therefore sought to investigate the fine-scale movement behavior of singing male humpback whales with animal-borne sound and movement tags (DTAGs). These tags record GPS, sensor and acoustic data providing a direct link between behavior and singing. Our aims were to investigate i) the type of behavior exhibited during singing bouts and ii) whether males transit to a new location between singing bouts, potentially to increase their acoustic active space. We analyzed 46 hours of tag data from four humpback whales on a breeding ground in Exmouth Gulf, Western Australia. We show that males sing for long bouts (49±34 min), during the day and night, and at high received levels ranging from 149-178 dB re 1uPa. Males exhibited both highly active (e.g. fast swimming) and stationary behavior during singing, showing that singing is dynamic and not produced solely during slow swimming or stationary behavior as previously documented. The body position of males during singing was both horizontal and vertical in the water column. Three whales tagged with GPS covered 4.8±2 km/hr, with this movement between singing bouts showing an active increase of active space of song. By improving our understanding of male humpback behavior on breeding grounds we can better inform conservation efforts.

Humpback whale song variations in Reunion Island from 2016 to 2018

Sexually mature males produce very complex and highly structured songs which are shared at the population level. Song pattern (phrases) are culturally transmitted and have been described to evolve progressively with time, both over the breeding season and among years. Acoustic monitoring was conducted over multiple years around Reunion Island, within the southwest Indian Ocean breeding range, to assess temporal variation in song structure and in humpback whale occurrence. Continuous recording was undertaken during the austral winter (June-October) for 3 consecutive years in 2016-2018. A total of 44 samples containing high-quality song sequences from the early, mid- and late season were selected, representing 2 640 minutes of recordings. The analysis of song structure resulted in the description of 12 phrases and their variants. Low level of temporal variation was observed over the breeding season, with songs recorded in June being very similar to the one recorded late in late September-early October. Higher variations were observed between years, with some phrases from 2018 that may have evolved from phrases from 2017. In 2017 and 2018, more variants were described for each phrase type compared to 2016, in consistency with humpback whale occurrence.Very low number of humpback whales were observed around the island in 2016, which

might have resulted in a lower diversity in song pattern.

The missing whales: Accounting for "struck and lost" rates in the assessment of historical whaling impacts in the Southwestern Atlantic Ocean.

Open-boat historical whaling had a massive impact on a number of cetacean populations worldwide. Several attempts have been made to estimate the actual number of individuals taken by this activity. Most of them were based on the records of oil barrels or baleen plates discharged at port at the end of each whaling voyage. But what about whales that were struck, slightly or severely injured, and subsequently lost by whalers? These deaths may have contributed to the demographic impact of whaling over some cetacean populations. Here we consider the records extracted from 255 logbooks from the offshore historical whaling industry in the Southwestern Atlantic Ocean. Data from approximately 20,000 days on effort were extracted from the period ranging from the end of the XVIII century until the first decades of the XX century. According to these records, whalers first targeted the Southern right whale (*Eubalaena australis*), reporting approximately 2,500 sightings and 658 catches, and during the latter period, the sperm whale (*Physeter macrocephalus*), reporting 1,155 sightings and approximately 800 catches. When assessing these logbooks for the "struck and lost" rates, however, these numbers increase, with over 340 additional Southern right whales and 90 sperm whales lost after being wounded. The different rates for the two species may be related to behavioural differences of the two species or to an improvement in whaling techniques, proportionally reducing "struck and lost" rates in the latter period, when the operation mostly focused on sperm whales. For the Southern right whale, however, whose population was drastically reduced by whaling, we estimate that the proportion of whales killed was approximately 1.5 the number of whales actually caught and taken to port. Accounting for these "lost" individuals is fundamental when reconstructing demographic trends of cetacean populations targeted by whaling.

Anthropogenic activities related to the production of underwater sound are subject to a wide range of environmental regulations. The decision making and regulatory communities must often rapidly synthesize new scientific research results to properly implement regulations and accurately assess potential impacts of proposed projects. To address these needs, the University of Rhode Island Graduate School of Oceanography teamed with Marine Acoustics, Inc. on the *Discovery of Sound in the Sea* (DOSITS) Project. The Project's foundation is an interactive website (dosits.org) that synthesizes peer-reviewed science related to underwater sound, including content on sound sources, potential impacts on marine life, and how animals and people use sound underwater. The site has over 400 content pages and is updated semi-annually with newly published information after a thorough review by a panel of scientific experts. To identify regulator and decision maker needs, four surveys were conducted (2015-19), leading to the development of high-need underwater acoustics content and associated resources. Current DOSITS Project activities include webinars, which consist of presentations by experts followed by real-time, interactive sessions, all of which are archived on the DOSITS website as a permanent resource. Webinars were conducted in 2015-2016 and 2018, with modules on the science of underwater sound, sound production and reception by marine mammals, effects of sound on marine mammals, sound production and reception in teleost fishes, and effects of sound on fishes. The 2019 webinar series focused on sound sources, including wind turbines, pile driving, seismics, echosounders, sonar, and shipping. In addition to the webinars, tutorials, instructional videos, and e-books have been developed to address content prioritized in the decision makers' surveys, such as science of sound fundamentals, hearing sensitivities, and updates on potential effects of underwater sound on marine animals. This presentation will provide an overview of the survey data and available DOSITS resources.

Assessing the effect of windfarms on marine mammals using point process pattern analysis

Vilela, Raul[1]; Bachl, Fabian; Diederichs, Ansgar[2]

Corresponding Author: raulvile@gmail.com

The effect of operating wind farms on marine mammals still remains controversial, with different studies pointing to either positive, neutral and negative effects. We assess the impact during the operational phase of the windfarm "Butendiek" in the German North Sea on three different marine mammal species: Harbor porpoise (*Phocoena phocoena*), Harbour seal (*Phoca vitulina*) and Grey seal (*Halichoerus grypus*). Butendiek was selected for its isolation and good aerial coverage, which allow us to exclude interactions from other windfarms close by. The study was based on a series of 18 digital video aerial surveys (HiDef-technique) carried out between 2015 and 2018 and spread over different seasons of the year after the construction of the windfarm. We assumed spatial location of marine mammal occurrences as point processes to propose a model-based inference using a spatial log-Gaussian Cox process. The method adopts a flexible stochastic partial differential equation (SPDE) approach to model spatial structure in density and integrated nested Laplace approximation (INLA) for Bayesian inference. It allows simultaneous fitting of detection and density models and permits prediction of density at fine scale while specifically accounting for the local-scale dependence structure of the data. Results show a neutral effect of the windfarm Butendiek on the three analyzed species which supports previous observations in German waters.

The energetic cost of being a humpback whale and the consequence of losing energy to disturbance

Villegas-Amtmann, Stella[1]; Schwarz, Lisa[2]; Costa, Daniel[3]

Few whale species have recovered to their pre-whaling numbers, such as the humpback whale (*Megaptera novaeangliae*). Found in all major oceans, they perform extensive seasonal migrations between high-latitude to low-latitude foraging and breeding grounds which exposes them to new anthropogenic threats that could affect energy intake or expenditure. Following previous models we developed for gray whales, we created a 2+ year breeding cycle bioenergetics model for humpback whales to determine the consequences of losing energy to disturbance. We considered various lactation costs: 50-100% when calves are 6mo. (calves start to forage)-10.5mo. (weaning). Total energy requirements for a 2-year reproductive cycle are 142.8-152.8 x 10^4 MJ. Total reproductive costs are 98.4-106.7 x 10^4 MJ. Our model predictions suggest that if a pregnant female loses 24-31% of the energy needed, she would not calf that year and if she loses 48-53% she will not calf for two consecutive years. Mortality could occur with a 50-55% energy loss. A resting female will not calf for two consecutive years with a 50-55% energy loss, and mortality could occur with a 52-57% loss. A lactating female at the foraging grounds (assuming previous energy losses prevented females from acquiring all energy required for lactation), would not calf the following year (resting) with a 13-9% energy loss. If she loses 16-12% she will wean her calf at a lower mass and could die if she loses 47-52%. Compared to gray whales, a greater mass allows for greater energy losses before losing a calf or dying. However, a smaller mass could sustain greater energy loss before weaning a calf at a lower mass. These findings need further exploration including other species and a greater mass range. Lastly, if we intend to maintain humpback whales de-listed conservation status, conservation measures should consider exposure to anthropogenic disturbance.

Integrated actions to conservation and management of the baleen whales in northwest Mexico

More than 50% of the total baleen whale species in the world can be found in the northwest Mexico (NWM). This represents a privilege, but also responsibility over their protection and management. The success in the conservation of the populations of cetaceans depends on the knowledge about their biology, ecology, threats, as

well as their use. Here we present the results that were based on three components: 1) Biological, 2) Social and 3) Public Policies. Concrete and articulated strategies were proposed for the conservation of whales in the NWM. Component 1) For fin whales with satellite transmitters, areas and seasons for transit and feeding were identified within the Gulf of California (GC), and with the study of 10 steroid hormones, photo identification and historical records of sightings, an area and season of reproduction were identified. Regarding the threats for humpback, gray, and fin whales, information about entanglement and collision events with boats in the NWM was compiled. Component 2) Courses were given in ten fishing communities with the objectives of forming a network of trained observers in the identification and registration of cetacean species and their threats, as well as training the community in good whale watching practices. Finally, 3) Three proposals for Regional Protection Programs were prepared: a) Conservation of the Gray Whale, in its route of connectivity between two lagoons of winter aggregation in the Mexican Pacific, b) Conservation of critical habitats of the fin whale resident population, And c) Conservation of critical habitats for humpback, blue, fin and Bryde´s whales in the GC. In these programs, conservation areas and actions in the short, medium and long term were included, in order to ensure the conservation of whales that live or transit in the Northwest region of Mexico.

Social structure and demography of Blainville's and Cuvier's beaked whales at El Hierro, Canary Islands.

Vine Afonso, Raquel[1]; Reyes Suérez, Cristel[2]; Schiavi, Agustina[2]; Aguilar de Soto, Natacha[3]

Little is known about the social structure and demography of most of the 22 species of Ziphiids, in spite of the importance of these data to assess population dynamics and inform conservation management. Here we analyze a multiyear (2008-2018) photoID database of Blainville´s and Cuvier´s beaked whales from El Hierro (Canary Islands, Spain), where both species have year-round populations estimated in 103 (87-130) and 87 (78-106), with core use area subpopulations of 33 (CV 55%) and 39-53 (CV 36%) (Blainville´s and Cuvier´s, respectively). We observed mean inter-calf intervals of 3-4 years for "best breeders", but longer, up to 17 years, non-breeding periods in other females, and an apparent low survival of first year calves. Social analysis was performed with SOCPROG using 164 (Md) and 272 (Zc) group encounters where all whales were recognized, including 66 (Md) and 81 (Zc) identified individuals. Both species form small groups: Md (3,09 ±1,98) and Zc (1,98 ±1,25) and show a high estimate of social differentiation: S=0.847 SE=0.061 (Md) and S=0.709 (SE=0.038) (Zc). For both species the overall mean individual association index is low, but this is not homogeneous, as for some individuals it can exceed 0.5. In Blainville´s, males are rarely seen together in a group, females can have relatively long-term associations (25% probability of been seen together after 2 years), and females-male may form strong short-term associations (70% probability of a female by a male been seen together again after 30 days). In contrast, most stable associations among Cuvier´s are among males, which can remain together up to 7 years, while there are no long-term associations among females nor inter-sexes. Our results are consistent with previous descriptions of harem groups in Blainville´s beaked whales and loose fission-fusion societies in both Blainville´s and Cuvier´s beaked whales, but also unveil non-random long-term associations.

Evidence of sperm whale (Physeter catodon) lactation in Ligurian Sea: A breeding area in the North of Mediterranean Sea.

The sperm whales (*Physeter catodon*) spend part of their life in matrilineal social units composed of females and their offspring. As odontocete, female differ from baleen whales in migrations, that do not typically involve a wide latitudinal shift, and in adult feeding throughout lactation, that lasts ~24-25 months. At birth and at weaning, the average body length is 4.05 m and 6.7 m respectively. Sperm whale calves suckle when performing a surface behaviour of repeated, short dives alongside an adult escort. Here, we report and analyse suckling behaviour of a sperm whale calf in Ligurian sea, at

the beginning of October, using aerial drone video footage on a group of three individuals – two adults and a calf. Aerial videos of two different lactating events have been taken using drone. Through aerial images, the calf estimated length is ~6 m and corresponds to about two third of the adult. In both videos, the sperm whale calf approaches the same nursing female, at distance of the mammary slits. Two bout of peduncle dives have been recorded. During these dives, ~13 s long each, the calf stays beneath the mother, remaining in a parallel and upright position, repeating several head butting, and taking one breath between peduncle dives. Afterward, the calf approaching from behind, rolls laterally to its left attempting to suckle through its mouth. In the final frame, some milk coming out from the mouth of the calf is clearly visible and confirms the suckling event. These observations strongly confirm that both solitary males and herd of females use Ligurian sea as foraging area, in their migration route within the basin. Furthermore, considering several sightings of herd of female with calves reported in the Pelagos Sanctuary, this latter could be another significant breeding area in the North West of Mediterranean Sea.

Population dynamics and structure of sperm whales (Physeter macrocephalus) in the Mediterranean Sea.

The sperm whale (*Physeter macrocephalus*) has a cosmopolitan distribution. The Mediterranean sperm whale sub-population is classified as 'Endangered' according to the International Union for the Conservation of Nature. Even though this population hasn't faced the whaling age, it is currently threatened by other impacts which may cause direct mortality or stranding (i.e. ship strikes, debris ingestion, entanglement in driftnets, acoustic impacts). Previous genetic, acoustic and mark-recapture studies have indicated that this population is distinct from the North Atlantic population. Within the Mediterranean, the population structure is however unclear. Photo-ID data have shown three recaptures between the eastern and the western basins, though acoustic data revealed differences in the coda repertoires of social units between both basins. Our data from the Ligurian Sea to date, where 71 individuals have been identified, suggest that local recaptures are relatively infrequent in the western basin (30 in the Ligurian and 9 in the Tyrrenian Sea) in comparison with data for the eastern basin. Therefore populations may not be fully resident to local areas (based on photo-ID), but there is some evidence for divergence (based on acoustic data). Genetic differentiation among these basins has already been

confirmed for various dolphin and fish species. Here, we investigate population structure using ~5000-10000 single nucleotides polymorphism sites (SNPs) generated by restriction-site-associated DNA sequencing (RADseq). We have sequenced 160 samples from stranded and freeranging individuals, 34 samples from the eastern Mediterranean, 82 samples from the western Mediterranean and 44 samples from the eastern North Atlantic. We are analysing these data to address hypotheses about population structure, gene flow, demography, genetic variability and kinship within and among the analysed areas. These results will improve our knowledge of sperm whale demography and patterns of connectivity and are therefore essential for developing a more effective conservation management strategy for this endangered population.

Prospective impact assessment of offshore wind farm development on harbour porpoise distribution in the southern European North Sea.

In the North Sea, marine renewable energy projects, particularly offshore wind farms (OFWs), have undergone an intense development with potential impact on marine megafauna, including changes in behaviour or foraging patterns. The southern North Sea concentrates both intensive anthropogenic activities (*e.g.* shipping, OFWs) and high densities of harbour porpoises (*Phocoena phocoena*). Particularly, the number of wind farms is planned to at least double in the coming years (from 6 to about 14), stressing the need to mitigate the impact of human activities. We conducted 6 repetitive aerial surveys in the southern North Sea between April 2017 and May 2018 with the aims of (1) predicting monthly distribution and abundance of harbour porpoise, (2) assessing the relationship between porpoise and OFWs, and (3) investigating the potential impact of new OFWs to be implemented in the study area. Highest abundances were estimated in spring (25,000 individuals [5,700-52,200]) and the lowest in summer (2,500 individuals [970-4,200]). Porpoises exhibited a year-round avoidance of OFWs, and were mostly found at distances from them higher than 40 km. Based on this empirical correlation, we explored the effect of prospective OFWs in the study area on a monthly basis, and predicted that the overall porpoise abundance would be lower when these OFWs will be operating. This diminution would probably be linked to the avoidance of the new OFWs forcing porpoises outside the study area. Such an approach has the advantage to prospect simultaneously the cumulative risk impact of multiple OFWs (either operating or in development) in a rather small area. This suggests that risk assessment considering all OFWs in development rather than risk assessment focused on single OFW would be relevant for proactive conservation, particularly to anticipate or mitigate the effects of anthropogenic disturbances at a population scale.

Demographical analysis of the endangered population of the harbour porpoise from the Sea of Azov using a Bayesian-based model.

There is a separate population of the harbor porpoise in the Sea of Azov which is distinct for its morphology and life history. Here a demographical study is conducted based on the sample of porpoises which died in 2000-2013 in the southern Azov. Demographic parameters and abundance trends were assessed using the Bayesian inference and Syler's model with bycatch as mortality risk (the procedure by J. Moore). The abundance of Azov porpoises was consistently declining; as estimated here, in 2001-2012 it declined more than twice, from 13,500 to 6,000. Natural growth rate was within 2-4%, with high birth and natural death rates and high generation turnover rate; the greatest mortality rate falls on the first year of life. The population is endangered due to incidental bycatches in fishing gears. Bycatch was the greatest mortality factor. It led to annual decline in abundance by 27% in some years, because of mortality rise and great losses in birth rate due to takes of individuals which finally did not contribute to reproduction. Bycatch was shown to affect primarily juvenile and subadult animals: at the age of 1-5 years bycatch as the mortality factor was greater than all the natural factors. Notably, in 2000-2002 the population was already stressed under anthropogenic impact, then, in 2006-08, bycatch decreased, and the population stabilized. By 2011, the bycatch rate was lower than in 2000-2002; however, the population was more depleted than a decade before: life span declined (especially, in males), and mortality increased. The birth rate somewhat increased during the observation period, as follows from the model data; however, it did not

lead to recovery of the population. Bycatch impact is irregular in mid-term perspective; however, it is extremely great, and the risk of extinction is high for the Azov population.

My enemies' relatives are my friends: An unlikely relationship between killer whales, dolphins, and porpoises.

Despite the obvious risk to an animal approaching their potential predator, so called "predator inspection" behaviours have been described for several vertebrate species. Prevailing hypotheses suggest predation risk is offset by the information prey acquire about their predators during these encounters. Here, we describe an apparent variant of the predator inspection paradigm: dolphins and porpoises associating with members of a fish-eating killer whale ecotype (RKW) that is sympatric with, and closely resembles, a mammal-eating ecotype (BKW). We have observed this behaviour more than 50 times over the course of 34 field seasons in British Columbia, and examined it comprehensively in drone footage taken in 2018. Here, we describe consistent features of these observations, which involved Pacific white-sided dolphins (PWSD) and/or Dall's porpoise (DP) approaching groups of resting, travelling, or foraging RKW – swimming alongside them for periods ranging from minutes to days. Aerial recordings allowed us to rule out the possibility that PWSD and DP are hydrodynamically "hitching a ride" and – along with vessel-based observations – suggests this association is not strictly social, as RKW appeared to avoid the two species – briefly chasing them at times. PWSD and DP often approached RKW while they were foraging or prey-sharing, therefore it is possible that they occasionally obtain prey scraps. However, we hypothesize that the primary advantages of this association are that PWSD and DP gain protection from ambush attacks by BKW and allows them to acquire information about the agility, speed, and behaviour of killer whales. We present four lines of evidence in support of this hypothesis: (1) All four species are common in the study area; (2) BKW do not associate with RKW, and actively avoid them; (3) Predation of both PWSD and DP by BKW often occurs in the absence of RKW; (4) RKW very rarely harm either species.

Entanglements in the 'Nationally Critical' population of coastal New Zealand orca (Orcinus orca).

The New Zealand coastal population of orca (killer whales, *Orcinus orca*) is classified under the Department of Conservation (DOC) Threat Classification System as 'Nationally Critical', the highest category possible. This classification is based on, *inter alia,* their low population number (fewer than 200 individuals) and the wide range of threats they face including critical habitat destruction, pollution bioaccumulation, boat strikes, strandings and fisheries interactions which include shootings as well as entanglements. The latter is of particular significance due to the high number of events with least 21 orca (of both sexes and all age-classes including adults, juveniles and calves) becoming entangled since 1979. Entanglements have occurred in commercial fisheries gear, including gill and trawl nets, long-lines and cray-pot lines, as well as likely entanglements with private fishing gear from pots, rods and/or handlines. The outcome of these entanglements included seven confirmed deaths, another nine whose fate remains unknown (due to poor documentation) and only five who were actively disentangled and released. The DOC, although legally mandated to protect New Zealand marine mammals, did not participate in any disentanglements and instead the public and volunteer entanglement response networks responded and released them. Only one orca was photo-identified during the disentanglement process and she has been resighted on numerous occasions over the five year period since her release. To minimise entanglements of orca, easily-applied mitigation options are presented and these methods may also help reduce entanglements of other cetaceans around New Zealand. In addition to implementing mitigation options it is vital that the DOC work with the volunteer entanglement response networks to improve disentanglement rates for this Nationally Critical population to ensure its viability.

Bottlenose dolphin (Tursiops truncatus) in the water of Ischia Island (Gulf of Naples, Italy): A long term analysis on distribution, habitat use and photo-Identification.

This study presents data on a bottlenose dolphin (**Tursiops truncatus**) local population monitored in the waters off Ischia Island (Gulf of Naples, Italy) over a fifteen-year period (2004-2018). Data were collected during the Ischia Dolphin Project, an ongoing long-term research program on cetaceans. Surveys were conducted five days a week from May to October. Few additional outgoings were made in winter and spring.

1,186 daily surveys were performed, during which 58,332.47 km were covered. There were 91 encounters in which bottlenose dolphins were followed for a total of 877 km and 156 hours. Group size ranged between 1 and 130 animals (mean 37; SD±33.23). 79% of the observed groups included immature individuals (calves and/or juveniles n=72), with most of these including calves (n=54). Dolphins were mainly distributed in coastal waters (range 9.63-855.78; average 139.75; SD±187.42), with the highest concentration in the area NW of Ischia. Preliminary photo-identification analysis was performed on 68 sightings, resulting in cataloguing 207 individuals. 108 individuals (33 females) were resighted during years (range 2-10yr). 71 behavioural sequences (>40') were analyzed (mean duration 121', range 41-417). Dolphins were mostly seen feeding (54%) and travelling (44%). Socializing was recorded in 21% of the encounters, while milling (8%) was the least observed behaviour.

The data here presented show that the waters around Ischia Island represent a feeding area, as well as a calving and nursery area for the bottlenose dolphin local population. The study area has been classified as a Marine Protected Area ("Regno di Nettuno" MPA) and recently, the area has been recognized as Important Marine Mammals Area (IMMA) by the IUCN, with common dolphin, bottlenose dolphin and fin whale as qualifying species. However, despite the severe anthropogenic pressure (overfishing, traffic, pollution) in the area, no management action aimed at preserving the local ecosystem was implemented.

Calibrating Unoccupied Aerial System (UAS) photogrammetry to derive delphinid population demographic parameters.

Understanding the dynamics of cetacean populations is important to optimally manage these species. Healthy populations exhibit stable age structures, while deviances from such indicate unstable populations. Quantifying the age structure of free-ranging cetacean populations has previously required years of intensive survey effort. However, new technologies allow for the development of novel approaches to accurately and efficiently quantify population age structure and growth. Such parameters may provide early insights into whether there may be cause for concern for certain populations. Aerial photogrammetry has become common practice in cetacean surveys, and emerging Unoccupied Aircraft Systems (UASs or 'drones') have facilitated the collection of such imagery. To date, studies have not ground-truthed UAS-derived morphometric measurements of cetaceans with their true sizes and few studies have collected aerial photogrammetric measurements of delphinids. This study aims to compare physical and UAS-derived measurements (length, girth, width and volume) of 12-18 bottlenose dolphins *(Tursiops truncatus)* and one false killer whale *(Pseudorca crassidens),* all of known age, housed at Sea Life Park Hawaii and Dolphin Quest Oahu, Hawaii. Two different UAS platforms will be flown consecutively over each individual at five altitudes. Individuals will be measured when a) lying flat (not curved) at the surface to assess length and width and b) performing a natural surfacing to account for body curvature. The objectives of this study are to 1) quantify the precision and accuracy of aerial photogrammetry in assessing these measurements, 2) infer individuals' age-class based on their length and 3) cross-calibrate UAS-derived measurements. While sampling is currently ongoing, we believe this innovative and non-invasive methodology will provide precise information on UAS-derived length measurements and represents the first step in using UASs to assess demographic parameters of free-ranging delphinids.

Impact of herring spawning events on killer whale migratory behavior.

Killer whales*(Orcinus orca)* are a widely distributed marine mammal. These toothed cetaceans are top predators that typically specialize on specific prey types. While Antarctic and Pacific killer whale prey has a strong influence on their respective movement patterns, little is known about the seasonal movements of the North Atlantic killer whales off the Norwegian coast. Visual observations and photo identification have been used to track the movements of Norwegian killer whales, but effectively limit monitoring to near-shore and inner-fjord behaviors. Bio-telemetry has the potential to reveal offshore behaviors and has been successfully used to track these whales. Along the Norwegian coast killer whales are believed to be strongly associated with the Norwegian Spring-Spawing(NSS) stocks of Herring (*Clupea harengus*). To evaluate the impact of herring spawning events on Norwegian killer whale migratory behavior we analyzed data from over 30 individuals tagged with ARGOS transmitters from November to February at three different herring overwintering areas; 2000-2001 in Tysfjord/Lofoten, 2015-2016 outside Tromsø and 2017-2019 outside Skjervøy. We cross-correlated bio-telemetry data with annual standardized NSS herring stock assessment that identified spawning hotspots to evaluate the impact of spawning events on killer whale migratory behavior. Killer whale behavior was strongly associated with herring spawning hotspots. Annual variations in the location and magnitude of these hotspots were also reflected in killer whale movements. After the spawning events, some killer whales followed the herring to their summer feeding grounds in the Norwegian Sea, while others entered the Barents Sea, reaching as far as the ice edge off Novaya Zemlya. Our results confirm the importance of NSS herring and its phenology for Norwegian killer whales. Furthermore, bio-telemetry tools allowed us to document previously unobserved offshore herring-associated behaviors.

Are near-distance seal scarer effects as strong as the effects of offshore piling noise on harbour porpoise (Phocoena phocoena)?

To protect its only resident cetacean species in German Waters from noise damage, offshore wind park operators are required to acoustically deter harbour porpoises (*Phocoena phocoena*) out of the impact zone prior to pile driving. But what if the deterrence measures stress porpoises disproportionally and are as disturbing as noise-mitigated piling? We analysed porpoise detections from up to 3 hours before deterrence until 3 hours after piling for six offshore wind farms constructed from 2014 to 2016 in the German Bight. Seal scarers were used as acoustic deterrent devices. All pilings were noise-mitigated and sound levels (SEL_{05}) were below 160dB at 750m distance from pile driving locations, which is the German noise-protection threshold. We compared porpoise detections at 750m and 1500m distance to pile driving locations of 302 piling events. C-POD data were split into the phases of before piling, during deterrence, during piling and after piling. We analysed data using a Generalised Linear Mixed-effects Model (GLMM), accounting for project- and foundation-specific variance and temporal autocorrelation of porpoise click detections. At 750m, deterrence was close to 100% effective as generally no detections were recorded then and during subsequent piling. At 1500m however, the probability of porpoise detections was higher than at 750m, although still significantly reduced by 36-41% during deterrence and piling, compared to the few hours before deterrence. The effects of deterrence and piling activity were statistically not distinguishable. This raises the question on the effect strength of seal scarers on harbour porpoises with respect to noise mitigated piling as in distances of 1500m the sound levels were generally below the threshold set to avoid hearing damage. In literature, seal scarer deterrence effects were found up to 7km from construction sites. Is the displacement effect by seal scarers in relation to disturbance by pile-driving noise stronger than necessary?

Aggressive behaviors of adult male Atlantic spotted dolphins: Making signals count during intraspecific and interspecific conflicts.

Volker, Cassie[1]; Herzing, Denise[2]

(2) Wild Dolphin Project and Florida Atlantic University, Dept of Biological Sciences
Corresponding Author:
dlherzing@wilddolphinproject.org

Sympatric species exist together in the same immediate habitat and are often in competition for resources, which can result in aggressive interactions. Some species, including chimpanzees and noisy miners, have been known to exhibit behavioral plasticity by altering their aggressive behavior (during both *intraspecific* and *interspecific* encounters) based on their opponent. Atlantic spotted dolphins (*Stenella frontalis)* and bottlenose dolphins (*Tursiops truncatus*) are two sympatric species resident to the northern Bahamas. We examined whether groups of spotted dolphins were behaviorally plastic during aggressive behaviors. We described and compared the aggressive behaviors used by groups of adult male spotted dolphins during *intraspecific* aggression and *interspecific* aggression with bottlenose dolphins. Between the years 1991-2004, twenty-two aggressive encounters (11 *intraspecific*, 11 *interspecific*) were behaviorally analyzed. Twenty-four specific aggressive behaviors termed behavioral events, further grouped into three behavioral classes, were examined throughout these encounters. Both similarities and differences in the use of the behaviors occurred during *intra*- and *interspecific* aggression. Within the Pursuit behavioral class, chasing (a behavioral event) was used significantly more during *interspecific* aggression. Within the Display behavioral class, open mouth displays, were used significantly more during *intraspecific* aggression. Lastly, the Display behavioral class was used significantly more than the Contact behavioral class only during *intraspecific* aggression. Spotted dolphins changed their aggressive behavior by using a more energy-intensive behavior and more overt communication signal, the chasing behavioral event, and less open mouth displays during *interspecific* aggression. Spotted dolphins may change their behavior during aggressive encounters with the bottlenose for potential mating opportunities or to avoid physical harassment. The dynamics of sympatric aggression may provide insight into resource use and may be useful to monitor for any future changes in the environment.

Recent insights into the susceptibility of harbor porpoises (Phocoena phocoena) to airgun exposures

von Benda-Beckmann, Alexander[1]; Kastelein, Ron[2]; Helder-Hoek, Lean[3]; Cornelisse, Suzanne[4]; Lam, Frans-Peter[5]; de Jong, Christ[1]; Jansen, Erwin[1]; Ketten, Darlene[6]

To understand the effects of airguns on harbor porpoises, exposure experiments were carried out with captive animals exposed to down-scaled airguns. To quantify temporary threshold shift (TTS) caused by airgun-exposure and the subsequent hearing recovery, the hearing of one harbor porpoise was tested by means of a psychophysical technique. TTS was after exposure to 10 and 20 consecutive shots fired from two airguns simultaneously (cumulative sound exposure level, or SELcum: 188 and 191 dB re 1µPa^{2}s) during a first set of experiments. Although most of the airgun's acoustic energy was below 1 kHz, statistically significant initial TTS$_{1\text{-}4}$ (1-4 min after sound exposure stopped) of ~ 4.4 dB occurred only at the hearing frequency 4 kHz, and not at lower hearing frequencies (0.5, 1 and 2 kHz). Recovery occurred within 12 min post-exposure. The study indicates that frequency-weighted SELcum was a good predictor of low levels of TTS. In a second set of experiments with the same animal, but with up to 4 airguns no TTS occurred both at 2, 4 and 8 kHz, even though the exposure levels were higher (SELcum up to 199 dB re 1µPa^{2}s). It is not clear why no TTS was measured during the second experiment, but possibly the porpoise was reducing the received SEL by self-mitigation. Opportunistic observations of animal behavior during these experiments indicated that behavioral response to the sound differed between two individuals tested. In addition, both animals showed no response to airgun exposure when a screen of encapsulated air bubbles, which effectively reduced the high-frequency (> 200 Hz) content of the airgun sound, was placed between the airgun and the porpoises. The results of these studies highlight the importance of the frequency content in driving both auditory and behavioral responses, as well as the variability in behavioral susceptibility between and within individuals.

Estimating calf production of Cook Inlet beluga whales using an Unmanned Aircraft System and photogrammetry

The endangered Cook Inlet (Alaska) beluga whale is a genetically distinct, geographically separated population that declined rapidly in the 1990s to a small population size, with no sign of recovery since. Although the abundance and trend of the Cook Inlet beluga population is monitored, little is known about vital rates that could help explain the lack of recovery. In 2017 we initiated a project using an unmanned aircraft system (a hexacopter) launched from a small boat to take high-resolution aerial photographs of beluga whales in Cook Inlet. A gimbaled laser altimeter on the aircraft provides precise estimates of altitude, which allows photogrammetric methods to be used to measure whales. The primary objective is to identify newborn calves to estimate an annual index of calf production, to ultimately determine whether this population exhibits a reproductive rate typical of that expected in a healthy population of belugas. The opaque waters of Cook Inlet prevent measurement of total body length; instead we measure relative body length (the distance from the blowhole to the dorsal ridge). In the first field season we conducted a total of 67 flights (11 hours of flight time) over 11 encounters with beluga whales, resulting in a total of 661 photographs of beluga whales that are measurable. Precision of the length estimates is sufficient; the average difference in relative length estimates of the same whale from multiple images is 2.8cm (range 0.1-7.4). Preliminary measurements indicate newborn calves (mean 57.7cm, range 52.9-65.2cm) can be unambiguously distinguished from presumed (from blue-gray color) one-year old calves (mean 79.4cm, range 71.3-88.1cm), showing photogrammetry can be used to identify young-of-the-year and estimate annual calf production. Early growth in neonates is also seen; neonatal calves with visible fetal folds (55.2, 95%CI 54.2-56.2) were significantly smaller than neonatal calves without visible folds (60.8, 95%CI 58.2-63.3).

Decadal and regional- scale response of the North-East Atlantic cetacean community to environmental change

Meteorological and oceanographic changes influence marine ecosystems. Warmer temperatures, altered ocean currents and increased storm frequencies directly impact lower trophic levels (plankton, fish and cephalopods). For instance, lower trophic levels could change distributions to coincide with preferred temperatures whereas changes in vertical mixing and nutrients may affect primary productivity and biomass. These changes at lower trophic levels will have indirect impacts on cetaceans by altering prey availability. Predicting future impacts of environmental changes on cetaceans requires an understanding of how previous changes have already impacted communities in vulnerable regions. Such analyses demand information on species prevalence at decadal and basin-scales. This study uses 2.68 million km of at-sea aerial and vessel surveys in the North-East Atlantic between 1985 and 2018 to identify changes in encounter-rates with species, and investigate associations between changes and environmental variables. Results indicate a general increase in warm-water species alongside decreases in cool-water species. For example, common dolphin *Delphinus delphis* and striped dolphin *Stenella coeruleoalba* have expanded whilst white-beaked dolphins *Lagenorhynchus albirostris* have declined. These changes in encounter rates were correlated with long-term trends (+5yr) in regional temperature, the Atlantic Multi-decadal Oscillation (AMO) and North Atlantic Oscillation (NAO). However, more complex patterns and relationships with environmental changes were also revealed. For instance, harbour porpoise *Phocoena phocoena* have increased in the southern but decreased in the northern North Sea. This suggests that responses to environmental changes are not always correlated to long-term trends in temperature or indices *per-se*, and that scale-dependent responses are sometimes present. It is proposed that an increased understanding of trophic links between cetaceans and prey could explain and predict these variations in responses to environmental changes.

Seven years intensive pile driving in the German Bight without consequences on Harbour porpoises abundance?

Harbour porpoises (*Phocoena phocoena*) react to pile driving noise of offshore wind farms by temporally swimming away from the noise source, which has been demonstrated in several studies. However, long-term effects on porpoise abundance still remain speculative and are predominantly predicted with models, whose assumptions are based on findings of short-term effects of single wind farm projects. In our study we use data from passive acoustic monitoring devices (porpoise detectors: C-PODs), which were deployed from 2010 to 2016 to detect deterrence effects of the 19 wind farm projects erected in the German Bight (including adjacent Dutch waters) during this period. We combine C-POD-data from 130 monitoring locations with 79,384 recording days in our analyses to assess long-term population level effects. Despite all pile driving activity, we found that porpoise detections increased from 2010 to 2016 in the German Bight. However, this trend was neither monotone over the years, nor uniform throughout the study area. The increase was strongest in the south-eastern part of the study area whereas porpoise detections even decreased in the central German Bight. Annual changes in porpoise detections could, however, not be related to pile driving activity in the area. As such, the pile driving activity in the central part of the German Bight was highest between 2011 and 2013. However, the strongest decrease in porpoise detections occurred after 2013. In other parts of the study area, porpoise detections changed seemingly independent of piling activity within that region. We thus can currently not prove a negative influence of pile driving activity on harbour porpoise abundance in the German Bight. This suggests that environmental factors are, up to date, the predominant factors influencing porpoises on population level more strongly than the generally noise-mitigated pile driving activities in the German Bight.

Echoes from harbour porpoise echolocation signals bouncing off gill nets propagates larger distances than previously assumed

Wahlberg, Magnus
Marine Biological Research Centre, University of Southern Denmark, Kerteminde, Funen, Denmark
Corresponding Author: magnus@biology.sdu.dk

Harbour porpoises (Phocoena phocoena) are caught in large numbers in gill nets. Even though acoustic pingers and changes in fishing practices have reduced a previously enormous bycatch, drowning in fishing nets is currently the largest single anthropogenic factor known to kill animals, and the only known factor having a significantly negative effect on porpoise populations. Therefore, it is important to understand why porpoises are entangled in the gill nets. Porpoises emit high-frequency echolocation clicks and have the most sensitive ears known in the animal kingdom. Even so, previous calculations have pin-pointed that they can only detect gill nets at distances shorter than 5-10 m. By measuring the echoes by simulated porpoise clicks on gill nets up to distances of 50 m in shallow waters and in a measurement tank, this study shows that previous estimates of the detection range of porpoises are seriously underestimated. The underestimation is well explained by the choice of transmission loss model used, in previously studied assumed to be spherical, but in this study (in line with theoretical deduction) shown to be cylindrical. This means that porpoises can probably detect gill nets at distances of 50 or more meters. This has large implications for our understanding of the reasons why porpoises get entangled in gill nets, and also for the design of appropriate changes in the currently used gill nets to avoid further bycatch.

Tracking and measurement of marine animals using unmanned aerial vehicles

Unmanned aerial vehicles (UAVs) enables researchers to gather images and video footage of marine animals like porpoises and seals. The value of these data for researchers can be increased by augmenting the data with information about the flight saved by the UAV. A flying UAV stores information about its position, altitude and orientation of the camera to a logfile.
By combining this information about the UAVs

flight pattern with observations in videos acquied during the flight, it is possible to determine the location of objects on the water surface in real world coordinates and also the distance between objects
in the water surface. To assist this process a computer program has been developed. The program can load a video and the associated log file from the UAV and it allows the user to annotate locations and measure distances along with the water surface.
The output from the program is a text file with timestamps, GPS coordinates and
associated lengths of each of the annotations.
By utilizing this information it is possible to analyze the movement of one or more marine animals in a recorded video; it is also possible to quantify the length and width of the observed animals. The accuracy of the determined position is limited by the used global navigation system and can under typical circumstances be determined within 5 meters. The relative accuracy of the determined lenghts is related to the uncertainty of the the altitude estimates of the UAV, and will under typical circumstances have a magnitude of 5%. The presentation describes the principles behind the developed program, investigates
the uncertainties that is to be expected by employing this approach and gives some basic guidelines for data acquisition using UAVs to ensure reliable measurements.

Reproductive success delays molt and increases thermoregulatory demands in the Weddell seal.

Energy conservation is a key consideration for all animals, with daily resting periods offering the opportunity to relax in anticipation of the next activity bout. For semi-aquatic mammals, daily haul-outs must occur between foraging bouts, which usually requires animals to haul-out on sand, rock, or ice that is spatially separated from prey resources. In addition, the duration of the daily haul-out periods may reflect the impact of physiological constraints and environmental conditions on energetic balance. Weddell seals (*Leptonychotes weddellii*) undertake daily haul-outs on Antarctic sea-ice in order to rest, reproduce and molt. However, there are two factors that may increase the duration and scheduling of haul-out periods: cold air temperatures and wind can increase heat loss, and this can be exacerbated when skin is perfused during the annual molt. To assess how physiological (reproduction/molt phenology) and environmental (weather conditions) factors influenced haul-out durations and corresponding in-air heat flux, time activity budgets of 55 adult females were measured across the austral summer. Females who skipped reproduction in the early summer hauled-out for longer durations and more frequently during sunny afternoons, whereas post-reproductive females spent less time hauled-out, and showed no diel preference in haul-out timing. Furthermore, because post-reproductive females molted later in the summer, in colder ambient conditions, they exhibited significantly higher in-air calculated heat flux across the active molting season compared to skip-breeders which hauled-out and molted in optimal summer conditions ($p < 0.001$). Overall this indicates there is an added thermoregulatory cost associated with reproduction that is not often considered when quantifying reproductive energy costs. This research address how behavior can be used to inform energy budgets for polar pinnipeds in a changing climate, and can further aid in understanding how haul-out requirements during molt of Arctic species may be further impacted by limited ice haul-outs and terrestrial predation.

UK recommendations to reduce marine mammal disturbance from marine tourism.

Commercial marine mammal watching is growing in popularity in the UK and together with a rise in water-based recreational activities occurring around the coastline, appears to be causing an increase in disturbance incidences of cetaceans and seals. The EU Habitats Directive provides some protection from harassment or disturbance of marine mammals. However, other than in Scotland, where legislation exists to protect seals at designated sites, there are no specific legislation, regulation or licence requirements for commercial wildlife watching operations or recreational activities to prevent marine mammal disturbance. Voluntary guidelines and codes of conduct do exist and there is a national scheme (WiSe) which aims to promote responsible wildlife watching through training, accreditation and awareness-raising of boat operators. However, none of

these measures are required to operate a vessel nor enforceable by law.

The UK Governments and conservation agencies, together with NGOs and Wildlife Crime enforcers, recognise that incidences of disturbance are increasing, that awareness of what causes disturbance is generally low and there are few management measures to protect marine mammals from these activities. The UK has therefore developed a 'Dolphin and Porpoise Conservation Strategy', with a range of action plans, one of which concerns marine tourism. The aim is to review options for management measures including regulations, licensing and disturbance monitoring. Here we review approaches from elsewhere in the world to provide recommendations of possible management measures, but also highlight the challenges that will need to be addressed to ensure effective management and protection of marine mammals from disturbance in UK waters.

A reserve network of translocation brings hope and offers opportunities for the recovery of the critically endangered Yangtze finless porpoise

Since the first five individuals of the Yangtze finless porpoise were translocated to the Tian-e-zhou oxbow in 1990, this reserve has seen great adaptation of these animals and steady population growth. This successful experience has led to a reserve network with two more translocation populations established. Exchange programs among these populations have been implemented aiming to maintain the genetic diversity. Now with more than 120 individuals, this reserve network provides insurance against the threat of extinction and provides opportunities for reintroduction to supplement wild populations. We hope this work will shed light on the conservation of other endangered aquatic animals.

Sounding the alarm: Passive acoustic monitoring show marine protected areas in Hong Kong, SAR, China are insufficient to conserve the declining Indo-Pacific humpback dolphins (Sousa chinensis).

Corresponding Author: cetasiajohn@gmail.com

Indo-Pacific humpback dolphins (*Sousa chinensis*) of Hong Kong's waters are declining due to considerable habitat loss resulting from massive developments in coastal waters. As compensatory measures, two marine protected parks (Sha Chau & Lung Kwu Chau Marine Park, SCLKCMP, and Brothers Island Marine Park, BMP) were established in 1997 and 2016, respectively. However, the effectiveness of these marine parks is unknown. In 2013-14 (prior to a mega-development project), CPODs were used to obtain some initial passive acoustic monitoring data at two sites, one each in the SCLKCMP and BMP. Towards the end of one mega-project and the beginning of another in 2017-18, CPODs were deployed again at the same two sites. In 2013-14, 120.10 and 128.22 logged days of data were obtained from the SCLKCMP and BMP sites, respectively. In 2017-18, CPODs obtained about the same number of logged days on the same dates/times for the two sites as in 2013-14. Overall, daily detection positive minutes (DPMs) declined significantly from 2013-14 to 2017-18 (Mann-Whitney $U=21368.5$; $p<<0.0001$). While DPMs for the two sites were not significantly different from each other in 2013-14 ($U=7770.0$, $p=0.869$), SCLKCMP site had more DPMs than the BMP site in 2017-18 ($U=92.0$, $p<<0.001$). Daily DPMs at the BMP site declined to near zero DPMs (Wilcoxon $T=73.5$, $p<<0.00001$) but increased at the SCLKCMP site ($T=2309.5$, $p<0.0005$), however, not to the same level as the BMP decrease. Although some displaced dolphins likely increased their utilization of SCLKMP waters (where impacts are lower), the tiny marine parks used as mitigation measures for large losses of habitat are clearly failing to prevent the dolphin decline in Hong Kong's waters. Much more habitat needs to be protected and prior to further development to ensure the dolphin declines can be stopped and reversed.

Estimating abundance and the effects of ocean conditions on survival and natality in steller sea lions (Eumetopias jubatus) using an integrated population model.

Integrated population models (IPMs) that combine disparate data sources can improve the precision of abundance estimates and demographic rates through the simultaneous analysis of the state of a population and the dynamic processes that underlie that state. Despite the utility of this approach particularly for data-limited species or situations, few IPMs have been developed for marine mammals. Here we present a Bayesian IPM for the western distinct population segment of Steller sea lions (*Eumetopias jubatus*) that combines aerial survey data with mark-recapture data from 2000-2017, thereby allowing robust inference about intrinsic characteristics and ecosystem features influencing age-specific survival and natality over a longer period than has been examined to date. Though the decline and subsequent recovery of Steller sea lions has been studied extensively, the influence of oceanographic conditions on demographic rates has not been explored and aerial survey data have been used at the coarser level of pups versus non-pups rather than a more robust age-based approach. The hierarchical model framework facilitates the inclusion of environmental data (e.g., upwelling and large-scale oscillations), individual characteristics (e.g., pup weight and natal region), and survey features (e.g., sampling intensity) when modeling both the state and observation processes that give rise to abundance data. The multi-event mark-recapture component of the IPM was evaluated using Bayesian model selection approaches, identifying small but notable effects of pup weight and ocean conditions on pup survival and natality. This model provides much-needed updated abundance estimates, improves predictions of population viability, and advances efforts to identify factors driving regionally-divergent abundance trends. Examining the relationship between predators and their environment through one of the first IPMs for an otariid species informs efforts to quantify the regional impacts of human activities and provides new insights that are foundational to ongoing conservation and management with respect to future climate variability.

Spatio-temporal distribution of pygmy and Antarctic blue whales in central New Zealand, via passive acoustic monitoring

Passive acoustic monitoring provides an effective method for studying visually-cryptic, but acoustically diverse, vocal organisms. Two sub-species of blue whales, pygmy and Antarctic, co-occur around New Zealand. Visually, the two sub-species are difficult to distinguish in the field, however, songs produced by males are markedly different and can be used for sub-species identification. Acoustic data were collected from four recorders placed in the Cook Strait region, between New Zealand's North and South Islands, during 2016 and 2017, to investigate the spatial and temporal distribution and overlap of the two blue whale sub-species.

Pygmy blue whale song units were recorded throughout the region during all months of recording. Detection of these sounds peaked between March and May (58% of all units were detected in this period), and detections were fewest during September and October (austral spring). A total of 85% of pygmy blue whale song units were detected to the west of Cook Strait (South Taranaki Bight). At this westerly recorder, a large number of feeding-associated calls (not sub-species specific) were also detected, suggesting blue whales could use the area for foraging.

Detection of Antarctic blue whale songs peaked from June to August (92% of calls), with a smaller peak during October (7% of calls), likely indicative of northbound and southbound migration, respectively. The period between June and October is presumed to be the breeding season, and fewer calls were detected with poor quality suggesting breeding occurred away from the acoustic recorders. A vast majority (77%) of Antarctic blue whale song units were detected to the east of Cook Strait, suggesting that migration past New Zealand occurs over deep water.

During Antarctic blue whale migration, the two sub-species are sympatric in New Zealand waters, but with different residency patterns.

Potential resource competition between narwhal and beluga in northern Hudson Bay, Canada

Watt, Cortney
Fisheries and Oceans Canada, Winnipeg,

Manitoba, Canada
Corresponding Author: cortneywatt@gmail.com

Narwhal (*Monodon monoceros*) and beluga (*Delphinapterus leucas*) are the only two extant monodontid species and both have an Arctic distribution. The species are often found in different areas, and news of a single narwhal observed travelling with a pod of beluga in the St. Lawrence River sparked worldwide attention. However, both species regularly occur in northern Hudson Bay in the central Canadian Arctic during the summer months. Little is known about how they interact with one another and whether they compete for prey or specialize on different prey during this seasonal overlap in their home range. To investigate potential interspecific competitive pressure, we estimated 1) range and abundance by conducting an extensive aerial survey of the area in August 2018 and 2) the extent of dietary overlap between both species through stable isotope (SI) analysis in skin, and fatty acid (FA) analysis in blubber samples. Aerial observations revealed narwhals and belugas travelling in pods only a few meters apart, and distance analysis showed higher narwhal density and abundance in the area. Statistically significant overlap in SI and FA measures between the two species suggests they compete for similar prey resources. Intraspecific competition with a high density of beluga in western Hudson Bay may drive some belugas into northern Hudson Bay, where they encounter narwhal and increased interspecific competition for prey. Since this area has a lower whale density overall, beluga may face less competitive pressure by distributing further north. Whale density, prey availability and distribution, and philopatry all contribute to defining regions where narwhal and beluga can coexist. Interspecies competition may drive niche partitioning between narwhal and beluga over time.

Behavioral response function for Cuvier's beaked whales on a Navy training range

The behavioral response to mid-frequency sonar has been documented for a variety of cetacean species, with impacts including increased swimming speed, travel away from a location, changes in orientation or group synchrony, cessation of resting or vocal behavior, and stranding. Additionally, multiple species (Blainville's and Cuvier's beaked whales, killer whales, blue whales, and sperm whales) have shown impacts to foraging behavior. For beaked whales, passive acoustics allows for the quantification of foraging impacts by examining changes in the distribution of detections of echolocating foraging groups during sonar activity, as was demonstrated for Blainville's beaked whales, to develop a behavioral response function (BRF). Here we will develop a BRF for another species of beaked whales, Cuvier's beaked whale (*Ziphius cavirostris*), found on the US Navy's Southern California Anti-Submarine Warfare Range (SOAR). Previous analyses at SOAR have demonstrated that passive acoustic detections of active foraging groups declined significantly during sonar training events, but returned to pre-event levels within hours of the sonar ending. Additionally, data from tagged whales showed that the time between foraging dives increased as proximity to sonar events decreased. To understand the overall impact of sonar on foraging at SOAR, we modeled received levels during actual sonar training events, using the Navy Acoustic Effects Model (NAEMO), across a variety of sonar training events, with different types of mid-frequency sonar sources, to cover the variability in training events that occur on this range. Foraging activity in time periods without sonar were used to estimate baseline foraging level. A generalized additive model was used to model the presence or absence of foraging groups on each hydrophone as a function of the sonar received level, and hence a BRF. Comparison to the BRF for Blainville's beaked whales in the Bahamas will be discussed.

Environmental pollution impacts lipid metabolism and adipogenesis in polar bears

Waugh, Courtney Alice[1]; Tartu, Sabrina; Aars, Jon; Lefai, Etienne; Lee, Megan; Strand Lundgren, Silje; Routti, Heli[2]
(1) Norwegian University of Science and Technology, Gold, Norway
(2) Norwegian Polar Institute
Corresponding Author: c.waugh@uq.edu.au

Polar bears annually undergo a physiologically stressful fasting period, during which they must maintain optimal control of their metabolism if they are to survive. However, their ability to store energy for survival is challenged by the decline of Arctic sea ice. This has been linked to negative impacts on survival and reproduction, due to longer periods of fasting and a greater dependence on physiological processes.

The polar bears physiological ability to respond to this challenge may also be limited. As apex predators in the Arctic, with large lipid stores, they are exposed to significant environmental pollution. Over 90% of their body burden of pollutants are found in white adipose tissues, thus adipose tissue is at special risk for toxic effects. White adipose tissue consists mainly of adipocytes, with the primary function of storing lipids in periods of excess energy and mobilising lipids during energy deprivation. Results from correlative field studies and *in vitro*studies already indicate that pollutants disturb polar bear lipid metabolism. However, the mechanisms by which this occurs remains elusive.

Thereby we studied the effect of pollutants on adiponectin levels and the expression of two miRNAs important for adipogenesis (miR-27a and miR-130) in n = 112 polar bear blubber biopsies obtained from populations inhabiting Svalbard, Norway. We provide evidence that pollutants decrease the expression of these miRNAs and limits adiponectin levels.

Modulation of these miRNAs away from their equilibrium (both overexpression or under expression) has been shown to limit adipogenesis in mammals. Thereby, exposure to pollutants may be limiting polar bears ability to store and remobilise lipids when needed, contributing to decreased survival and reproduction.

Long-term dolphin declines in anthropogenic disturbance "Ground Zero"

Weaver, Ann
John's Pass Dolphin Study, Good-natured Statistics Consulting, St Petersburg, FL
Corresponding Author: annstats54@gmail.com

After direct harvesting, noise pollution is the anthropogenic activity with the most negative impacts on coastal cetaceans like bottlenose dolphins (*Tursiops sp.)*. A 14-yr BACI study of a 5-year, geographically-localized bridge construction project over a vital dolphin corridor connecting the ICW and Gulf of Mexico in western Florida provided a case study of bottlenose dolphin occurrence patterns concurrent with chronic habitat disruption, primarily noise pollution. This report compares dolphin occurrence in the area directly impacted by construction activities or "ground zero" before, during, and after construction. Dolphins were documented on small boat surveys 2-4 times/wk, N = 1327 surveys, 2005-2017. Occurrence was examined as total numbers of dolphins and presence/absence. For total numbers, ANCOVA revealed a significant steady decline after controlling for time, temperature, and total dolphins in the entire study area. After construction, dolphin numbers dropped below the grand mean and stayed uniformly low for 7 years without evidence of recovery. In contrast, for absence/presence, odds stayed at 'even odds' and logistic regression showed that relationships between social/environmental parameters and sighting odds also remained consistent. Findings were that habitual use of this vital dolphin corridor did not change despite steadily fewer dolphins using it in the 7 years post-construction. Conclusions are that changes in coastal cetacean behavior concurrent with coastal construction may last long after anthropogenic disruption has ended without signs of obvious recovery but could be easily missed without concerted scientific documentation. Marine mammals need urgent conservation measures and this study provides important management information about potential longer-term effects.

Satellite imagery and citizen science reveal the ecology of abundance and distribution of Crabeater seals in the Weddell Sea

Wege, Mia[1]; LaRue, Michelle[2]; Salas, Leo[3]
(1) MRI, University of Pretoria, Pretoria

(3) Point Blue Conservation Science, Petaluma, California
Corresponding Author: mia.wege@gmail.com

Crabeater seals (*Lobodon carcinophaga*) are labelled as the most abundant seal species in the world. Native to Antarctica, with a circumpolar distribution, their population estimates range from 2-75 million (current best estimate = 8 million). Based on observations from shipboard and aerial surveys, crabeater seals prefer to live and breed on loose pack-ice – however, this potentially biases current knowledge about crabeater seal ecology given ship surveys are limited by sea ice conditions. Thus, much of the inaccessible and highly concentrated pack ice has been little explored for seal abundance. Here, we combine satellite images and citizen science to determine firstly the population size and density of crabeater seals in the Weddell Sea and secondly, to

understand the abiotic factors that influence crabeater seal distribution. High-resolution satellite images covering an area of ~18,000 km2 in the Weddell Sea (October 2018) were hosted on the crowd-sourcing platform Tomnod (DigitalGlobe). Citizen scientists marked maps where seals were present or absent, and experienced observers manually counted seals from the reduced number of images. About 2% of maps were open water, 60% were covered by extensive sea ice, and 17% of maps contained small or mixed ice floes. Crabeater seals were present on 71% of the mixed size ice floes at a density of 0.065 seals/km2. Abiotic variables, such as ice concentration and floe size were used in habitat suitability models to understand seal abundance and distribution. Crabeater seals preferred small ice floes within the Marginal Ice Zone; the deep Weddell Sea with extensive year-round ice were almost devoid of seals. These new and comprehensive insights into the distribution and abundance of crabeater seals will provide a baseline to which future population estimates can be compared and allow us to predict how crabeater seals will respond changes in sea-ice composition due to climate change.

Translating science into policy: How the presence (or absence) of evidence can be used to develop conservation measures for endangered whale populations.

Weiler, Colleen[1]; Asmutis-Silvia, Regina[2]; Giles, Deborah[3]; Wasser, Samuel[4]

(2) Whale and Dolphin Conservation, Plymouth, MA
(3) University of Washington, Friday Harbor, WA
(4) Center for Conservation Biology, Seattle, WA
Corresponding Author: cmweiler77@gmail.com

Strong conservation measures for endangered species should, according to the U.S. Endangered Species Act, be based in the best available science. With the considerable challenges in collecting data on highly mobile and widely distributed marine mammal species, however, the best science is not always available. When developing management initiatives to protect highly endangered marine mammal populations, such as Southern Resident orcas and North Atlantic right whales, an absence of evidence is sometimes misinterpreted by those influencing policy decisions as evidence of absence. Science on marine mammals often raises additional questions, reminding us more about what we don't know than confirming what we do know. Translating this information into concrete policies presents considerable challenges from the conservation perspective. How do we ensure strong measures are developed and enacted to protect endangered orcas and right whales when significant data gaps exist for these populations, and how can researchers and conservationists help policymakers fill in those gaps? For example, scat collection from Southern Resident orcas can provide information on nutritional status and toxicant loads for individual orcas, but is usually only collected when the orcas are in their summer foraging habitat. This leaves an absence of information on the condition of the orcas' winter and spring habitat and prey resources; however, the nutritional status of individuals as they return to their summer range can be used as a proxy for the health of their winter and spring environment, and can help guide the development of additional protective measures. Researchers and conservationists can work together to use the "best available science" to bridge the data gaps and translate science into policy for the sake of endangered species recovery.

Behavioral and environmental context of Antarctic minke whale vocalizations

Acoustic signaling is the predominant form of communication between cetaceans, and understanding the behavioral state of calling individuals can provide insights into the specific function of these vocalizations. For cryptic species, this information can be especially useful when evaluating passive monitoring data sets to estimate species presence, density, and behavior. The most numerous baleen whale in the Southern Ocean is the Antarctic minke whale, however little is known about their acoustic behavior. We used motion-sensing tags with concurrent video and acoustic recording abilities deployed on 29 Antarctic minke whales around the Western Antarctic Peninsula. We used the data collected from these tags to characterize the whales' vocal repertoire and assess the associated behavior of both tagged individuals and others present in animal-borne videos. Acoustic data was manually audited for calls when concurrent video data was also available. Vocalizations were sorted into distinct call types based on several known acoustic parameters including 90% call duration, frequency bandwidth, and frequency quartiles. Call types were then

compared to concurrent video data to determine the behavioral state and environmental conditions (e.g., sea ice cover) of the individuals during periods of vocal activity. Our results demonstrate that Antarctic minke whales produce several distinct sound types ranging in frequency from 180-560 Hz, and consist of pulse trains, down-sweeps, growls, and other sound types not previously described in the literature. Vocalizations are produced during distinct behavioral states including foraging, travel, socializing, resting and are emitted both in solitary and in groups of up to five animals. Additionally, vocalizations were emitted in both open water and heavy sea ice conditions. Our results represent a significant advancement in our understanding of the life history and behavior of Antarctic minke whales and improve our capacity to acoustically monitor this species in an ever-changing Antarctic region.

Effects of body size, food type, and ontogeny on chewing cycle duration in West Indian manatees (Trichechus manatus).

Mastication is the cyclical pattern of mandibular movements in mammals and can be measured as a rate (chews/sec) or the inverse (chewing cycle duration; CCD). Mastication rate is a key variable in models of feeding ecology. A positive, interspecific relationship exists within mammals between CCD and body mass; however, intraspecific patterns have not been as clear. This study investigates the effects of body size, food type, and ontogeny on CCD in West Indian manatees (*Trichechus manatus*). We recorded 18 captive manatees of varying body lengths consuming two food types. Additionally, nine of these manatees were recorded on two separate occasions, six years apart, allowing us to examine ontogeny. Curved body length was measured along the dorsal surface. CCD was extracted from the recordings using Raven Pro 1.5. Food type ($r = 0.78$, $p = 6.8x10\text{-}5$, $n = 17$) and body length ($r = 0.53$, $p = 0.033$, 95%CI 0.14-1.00, $n = 17$) significantly affected CCD. Individual variation remained consistent even while CCD changed during growth. Both CCD and body length increased over time; however, our small sample lack the statistical power needed to show a significant correlation between ΔCCD and Δbody length ($r = 0.44$, $p = 0.24$, 95%CI -0.198-1.00, $n = 9$). Considering all three contributing factors influencing CCD, we conclude from our study that it might be difficult to accurately estimate body length from mastication sounds due to individual variation (independent of body size and food type). It may possible to determine relative body size if food type is controlled for. In addition, while mean CCD (543 ms) varied between manatees by as much as 144ms, each individual chewed at a consistent rate (mean SD = 41), which may allow individuals to be distinguished from each other in the wild.

Distribution and movements of sei whales (Balaenoptera borealis) on coastal feeding grounds in the Falkland Islands (Malvinas).

Southern Hemisphere sei whales (*Balaenoptera borealis*) were heavily impacted by 20th century whaling operations. Knowledge of their present-day distribution, abundance and ecology is poor. To address that data gap, boat-based surveys targeting sei whales were carried out around the Falkland Islands (Islas Malvinas) during the austral summer and autumn between 2017 and 2019, focussed on three coastal (≤30 km distance from shore, and ≤100 m depth) study sites. Standardised visual methods, photo-identification, faecal sampling and biopsy sampling were implemented. Sei whales were the most frequently-sighted cetacean species, and were distributed throughout the coastal waters surveyed, including nearshore habitat (to <200 m from the shoreline), inside semi-enclosed inlets and channels, and over shallow water depths (500 m grid cell values: 2 to 107 m depth). Approximately 300 sei whales were photo-identified from natural markings including scars and dorsal fin marks. Photo-identification analysis revealed movements of individuals between the east and west coasts of the Falklands, and recaptures in different years. Observational and faecal sampling data indicated that sei whales use Falkland waters for feeding, with over 100 faecal events observed over the three seasons. Visual analysis via microscopy of 19 faecal samples from 2017 revealed the body parts of the crustacean squat lobster (*Munida gregaria*) in all samples. Surface feeding was observed on *M. gregaria* during 2017 and on the amphipod *Themisto gaudichaudii* during 2019. The presence of several cow-calf pairs during 2019 suggests that Falkland waters could be used by lactating females following calving the previous winter/spring. These

combined data indicate that the Falkland Islands represent a significant coastal foraging ground for globally endangered sei whales. Further understanding of their distribution, population dynamics and ecology is integral to maximising effective conservation management of the species in the Falkland Islands, and throughout the wider South Atlantic region.

Defining shelf break soundscapes of southern Georges Bank, western North Atlantic Ocean.

Within a soundscape, anthropogenic sound occurs in and often dominates frequency ranges used by certain species, leading to overlap of signals and potential communication masking. To evaluate the extent of this acoustic overlap, it is helpful to understand how species utilize different acoustic niches across time. This study's primary goal was to assess the co-occurrence of cetacean species and anthropogenic activities, and to present simple and accessible visualizations of the temporal and spectral overlap representing site-specific acoustic niches. Acoustic data were collected using archival underwater acoustic recording devices, known as High-frequency Acoustic Recording Packages (HARPs). Programmed to sample continuously at 200 kHz, HARPs were deployed near three deep-water canyons (Heezen, Oceanographer, and Nantucket) along the continental shelf break of Georges Bank from April 2015 to March 2016. Recording durations were 271, 288, and 145 days, respectively. Daily presence data were compiled for six baleen whale species (North Atlantic right, fin, blue, sei, humpback, and minke), five odontocete species and/or groups combined according to the primary frequency ranges and ease of identification of their sounds (delphinid spp, sperm whales, Kogia spp, Sowerby's and Cuviers'/True's/Gervais' beaked whales), and four anthropogenic sound sources (airguns, vessel noise, echosounders, and explosions). At each site, both cetacean and anthropogenic sources were found to be major contributors to the soundscape. Individual cetacean species or groups were present from 0.37% to 100% of days across sites, with dolphins, sperm whales, and fin whales detected most consistently. Airgun noise was the most frequently detected anthropogenic signal, ranging from 50-91% of days across all sites, followed by vessel noise (21-59% of days), and echosounders (4-20% of days), with one explosion detected at Oceanographer Canyon. This approach allows for broad comparison of species and anthropogenic activity composition, providing an understanding of variability in acoustic overlap and potential masking between sites.

Bottlenose dolphins and red tide harmful algal blooms: Are patterns of dolphin responses emerging from repeated events?

Bottlenose dolphins exhibit strong site fidelity to many Gulf of Mexico bays that experience red tide (*Karenia brevis*) harmful algal blooms. Blooms vary in spatial coverage, duration, and severity, but can cause direct dolphin mortality from brevetoxins, as well as lagged ecological impacts from prey fish mortalities. A severe red tide along the central west coast of Florida in 2005-06 was

associated with temporary changes in dolphin habitat use, declines in body condition, and increased adverse human interactions, including deaths of 2% of resident Sarasota Bay dolphins from recreational fishing gear ingestion. Fish surveys documented a decline of 75% for the dolphins' primary prey fish, suggesting a reason for increased interest in anglers' bait and catch. Fish numbers did not return to pre-bloom levels for two years, and dolphins continued to exhibit elevated levels of human interactions. Were the changes observed in association with the 2005-06 severe red tide a model for what may happen as blooms are expected to increase in severity and frequency with climate change, and if so, what can be done to reduce human impacts to dolphins? A severe red tide in 2018-19 is providing an opportunity to look for patterns of changes. To date, we have documented the loss of 88% of dolphin primary prey fish, and initial findings indicate changes in dolphin behavior, trophic level at which they are feeding, body condition, and occurrence of skin lesions. Our passive acoustic monitoring network is documenting dramatic ecosystem changes. Within a 3-week period, we disentangled two 2-yr-old calves from recreational fishing line in areas affected by the bloom. Continuing research is focused on determining whether we can predict circumstances under which increased adverse human interactions might be expected to occur, allowing us to proactively target outreach efforts to try to reduce anthropogenic impacts.

Effects of distance and received level on sonar-induced behavioural disturbance in two deep-diving cetaceans.

Quantitative environmental impact assessments for naval activities typically use acoustic received levels to predict behavioural disturbance in marine mammals. However, recent observations in areas with frequent sonar activity suggested that deep-diving cetaceans may learn to associate exposures from distant sonar sources with lower perceived risk. We conducted at-sea experiments with northern bottlenose whales (n=12 individuals) and sperm whales (n=16 individuals) to investigate the roles of received level and source distance on their behavioural responses to naval sonar. Subjects were tagged with high-resolution archival DTAGs or medium-resolution satellite tags and subsequently exposed to pulsed sonar in the 1-4 kHz frequency band. Our novel experimental design included different sonar systems with different maximum source levels including a full-scale operational sonar source, and dose escalation with a ramp-up of source level, to separate received level from source distance as the main driver of response. Experiments with northern bottlenose whales were conducted in the relatively pristine underwater acoustic environment of Jan Mayen. Sperm whales were experimentally exposed in waters off mainland Norway, in an area with more frequent naval sonar activity. Northern bottlenose whales exhibited relatively severe behavioural responses with avoidance threshold sound pressure levels ranging from 117-126 dB re 1 µPa, similar to other tagged beaked whales. The onset and intensity of their responses did not appear to be influenced by source distance (to the 28 km tested). In contrast, sperm whales exhibited less severe behavioural responses which abated more quickly and generally were initiated at higher received levels and shorter distances to the source. Combined, these experiments highlight the importance of exposure factors such as received level, as well as of contextual factors such as species and pristineness of the habitat. Our results enable more accurate predictions of behavioural disturbance in deep-diving cetaceans and should help navies to reduce the environmental effects

A computer model for studying fishing gear modifications in virtual reality to prevent large whale entanglements

Whale entanglements occur worldwide in all types of fishing line and netting, and involve all species of baleanopterids. For some species and

populations, such as the critically endangered North Atlantic right whale (*Eubalaena glacialis*), it is the most immediate threat to its persistence and recovery. Evaluating fishing gear modifications for threatened species is challenging given that low population abundance makes entanglement events relatively rare, and therefore field experiments to compare the effects of gear alterations with control (typical) gear cannot generate sufficient statistical power. The fishing industry and regulators therefore rely on intuition or limited scientific evidence when implementing gear changes. To provide a more evidence-based approach for making decisions regarding reducing whale entanglement incidence and severity, we developed a computer model that graphically simulates encounters between a North Atlantic right whale and pot gear. The whale is an anatomically accurate model capable of articulating in ways similar to an actual right whale, and the fishing gear was constructed using actual physical properties of ropes. Among the initial evaluations of this model, we examined rope with a breaking strength of

Biomechanics of the rorqual temporomandibular joint.

Rapid engulfment and expulsion of massive volumes of water (15-80+ m^3) during rorqual (balaenopterid whale) lunge feeding—dubbed the greatest biomechanical action in the animal kingdom—depends on a strong yet flexible jaw joint that can withstand intense forces. We investigated the mobility, strength, and elasticity of the temporomandibular joint (TMJ) in adult, juvenile, and fetal minke (*Balaenoptera acutorostrata* and *B. bonaerensis*) and fin (*B. physalus*) whales. Using a strain gauge potentiometer attached to jaws of deceased specimens, we recorded rotational angles in three dimensions (jaw abduction, longitudinal rotation, and horizontal displacement around condylar and symphyseal axes) and found that at full gape (>90 degrees), the posterior (condylar) end of the mandible is medially rotated ~30 degrees, laterally displaced, and slightly elevated and retracted. However, during an early phase of jaw abduction the mandible rotates laterally ~7 degrees and the condyle is slightly medially displaced, suggesting an unstable intermediate position. These changes may aid in locking/unlocking and strengthening gape during lunge feeding. Joint angles were verified via goniometer and confirmed by CT scans showing bony and soft tissue movement. The non-synovial rorqual TMJ has a large fibrocartilage pad with scattered collagen and elastin fibers. Laboratory and field experiments revealed multidimensional stress/strain curves as the TMJ pad is loaded and unloaded, with slightly greater elasticity in the mediolateral plane (with deformation of about 200% under tensile stress of 35 MPa and deformation of nearly 100% under compressive loading of almost 25 MPa) relative to the anteroposterior plane, and with the least "stretchiness" (in compression and tension) in the dorsoventral plane. These give the rorqual TMJ a tremendous capacity to dampen acceleration and absorb shock during engulfment, and to aid in gape closure during filtration by elastic recoil with conversion of stored potential energy into kinetic energy.

3-D modeling to assess habitat impacts from underwater noise

The soundscape of the marine environment includes biologically relevant information for marine species and affects their ability to detect predators and prey, locate conspecifics, and orient themselves within their environment. While most regulations relevant to sound in the underwater environment focus on the acute impacts of acoustic and explosive noise on individual marine species, the quality of the acoustic environment within the habitat has recently become an international focus for assessing impacts to marine species. In the United States (U.S.), the description of critical habitat for the endangered Main Hawaiian Islands insular false killer whale (*Pseudorca crassidens*) distinct population segment includes sound levels that would not significantly impair false killer whales' use or occupancy of their habitat. The European Union (E.U.) has established a goal of ensuring underwater noise does not adversely affect the environment. However, both in the U.S. and the E.U., there are no standard methods to estimate the impact of future actions. The U.S. Navy has used the Navy Acoustic Effects Model (NAEMO) to quantify impacts of navy sonar and explosives on

marine species. Here, we demonstrate the viability of using this model to analyze the spatial and temporal contribution of Navy activities on habitat soundscapes. Habitat modeling will identify the proportion of habitat that is impacted at different levels and types of anthropogenic activity. Proportions of habitat will be quantified where individual animals could incur injury, behavioral changes, and masking. Habitat modeling allows for a broad analysis and anticipates the need to analyze with a more comprehensive approach in future analyses.

A novel pulmonary vasculitis in grey seals (Halichoerus grypus) associated with Otostrongylus circumlitus infection.

Lungworm infection in seals is an important cause of morbidity and mortality inducing bronchopneumonia affecting population dynamics in some areas of the world. We present a series of cases of lungworm infection in grey seals associated with novel, significant and highly unusual pulmonary vascular changes.180 grey seals either stranded, in rehabilitation or long-term captivity from the UK were subject to post-mortem examination between 2012 and 2018. Lung was collected from 47 individuals for histopathological examination. Nematode morphology within sections was evaluated histologically. PCR on FFPE material was attempted for parasite identification on selected sections using lungworm specific primers.14/47 (30%) of grey seals showed evidence of segmental granulomatous and eosinophilic vasculitis with intramural Splendore-Hoeppli reaction in medium to large pulmonary arteries. Intra-vascular nematodes suggestive of *O. circumlitus* were seen in 2 cases. PCR on FFPE material was unable to detect a signal on selected tissue sections. 9 animals had concurrent bronchopneumonia and 4 had intra-alveolar/bronchiolar *Parafilaroides species*. 13/14 animals with vasculitis lesions were weaned pups with only 1 adult affected. Previous pathological descriptions of lungworm infection in grey seals have dealt mainly with the bronchopneumonia. This case series has identified previously unrecorded vascular changes characterised by the deposition of intra-mural Splendore-Hoeppli reaction. Such change would impact on vascular integrity increasing the likelihood of vascular rupture with pulmonary haemorrhage and increased risk of intravascular coagulation. An aberrant host-parasite relationship with the persistence of antigenic material following close contact with or migration through the blood vessel wall is suspected.

Oxytocin quantification in serum using liquid chromatography/mass spectrometry (LC/MS) and enzyme immunoassay (EIA) in bottlenose dolphins (Tursiops truncatus)

Oxytocin is a neuropeptide synthesized by the hypothalamus and secreted by the posterior pituitary gland which has been shown to a play a role during the *periparturient* period, lactation, and maternal and offspring bonding in terrestrial mammals but its role in cetaceans is not known. An accurate and reliable method for quantitating circulating concentrations of oxytocin will provide a tool to evaluate the role and diagnostic and prognostic value of oxytocin during various reproductive states in cetaceans. A liquid chromatography-mass spectrometry (LC-MS) method was adapted for measuring oxytocin in dolphin serum. A calibration curve was established for 0.10-100 ng of oxytocin, correlating to a serum concentration limit of detection at 125 pg/mL. However, oxytocin was not detected in pooled serum from adult bottlenose dolphins (0.5 mL sample volume). Additional oxytocin extraction and concentration steps on larger serum volumes will be needed to detect and quantify oxytocin by LC-MS. In parallel, an oxytocin enzyme immunoassay (EIA) kit (Arbor Assay) was adapted for use with dolphins using a pool of serum from adult animals. A minimum of 3.2 mL of serum was used for extraction to yield a x10 concentrated sample. Parallelism relative to the oxytocin standard curve was indicated using dilutions (x10, x5, x2) of the extract. Recovery of 101% was indicated after low, medium, and high oxytocin standards were added to the extract. Sensitivity of the assay was 19 pg/mL. Results indicated a need for sample extraction to concentrate oxytocin for EIA, which is in accordance with that previously reported in cattle, horses, pigs, goats and sheep. While these initial

results provided successful validation of the LC-MS and EIA performance and quantitation of oxytocin in a pool of dolphin serum, the biological relevance in serum samples from *periparturient*, lactating, and non-lactating female and male bottlenose dolphins needs to be assessed.

Palaeogenomic and stable isotope data reveal the responses of bowhead whales to climatic perturbations during the Late Pleistocene and Holocene.

Westbury, Michael[1]; Bachmann, Lutz; Dyke, Arthur S; Wiig, Øystein[2]; Szpak, Paul; Lorenzen, Eline

The bowhead whale (Balaena mysticetus) is the only baleen whale endemic to Arctic waters. It plays a central part in the Arctic ecosystem and its evolutionary history is closely tied to the environmental dynamics of the region. The bowhead whale has a uniquely large fossil record in the central Canadian Arctic and Svalbard spanning the last approximately 50,000 years. This sample set enables a comparative study of the environmental changes in two independent locations and the resultant evolutionary responses of bowhead whales during the Late Pleistocene and Holocene. Using carbon and nitrogen stable isotopes recovered from this unique assemblage, we address how the bowhead whale diet changed in real time, giving insights into shifts in primary producers and by proxy, shifts in the Arctic palaeoclimate. Furthermore, using high throughput next generation sequencing of ancient DNA (aDNA), resulting in both mitochondrial and nuclear genomes, we uncover the genetic responses of bowhead whales to the climatic changes throughout the Late Pleistocene and Holocene. The genetic data allows us to directly investigate how changes in the environment influenced population structure and uncover patterns of genetic isolation and gene flow through time. Our findings provide an in-depth understanding into the genetic responses of bowhead whales to past climate change and can aid in the formation of informed inferences about the resilience of bowhead whales to rapid current global climate change.

Western Hudson Bay estuary use for calf rearing

Westdal, Kristin[1]; Ferguson, Steven[2]; Roth, Jim[3]

Social and spatial segregation of sexes is common amongst vertebrates that live in groups. Whale species such as the North Atlantic right whale (*Eubalaena glacialis*), North Pacific gray whale (*Eschrichtius robustus*) and bowhead whale (*Balaena mysticetus*) are known to have nursery areas where females feed and take care of their young. Although segregation of older adult males from immature males and females is known to occur in some beluga whale (*Delphinapterus leucas*) populations, it is unclear if adults accompanied by calves segregate for periods of time during the year in the eastern Canadian Arctic, where the largest summering population is found. A long held hypothesis has been that western Hudson Bay estuaries are critical for calf rearing by offering protection from predators, warmer waters for thermal advantage, and feeding opportunities, but no study has looked closely at the distribution and habitat use of mothers with calves. Using imagery from a photographic survey conducted in August 2015, we evaluated whether adults accompanied by calves use estuaries and near shore habitat more than other age classes in western Hudson Bay in the summer. Photographs were taken using two Canon cameras (25 mm and 50 mm lenses) mounted on a twin otter flying at 2,000 feet over the Churchill and Seal River estuaries (complete photographic coverage) and offshore areas (transect coverage). Belugas were identified and classified by age manually using an identification decision tree that considers length and color and GPS coordinates were plotted in ArcGIS. Distribution by age class was examined in relation to distance to coastal habitat and bathymetry (predation theory), water temperature (thermal advantage), and chlorophyll-a (as a proxy for feeding opportunities). Further understanding of spatial patterns of belugas habitat use in western Hudson Bay is necessary to provide conservation and management advice.

Did grey seals reproduce in the German Baltic Sea before their extinction in 1920? Historical records provide answers to a controversial question determining future management decisions.

Westphal, Linda[1]; Dähne, Michael[2]; von Nordheim, Henning[3]

(2) German Oceanographic Museum, Stralsund, Germany
(3) Federal Agency for Nature Conservation, Putbus, Germany
Corresponding Author: linda.westphal@meeresmuseum.de

After a strong population recovery, in 2018 and 2019 the first two grey seal births were recorded in the German Baltic Sea since their return into this waters in 2005. Simultaneously, a rising number of juvenile grey seals resting on beaches and carcases of juvenile seals washing up was recorded in the last few years. The last grey seal was shot in 1920 in the German Baltic Sea. Nowadays, grey seals are present year-round and with increasing densities again, especially around the island Rügen. The return of grey seals was a great success of effective, long-term, international nature conservation measurements. In many cases, the return of a top predator causes controversial and highly emotional conflicts between different interest groups. Therefore, the question if grey seals had reproduced in this region of Germany, before they got extinct, is of high importance for future management decisions. Unfortunately, historical records, partially handwritten notes, are rare. Consequently, we collected and analysed all available data about "white pups", indicating grey seal pups with lanugo fur. There are 26 evidences of grey seal pups between 1893 and 2019 for the German Baltic coast, with only one clear evidence before the extinction in 1920. Surprisingly, there are 13 evidences of grey seal pups in the time span of its presumed absence in Germany, indicating that grey seals had never entirely disappeared. In recent years, the number of pups sighted increased steeply, though most of these pups were already several weeks old, they are not deemed to be born here. The 2018 and 2019 birth records show that births occur on our coast. Therefore, the Southern Baltic Sea, including the German coast, probably was and is an reproduction area of grey seals even though there were no proofs of a historic established pupping sites in the German Baltic.

Recent occurrence of marine mammals off Angola and first report of right whales since whaling era

Marine megafauna occurrence was recorded in deep offshore waters during an Environmental Baseline Study. The goal of this study was to characterize the habitat and biodiversity of an area of oil and gas exploration 400 km northwest of Luanda, Angola. These offshore shipboard surveys were conducted during September 2018, in water depths ranging from 2,350 m to 3,850 m. We recorded opportunistic sightings of marine mammals during daytime visual observations and conducted passive acoustic monitoring at night to record vocalizing marine mammals. A variety of species were visually recorded, including humpback whales (*Megaptera novaeangliae*), sperm whales (*Physeter macrocephalus*), common dolphins (*Delphinus* spp.), and striped dolphins (*Stenella coeruleoalba*). Most notably, southern right whales (*Eubalaena australis*) were visually confirmed in these waters. This is the first confirmed record of this species in Angolan waters since the early 1900s. In addition, a five-second bout of variable-frequency-range clicks spanning 7 kHz to 40 kHz was recorded, as well as additional click bouts potentially suggestive of sperm whale and other odontocete vocalizations.

Porpoises versus people? Mental models, conflict, and conservation pathways in the case of vaquita (Phocoena sinus) conservation.

Whitty, Tara Sayuri; Young, Samantha; Hernandez Martinez, Areli; Vargas Zendejas, Veronica Y.
International Union for Conservation of Nature
Corresponding Author: tara.whitty@gmail.com

The steady slide of the vaquita (*Phocoena sinus*) toward extinction has been a high-profile, high-conflict conservation disaster. The main threat to this Critically Endangered species is bycatch in gillnets for shrimp (a vital livelihood for local communities) and the illegal totoaba fishery. Conservation actions, including a gillnet ban with a compensation scheme, ignited conflict between conservation and communities. Generally, such conflict has been shown to seriously impede conservation efforts, and can be driven by differing mental models or worldviews held by stakeholders; understanding these differences can elucidate drivers (and potential solutions) of conflict. We conducted semi-structured interviews of fishers, community members, government agencies, conservation groups, and researchers about their conservation values and perceptions about the process and impacts of conservation. Findings confirm substantial discrepancies, but also unexpected alignment, between mental models of conservation-affiliated stakeholders and local communities on several topics, grouped in four categories: general interactions (trust, communication, inclusion); management (priorities, scope, value of the vaquita); social impacts (type and severity); and other stakeholders (and their presumptive mental models). Among a subset of respondents, there was a disconnect between their negative assumptions of the values of the "other group" (conservation or community) and what respondents from that "other group" expressed about their own values. The situation is much more nuanced than a dichotomous "pro-porpoise versus pro-people" conflict, though it is often framed as such. Sharing mental models might indicate unexpected

commonalities while promoting empathy for conflicting viewpoints, which is essential for conflict transformation. For the vaquita, it is almost certainly too late to integrate understanding of mental models into conservation. However, other important local management issues remain that will require better conservation-community relationships. This evaluation also holds important insights for the global issue of bycatch; learning from this conservation failure is one way to salvage something from the vaquita's plight.

An evaluation of Mahalanobis distance as a method to detect behavioural response in marine mammals from tag data

Behavioural response studies aim to identify and characterize how animals respond to disturbances such as naval sonar or noise from marine renewable development. Many studies use Mahalanobis distance to collapse multiple data streams, recorded from animal movement tags, into one metric that represents how behaviour changes over time; however, there is little information on how well Mahalanobis distance can detect different types of behaviour change or how different implementations of the method affect performance.

Here, simulations were developed to evaluate the Mahalanobis distance approach with different species, tags, and method implementations. From this, we provide recommendations on how best to use this method in future analyses.

The simulations considered two focal species: Cuvier's beaked whales (*Ziphius cavirostris*) and harbour seals (*Phoca vitulina*). We simulated tag time-series data that represents both baseline behaviour and responsive behaviour. Real tag data were used to calibrate a simulator of both high-resolution multi-sensor tag data (pitch, roll, heading) and low-resolution tag data (e.g. satellite tags); responses were simulated based on those reported in the literature. For the multi-sensor tags, data streams were simulated for each dive by categorising dives into types (e.g. shallow, foraging) and simulating data for each dive phase separately as a multivariate autoregressive process, capturing the dependence between data streams. For the low-resolution tags, locations were simulated as a discrete-time multistate correlated random walk where movement could be biased away from centres of disturbance. For both tag types, several Mahalanobis distance methods, each differing by how behaviour change is computed, were applied. From this, the performance of each implementation was compared across species, tag type, and differing responses.

Chemical fingerprints suggest direct familiarisation rather than phenotype matching during olfactory recognition in Australian sea lions (Neophoca cinerea)

Olfaction is one of the most commonly used senses for communication among animals and is of particular importance to mother-offspring recognition in mammals. The use of smell in offspring recognition has been well studied, however, we often lack information about the underlying mechanistic basis for olfactory recognition. Using gas chromatography-mass spectrometry (GC-MS), we examine chemical profiles of two different colonies of Australian sea lions (*Neophoca cinerea*) and assess the similarity of chemical fingerprints in mother-pup pairs. This analysis allows us to examine whether a chemical base for phenotype matching exists in this species. Our results showed no GC-detectible mother-offspring similarity in the overall chemical fingerprints, suggesting that direct familiarization is a more likely mechanism used by Australian sea lion mothers for recognition of their young. Our analysis also demonstrates that colony differences are encoded within chemical fingerprints and appear to be highly influenced by environmental compounds. The study improves our understanding of how Australian sea lion females use odours for selective offspring recognition and the potential importance of environmentally acquired chemical

compounds in the overall odour bouquet used in mother-pup interactions.

Trophic connections between sperm whales and their prey in the Gulf of Alaska.

Understanding top predator diets and their role in food webs is important to managing fisheries and mammals from an ecosystem perspective. Sperm whales, a top predator, overlap and interact with economically important groundfish fisheries offshore in the Gulf of Alaska. Stable isotope analysis (SIA) provides a viable way to estimate trophic position and food web connections as a proxy for diet. In particular, SIA has been used increasingly in dietary mixing models to estimate contribution of prey to predators' diets. This study aims to use SIA to better understand the trophic variability of sperm whales and their potential prey, and to estimate the importance of potential prey items to their diets. We analyzed skin samples from 33 sperm whales and 262 tissue samples from seven potential prey species (five groundfish and two squid). Samples were analyzed for stable carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$) isotope ratios, and diet composition was estimated using Bayesian isotopic mixing models. Two groundfish species, sablefish and spiny dogfish, were combined due to their overlapping isotopic signatures (sablefish/dogfish group). Mixing model results suggest that the sablefish/dogfish group, skates, and rockfish make up the largest proportion of sperm whale diets (35%, 28%, 12% respectively) in this region, though estimates have high uncertainty. The top prey items of whales that interact more frequently with fishing vessels consisted of skates and the sablefish/dogfish group (49% and 24% respectively). This is the first known study to provide a complete isotopic analysis of these adult groundfish and squid species, as well as of adult male sperm whales in this region. Additionally, it is the first study to attempt to assign proportional contributions of prey species to sperm whale diets in the Gulf of Alaska, thereby providing information to commercial fishermen and fisheries managers to better understand trophic connections of important commercial species.

Of shells and sponges - contrasting social transmission pathways of foraging behaviour in dolphins using social network analysis

Behavioural differences among groups can arise from differing ecological conditions, genetic predispositions or social transmission of different behavioural innovations. Previously, social learning has typically been inferred as responsible for the spread of behaviour by the exclusion of ecological and genetic factors. This 'method of exclusion' was used to infer that 'sponging', a foraging behaviour involving tool use in the bottlenose dolphin (*Tursiops aduncus*) population in Shark Bay, Western Australia, was socially transmitted. However, previous studies were limited in that they never fully accounted for alternative factors, and that social learning, ecology and genetics are not necessarily mutually exclusive drivers of behavioural variation. Here, we assessed the relative importance of these three potential drivers on the spread of two foraging behaviours, sponging and shelling, in western Shark Bay between 2007 and 2018. Using multi-network 'Network-Based Diffusion Analysis' (NBDA), we found compelling support for sponging being socially transmitted between mother and offspring ($\Sigma w_i = 0.837$), corroborating previous results. Mother-offspring similarities in foraging behaviour are common, as close association during prolonged periods of dependency favour conditions for vertical learning. In stark contrast, we found that shelling spreads among associated individuals ($\Sigma w_i = 0.771$), quantitatively establishing horizontal social transmission of a foraging tactic in toothed whales for the first time while also accounting for genetics and ecology. The opportunistic nature of shelling and extensive social tolerance among adults may have allowed for social transmission outside of the mother-offspring bond. Overall, our research suggests multiple pathways of transmission of foraging behaviour in dolphins, and illustrates the utility of social network analysis in elucidating the explanatory mechanisms behind the spread of behaviour in wild animal populations.

First documentation of coordinated bottom-feeding by humpback whales

Humpback whales coordinating prey capture efforts in surface bubble-feeding groups are well documented. Here, we provide the first documentation of humpbacks coordinating feeding behavior to capture prey on the seabed. Observations were made using multi-sensor/video-recording CATS-CAM tags placed on humpback whales feeding on sand lance (*Ammodytes dubius*) in the southern Gulf of Maine, USA. Visually documenting bottom-feeding behavior is challenging, since it characteristically occurs at night or in waters too deep to provide light for video-recording. From 2016-2018, we collected video data showing this behavior within and across years (1 from 2016, 3 from 2017, and 7 from 2018). Preliminary analyses describe 30 bottom feeding events occurring over 75 minutes from a juvenile female humpback (2018) in a three-member feeding group targeting sand lance schooled along the seabed at a depth of ~40m. In all events, animals were at or in contact with the bottom, often creating visible sand plumes. Individuals were oriented in a "star" formation, with rostrums pointed to a central location among the whales. Separation ranged from a few meters to rostrums almost touching. In each event, individual whales, identified by unique body markings, maintained the same feeding position relative to each other, usually 10 and 2 o'clock to the tagged whale. Animals opened their mouth within four (±3) seconds of each other. When gaped, animals were rolled ~90°, forming a "corral" with their open mouths, with sand lance visible in, and escaping from, the corral. When multiple feeding events occurred within a single dive, the animals repeated their original positions within the feeding group in as few as 23 seconds from the proceeding event. This behavior adds to our understanding of humpback complexity and makes them particularly vulnerable to bottom-set fishing gears.

Three concurrent Western Atlantic large whale unusual mortality events

Since 2016, three Unusual Mortality Events (UME) have been declared by the U.S. National Marine Fisheries Service for baleen whales in the Western Atlantic Ocean along the coast of the Canada and the United States. These three concurrent events involve humpback whales (*Megaptera novaeangliae*; 2016-present), North Atlantic right whales (*Eubalaena glacialis*, 2017-2018), and minke whales (*Balaenoptera acutorostrata*, 2017-present). To date, over 170 whales have stranded live or dead as part of these UMEs: 93 humpback, 20 North Atlantic right and 59 minke whales. This elevated stranding rate may have consequences at the population or stock level, particularly for North Atlantic right whales, as the most recent minimum population estimate is only 455 whales. Although the reasons for stranding have differed between the three species, all three have had evidence of human interaction in a sub-set of whales, including vessel strikes in humpback whales, rope entanglements and vessel strikes in North Atlantic right whales, and entanglements in minke whales. Additionally, a sub-set of minke whales has had evidence of

infectious disease, although a consistent primary pathogen has not been determined. The investigation is ongoing; the stranding network continues to respond and document new strandings and the investigative teams continue to explore population, ecological, anthropogenic, and other drivers that may be contributing to the increase in stranded whales. This presentation will review the current status of all three UMEs and identify commonalities and differences between the responses and investigations.

I get by with a little help from my friends: Understanding bottlenose dolphin social affiliations in response to shark-inflicted injury.

Social living has been, in part, suggested to be a behavioral response to reduce predation risk. While many studies have assessed the effects of prey group size on predation risk, few have evaluated if or how prey group size and social dynamics change in response to direct predation events. The Sarasota Dolphin Research Program has documented long-term, multigenerational residency of common bottlenose dolphins (*Tursiops truncatus*) in Sarasota Bay, Florida. Large sharks are known to inflict bite wounds on these dolphins. We assessed whether dolphins undergo shifts in their social behavior after injurious shark predation attempts. Using photographs collected during photo-ID monitoring surveys and capture-release projects, fresh shark bite wounds on resident dolphins were identified. For each dolphin with a shark bite, a dolphin of the same sex and life stage during the period in which the shark bite occurred was selected as a control animal to compare whether any potential shifts in number of affiliates were in response to the shark bite. Timing of a fresh shark bite could be determined for 56 unique Sarasota Bay dolphins. A Poisson generalized linear mixed model showed there was no significant difference in group size post-shark bite. This observation could be due to the differential response among individuals as some animals increased their group size after shark-inflicted injury, while others decreased or showed no change in their group size. Although the dolphins did not change their group size in a predictable direction, they may change with whom they associate, which is being investigated through social network analyses.

Juvenile harbour porpoises in the UK are exposed to a more neurotoxic mixture of polychlorinated biphenyls than adults.

Polychlorinated biphenyls (PCBs) are a group of 209 persistent and bio-accumulative toxic pollutants present as complex mixtures in human and animal tissues. Harbour porpoises accumulate some of the highest levels of PCBs because they are long-lived mammals that feed at a high trophic level. Studies typically use the sum of a suite of individual chlorobiphenyl congeners (CBs) to investigate PCBs in wildlife. However, toxic effects and thresholds of CB congeners differ, therefore population health risks of exposure may be under or over-estimated dependent on the congener profiles present. In this study, we found congener profiles varied with age, sex and location, particularly between adult females and juveniles. We found that adult females had the highest proportions of *octa*-chlorinated congeners whilst juveniles had the highest proportions of *tri*- and *tetra*-chlorinated congeners. This is likely to be a consequence of pollutant offloading between mothers and calves during lactation. Analysis of the individual congener toxicities found that juveniles were exposed to a more neurotoxic CB mixture at a time when they were most vulnerable to its effects. These findings are an important contribution towards our understanding of variation in congener profiles and the potential effects and threats of PCB exposure in cetaceans.

Killer whale predation on bowhead whales in the Pacific Arctic – on the rise?

Review of imagery and sighting data on bowhead whale (*Balaena mysticetus*) carcasses from a decade of aerial surveys in the eastern Chukchi and western Beaufort seas has provided new and robust evidence for killer whale (*Orcinus orca*) predation on bowhead whales of the Bering-Chukchi-Beaufort (BCB) stock. The Aerial Surveys of Arctic Marine Mammals project provides information on distribution, behavior, and relative density of marine mammals, including BCB bowhead whales and their only natural predator, killer whales. These surveys cover large areas of bowhead whale summer and early autumn habitat, and offer a long time series of consistent information on floating and beach-cast bowhead whale carcasses detected during line-transect surveys. A total of 33 bowhead whale carcasses were documented in July–October, from 2009 to 2018. Carcasses were distributed across the study area from 141.6°W to 168.1°W and 68.9°N to 72.0°N. Twenty-five carcasses (76%) were found floating and eight (24%) were beach-cast. Highest number of carcasses were observed in 2015 (10/33), followed by 2013 and 2018 (6/33 each year), and 2016 (5/33). Imagery review provided insight into the probable cause of death for 21 (63.6%) of the carcasses. Seventeen bowhead whale carcasses having injuries consistent with killer whale predation were photo-documented: four carcasses per year in 2016 and 2018, three carcasses in 2013 (including one calf/yearling), two carcasses per year in 2012 and 2015 (including one calf/yearling), and one carcass per year in 2010 and 2017 (a calf/yearling). Four carcasses, two in 2015 and one each in 2013 and 2018, were likely whales struck and lost during aboriginal subsistence hunting. Continued monitoring and documentation of BCB bowhead whale mortality, including killer whale predation is needed for assessing the status of the BCB bowhead whale stock and the ecological impacts of a changing Arctic.

The scale of the whale: Using video-recording tags to determine the sea ice habitat used by Antarctic minke whales (Balaenoptera bonarensis).

Advances in biologging technology have opened doors for new sensors and tools to aid in the remote study of wildlife. These tools allow researchers access to previously unobservable behavioral states and movement patterns of marine animals. In order to relate behaviors to environmental variables, features must be evaluated at scales relevant to the individual animal or behavior. Historically, remotely-sensed environmental data (collected via satellites) lacks the spatial or temporal resolution to adequately link with individual animal behaviors or bouts. The aim of this study is to establish a new method for remotely and continuously quantifying Sea Ice Concentration (SIC) at the scale relevant to individual whales. Motion-sensing and video-recording suction cup tags were deployed on 30 Antarctic minke whales (*Balaenoptera Bonaerensis*) in February and March of 2018 and 2019 around the Antarctic Peninsula. For each surfacing, observable surface area to be evaluated (m^2) is calculated at a constant depth as a function of tag pitch and camera angle of view. Sea Ice Concentration (SIC) was classified into one of six bins (0%, 1-20%, 21-40%, 41-60%, 61-80%, 81-100%) for the initial and final surfacing between dives. SIC was evaluated by two independent observers, and a third adjudicated disagreements, and a median of three values was used. Initial results from 6 tags show that Antarctic Minke whales spend 52% of their time in open water, and only 15% of their time in water with SIC greater than 20%. Over time, we find significant variation and switching between SIC concentrations between dives, indicating an extremely dynamic environment. Combined with information on underwater behavior, our ability to quantify SIC continuously at the scale of the animal will allow a more robust and accurate means to link animal behavior to these dynamic environmental variables,

something that is currently not possible from traditional remote sensing methods.

80 Years of chemical exposure profiles reconstructed through baleen whale earplugs

Organic contaminants have been a concern for cetaceans due to their adverse health effects and were initially measured in marine mammals in 1966. Cetaceans often serve as sentinels of the marine ecosystem, however, limitations in historical approaches often limit our understanding. Recently, scientific discovery has found that baleen whale earplugs have the ability to record and archive lifetime chemical exposure profiles and trends. Earplugs represent a unique opportunity to examine the spatial and temporal trends in our marine ecosystem. Baleen whale earplugs were collected from six whales (1 blue whale and 5 fin whales), including four adults from archived collections and two calves from recent strandings. Contaminant concentrations (reported in $ng \cdot g^{-1}$) were determined in layers (n = 35) and were combined with age estimates to reconstruct lifetime contaminant exposure profiles, and lifetime bioaccumulation rates 30 years prior to the initial measurements made in the 1960s. Dichlorodiphenyltrichloroethane (DDT), its metabolites, and polychlorinated biphenyls (PCBs) were found to be the most dominant contaminants within most individuals and were detected during their early usage periods (the 1930s) indicating immediate contamination of the marine ecosystem following mass production. Bioaccumulation rates over the past 80 years were approximately 55 times higher in the Pacific as compared to the Atlantic. This significant difference indicates whales in the Pacific are more likely to be exposed to contaminants and potentially have a health risk. Profiles also indicate a difference between maternal offloading and environmental exposure profiles

Accounting for environmental factors and behaviour when correcting beluga counts from photographic and visual aerial surveys: Effects on abundance estimates.

Accuracy of abundance estimates is essential for determining the conservation status of populations, whereas precision can reduce time for detecting significant population trends. The abundance of the Endangered, and currently declining St. Lawrence Estuary beluga population has been estimated using visual and photographic surveys, corrected for availability bias using a common correction factor developed for photographic surveys. However, not accounting for the longer detection time associated with visual surveys likely overestimated abundance in these surveys. A variety of other factors can affect availability, including turbidity, water depth, and animal behaviour. In this study, we developed a correction factor for availability bias during photographic and visual surveys using detailed dive profiles obtained from 30 beluga. We explored the benefits of including environmental factors and beluga behaviour when correcting for availability bias.

As expected, beluga availability to a passing aircraft was longer during visual than photographic surveys (0.308 vs 0.327-0.394 depending on perpendicular distance). Availability decreased significantly with increasing water turbidity; it also changed more rapidly over the first 3 to 4 m from the surface (5 to 23% per 0.5 m increment in depth), and more gradually at deeper depths (3 to 5% per 0.5 m increment in depth). Bottom depth affected availability through effects on dive duration, resulting in lesser availability when beluga were involved in area-restricted search than when in-between zones, where they were more likely to be in a travelling mode. Overall, turbidity had a larger effect on availability bias (1 to 5% per 0.5 m increment over the first 8 m) than animal behavior (-1% to 5% overall) and should be accounted for in priority. This study demonstrates

the importance of taking into account spatial heterogeneity and behaviour in correcting for availability bias.

Of whales and men: Understanding metal pollution in the Sea of Cortez through a one environmental health approach.

The Sea of Cortez is one of the most biodiverse seas in the world, which Captain Jacques Cousteau famously described as "the world's aquarium", and is home to 32 marine mammal species. Yet, despite its isolation and pristine appearance, there are potentially significant anthropogenic inputs of pollution from agriculture and metal mining. Metals have emerged as a global ocean pollution concern including for the Sea of Cortez. Therefore, we evaluated metal pollution in whales in the Sea of Cortez during two different time periods: 1999 as part of a global voyage focused on sperm whales (*Physeter macrocephalus*) and 2016-2017 as part of an ongoing series of voyages focused on the Sea of Cortez. We measured levels of 23 essential and nonessential metals in seven different cetacean species found in the area. We found magnesium, iron, aluminum and zinc to have the highest concentrations across all species and all years. For sperm whales, metal levels generally decreased over time, though some like nickel remained at levels of concern. Iron and chromium increased with time. Because chromium is a global marine pollutant, we used One Environmental Health and cell culture-based approaches to contextualize the data. Using human and sperm whale cells, we found prolonged hexavalent chromium [Cr(VI)] exposure induced chromosome instability, spindle assembly checkpoint bypass and centrosome amplification in human cells. However, the same exposure in sperm whale cells did not induce these outcomes. Overall, the data indicate a recent change in the metal input to the Sea of Cortez that suggests a decreased health concern for the ecosystem for some metals, but increased concern for the genotoxic metals Cr and Ni, and that whale cells have evolved cellular strategies to protect against metal-induced carcinogenesis. This work was supported by NIEHS grant ES016893 (J.P.W.) and donors to the Wise Laboratory.

Baseline variation of steroid hormones in short-finned pilot whales (Globicephala macrorhynchus)

Recent analytical advances have demonstrated that steroid hormones, which mediate behavior, reproduction, and stress, can be reliably measured in cetacean blubber. Integrating hormone analysis with photo-identification and genetics has the potential to enhance our knowledge of cetacean behavior, physiology and population dynamics. Increasingly, hormonal biomarkers are being used to measure the response of cetaceans to various types of anthropogenic disturbance, so it is important to establish baseline levels of these hormones. To characterize baseline concentrations of steroid hormones in short-finned pilot whales (*Globicephala macrorhynchus*), we adapted a liquid chromatography tandem mass spectrometry (LC-MS/MS) method for the quantitation of 11 steroid hormones in the blubber of this species. To assess the validity of this method, we conducted spike-recovery tests using blubber from stranded individuals. Accuracies for all hormones, which consisted of multiple androgens, progestogens, glucocorticoids, and a mineralocorticoid, fell between 86 and 112%, well-within accepted ranges. The biological validity of this method was confirmed through a comparison, which showed higher progesterone concentrations in known-pregnant females. To determine the effects of demography, seasonality, and sampling methods on baseline hormone profiles, we analyzed 73 biopsy samples, which were obtained in multiple seasons and additionally analyzed with PCR to determine sex. Preliminary analyses indicated distinct sex differences, with males and females exhibiting higher testosterone and progesterone concentrations

respectively. In addition to establishing baseline hormone relationships with sex and season, ongoing analyses evaluate hormone responses to sampling boat presence. This study establishes a framework for the comprehensive analysis of hormones in this species and highlights the importance of validations, relevant biomarkers, and contextual baseline references prior to conducting response studies.

Population density of the Northern sea otter (Enhydra lutris kenyoni) as an indicator of strep syndrome transmission mechanism

The Northern sea otter (*Enhydra lutris kenyoni*) in Alaska, U.S. has recently experienced unusual mortality events due to Strep syndrome caused primarily by *Streptococcus infantarius*, *Streptococcus bovis*, and *Streptococcus phocae*. The pathogenicity and transmission method of this disease is currently unknown, making it difficult to predict. Preliminary evidence from higher-density populations that have experienced significant mortality suggest that population density may affect transmission. To test this hypothesis, we acquired stranding data from the U.S. Fish and Wildlife Service (USFWS), partitioned the population into discrete ranges and calculated the percentage of infected individuals in these areas from 2001 to 2014. Using abundance data from USFWS and the United States Geological Survey (USGS), among other sources, we calculated population density for these regions over time. We then tested the relationship between infection and population density using linear models and generalized linear mixed models. Additional variables considered were infected individuals' age, sex, and body condition, which were included to identify characteristics associated with infection. Additionally, we determined the primary physical locations for bacterial infection. Previous literature has noted a high percentage of bacteria in the intestines and we sought to further elucidate the physical characteristics of infection. Results indicate that population density does not significantly influence Strep prevalence, but that males are at greater risk for the disease. These results suggest that Strep may be transmitted in a frequency-dependent manner and influenced by behavioral disparities between the sexes. Additionally, the relative frequency at which certain tissues, such as the spleen, test positively for streptococci bacteria contradicts previous literature regarding bacterial presence in the intestines. Therefore, the survival and transport of streptococci bacteria by macrophages requires additional research, as does the proposal of infection via the intestines. Overall, these findings can be used to guide federal agencies in research prioritization and management.

The simultaneous analysis of multiple reproductive and stress hormones in small blubber samples of gray (Eschrichtius robustus) and fin whale (Balaenoptera physalus) using liquid chromatography mass spectrometry .

The analysis of steroid hormones has been used to assess health in several species of vertebrates. In cetaceans, the simultaneous analysis of multiple steroid hormones can provide valuable reproductive and fitness data useful in the conservation and management of endangered and protected species. Minimally invasive blubber biopsy samples can be collected from healthy, free ranging animals and utilized in multiple analyses. The goal of this project was to develop a method, that used minimal tissue weight, to analyze a hormone panel to explore the endocrinology of the HPG and HPA axis of *E. robustus* and *B. physalus* as little data currently exists. Blubber biopsies were collected from free ranging *E. robustus* (n=38) in Baja California and blubber samples from stranded animals (n=14) off the coast of California. Similarly, samples were collected from free ranging *B. physalus* (n = 6) in the Gulf of California (n=6) and from stranded animals from California (n=3). Steroid hormones were extracted from blubber samples as small as 50mg using liquid-liquid extraction designed to address the high fat content of the tissue. Androstenedione, aldosterone, cortisol, cortisone, corticosterone, 17ß-

estradiol, estrone, 17α-hydroxyprogesterone, progesterone, and testosterone were analyzed via LC-MS/MS in either negative or positive ion mode. Additonally, we are going to compare the precision between polytron and Fastprep 24 homogenizers with *E. robustus* tissue along with a sensitivity analysis between 50mg and 150mg samples of *E. robustus* and *B. physalus* blubber to determine optimal homogenization technique and minimal tissue size requirements for steroid hormone analysis in these species. The limit of detection was 1ng/mL for most hormones. In most cases, there was minimal to no ion suppression in the matrix. This optimized method allows for the analysis and monitoring of reproductive and stress hormones in small samples of *E. robustus* and *B. physalus* blubber. Continued analysis is underway.

Using a novel 'baitSTR' approach to genotype thousands of short-tandem repeats simultaneously – Implications for Sousa sahulensis conservation

Little is known about genetic population structure of Australian humpback dolphins (*Sousa sahulensis*) along the eastern Australian coastline. Previous data suggested a fragmented metapopulation of four putative clusters with low overall genetic diversity and limited geneflow, resulting in small effective population sizes. We applied a novel approach (baitSTR) to genotype thousands of short-tandem repeat (STR) loci per individual. We generated panels through shotgun sequencing and assembly of a single individual. Putative STR regions were used to design probes based on their flanking regions for capture, sequencing and genotyping of all samples. Using baitSTR, we genotyped a panel of 2499 STR loci for a total of 63 *S. sahulensis* individuals from eight sites along the coast of Queensland, Australia. Of these loci, 2031 were polymorphic with up to 12 alleles. Using this methodology, our analyses identified four major genetic clusters along the coast and significant population structure within the Great Sandy Strait Marine Park with two geographically proximate populations being genetically distinct. Using Bayesian inference, we tested a set of increasingly complex demographic models and inferred demographic parameters including effective population sizes, asymmetric migration rates and population divergence between clusters. We found strong isolation between all genetic clusters with only low levels of directional gene flow from north to south. We demonstrate the immense potential of the baitSTR method to produce massive STR datasets for non-model species, making it a powerful tool to quickly and efficiently assess population genetic parameters in natural populations.

Marine megafauna bycatch in artisanal fisheries in Gorontalo, Northern Sulawesi (Indonesia): An assessment based on fisher interviews.

Wonneberger, Elena; Mustika, Putu Liza Kusuma[1]; Erzini, Karim[2]; Pasisingi, Nuralim[3]

While bycatch, the unintentional catch of untargeted species, is one of the main threats to large marine species such as cetaceans, sharks and turtles, fishers can also be negatively impacted by bycatch. Understanding local fisheries profiles, fishers' demography and their opinion is thus a necessary part of the strategy to mitigate artisanal marine megafauna bycatch. Interviews with 112 fishers in nine fishing villages were conducted in January and February 2018 in order to assess the magnitude of marine mammal bycatch, the dependency of fishers on the fishery and the potential for implementation of bycatch mitigation measures in the artisanal fishery in Gorontalo, northern Sulawesi (Indonesia). Quantitative and qualitative methods were used for the analyses. Regression trees showed that cetacean bycatch were mainly influenced by the fishing location. Cetaceans mostly escaped after being caught or were released, resulting in low mortality. Data extrapolation shows that an estimated 1,953 cetaceans are caught annually in artisanal fisheries in Gorontalo of which an estimated 48 animals die. Fishers had large households, typically averaging more than five people, and mostly seemed to be dependent on the fishery, often with few other sources of income. Fishers generally seemed to

favour bycatch reduction measures as bycatch often posed a financial threat rather than a benefit due to lost catch and broken gear. Future actions should include discussions with fishers on reduction options such as gear modification and spatial or temporal management of fishing seasons, coupled with a better understanding on the cetacean ecology and habitat use in Gorontalo.

Modelling spatial habitat use of the Northern bottlenose whale (Hyperoodon ampullatus)

Habitat use of the bottlenose whale (*Hyperoodon ampullatus*) in the northeast North Atlantic has long remained poorly understood. By establishing species-habitat models to relate shipboard sighting data off the Jan Mayen Island to selected environmental variables, this study aimed to identify significant predictors for bottlenose whale occurrence and provide spatial estimates of potential high-use regions. Covariate effects were examined by fitting Generalised Additive Models (GAMs) respectively to whale occurrence and additional whale sightings given presence, and spatial estimates of the actual number of sightings were calculated from multiplying the model-averaged results (occurrence x whale sightings). Higher occurrence probability was estimated at steeper topography, which is consistent with the deep-water behaviour of bottlenose whales. Likelihood of whale encounter was also positively correlated with concentration of chlorophyll below 0.4 mg m^{-3} and above 1 mg m^{-3}. Temporal lag between the peaks in chlorophyll concentration and whale abundance appeared to be more than two months. The number of additional sightings given presence was predicted to be higher at shallower water depths (<1000m) with steep topography, and deeper water depths between 1000m and 2700m with gentle seafloor slope. Spatial predictions largely corresponded with field observations that indicated high usage around the submarine canyon regions in the east and southeast of Jan Mayen Island. This study provided the first species-specific habitat model for northern bottlenose whales in the northeast North Atlantic. It highlighted the likely importance of bathymetric features in shaping the pattern of habitat use of this deep-diving species. Model predictions could support conservation and management efforts, and inform mitigation measures by minimising spatial overlap between potential high-use areas and anthropogenic activities.

Smooth hammerhead - Pantropical spotted dolphin predation event

Observing a predation event by a shark on a dolphin is rare and photo documentation is deficient. Different from larger species that sometimes survive attacks, the only way of confirming that they occur on smaller species of delphinid is from actual observations. On the 31st of December 2016 while conducting a dolphin/whale watch ~1km off western Oahu Hawai'i, USA, a smooth hammerhead (*Sphyrna zygaena*) predation event on a juvenile Pantropical spotted dolphin (*Stenella attenuata*) was observed and photo documented. At 10:00 am, in approximately 400m depth, a pod of around 20 spotted dolphins was encountered. As the boat, a 9.75m RHIB, approached the group, many individuals approached the vessel to ride the vessel's wake. Moments later we happened upon an additional ~150 spotted dolphins. At this time, one juvenile began leaping next to the boat with a remora observed on the body. The boat slowed and suddenly a small group (10-20) porpoised around the last spot the juvenile had landed. The outer periphery and seemingly the remainder of the large pod porpoised at a rapid speed in all different directions away from where the others had leaped. Immediately after, a dorsal and caudal fin of a shark was observed, followed by blood in the water. An observer, hanging over the side of the boat, put a camera into the water to document what was happening. The entire body, behind the juvenile dolphin's dorsal fin, was bitten off. Images taken show the shark grabbed the dolphin carcass multiple times from different angles as it sunk, eventually swimming away with it. The predation event lasted approximately 1 minute. In Hawaiian waters only tiger sharks (*Galeocerdo cuvier*) have been documented preying on spotted dolphins. This is the first documented event of a smooth hammerhead shark feeding on a dolphin species in Hawaiian waters.

Are Florida manatees (Trichechus manatus latirostris) wearing their teeth beyond functionality? Interspecific and intraspecific mesowear in manatees.

Manatees (*Trichechus* spp.) are herbivorous aquatic mammals found in warm waters. At maturity, they possess only supernumerary molars (SM), with 5-8 in occlusion in each quadrant. Manatees exhibit a dental replacement system in which they shed old teeth anteriorly and erupt new teeth posteriorly. This adaptation is thought to have arisen to deal with abrasive foods. Mesowear (facet development on occlusal surfaces of teeth) increases from posterior to anterior. Tooth functionality is linked to level of mesowear, with increased amounts resulting in decreased food-processing ability. Less functional teeth can result in an increase in feeding time, potentially decreasing fitness. Domning (1982) noted that Florida manatees (*T. manatus latirostris*) appeared to experience greater levels of mesowear compared to other manatee populations, however he did not quantify the difference. To address this we examined museum specimens from all manatee taxa: Florida (n=64), Antillean *T. m. manatus* (n=49), Amazonian *T. inunguis* (n=121) and African *T. senegalensis* (n=4) manatees. Photographs of the dental arcade (upper and lower) were taken and analyzed. Each SM in occlusion was numbered (posterior to anterior) per quadrant and classified into one of five discrete wear categories (level 5, extreme, being considered as non-functional). Total number of teeth per quadrant (TNTQ) and total number of functional teeth (TNFTQ) per quadrant were counted including missing teeth (evidenced by dental alveoli). Florida manatees had significantly fewer mean TNTQ ($H=130.03$, $p<0.001$) than other taxa except Antillean manatees, and fewer mean TNFTQ ($H=362.21$, $p<0.001$) than all other manatee taxa. In addition, except for SM1, Florida manatees had greater mean levels of mesowear (SM2-SM6) compared to all other taxa. Florida is not only a marginal habitat for manatees because of seasonally cooler water, but also because of the additional dental burden: where it appears they are wearing down their teeth faster than the replacement process.

Use and usefulness of photographic-identification in studying a growing community of harbour seals (Phoca vitulina) in SE England.

Woods, Fiona[1]; Arnott, John[2]; Hughes, Peter[2]; Marley, Sarah[3]

Corresponding Author: up814088@myport.ac.uk

Globally, harbour seals (*Phoca vitulina*) are displaying large variations in abundance, with many populations in the United Kingdom seen to be in decline. The development of a new, growing population in the Solent region of SE England has been documented since the early 1990s and is currently estimated to contain a minimum of 40 harbour seals. This study initially aimed to utilise photographic identification (photo-ID) in determining harbour seal residency and estimating abundance. Due to the variation in data quality resulting from an extremely muddy study area, the objective developed into also investigating how photo-ID can be used and improved in studying harbour seals in Chichester Harbour.

Photographs were collected during monthly boat-based counts between 2016 and 2018. The pelage patterns of hauled-out seals were examined, resulting in the identification of 106 individual seals. This indicates a much larger harbour seal community than previously estimated for the Solent. Resights were low, but may have been hindered by muddy substrate obscuring pelage patterns. To investigate this further, Chi-square tests were used to compare how often body areas were visible, and thus available for photo-ID, along with the number of times different body areas were used to identify an individual. Seals were identified using markings around the head significantly more than any other area, and identified least by markings on the stomach and flippers. There was an association between most commonly-used identification site and visibility of sites; the head was most visible and most used for identification, whilst the stomach was used least for identification and visible least. The differences in visibility are likely the result of the haul-out environment (muddy tidal flats). This study highlights potential for further use of photographic identification to determine

residency of populations, but emphasised the need for greater standardisation of images to be used for identification.

Calving rate decline in humpback whales (Megaptera novaeangliae) of northern British Columbia, Canada.

Wray, Janie[1]; Keen, Eric[2]

(2) Scripps Institution of Oceanography, La Jolla
Corresponding Author: janie@bcwhales.org

The humpback whale (*Megaptera novaeangliae*) is a globally distributed baleen whale that undertakes long-distance annual migrations between seasonal feeding grounds in high latitudes and breeding grounds in low latitudes. Worldwide humpback populations are widely recognized to be increasing, but recent estimates show variable trends in some regions, including alarming evidence of decline within Alaskan waters in recent years. Here we present early evidence of reproductive decline in the nearby feeding waters of Northern British Columbia (NBC) using fifteen years of photo-identification surveys (2004 – 2018) in the marine territory of the Gitga'at First Nation, a proposed critical habitat area for British Columbia humpback whales. Out of a growing catalogue of 544 humpback whale individuals, 75 were known mothers, 28% of which were seen in 10 or more years of the study. Within this population we observed annual per-capita and per-mother calving rates of 0.006 – 0.05 and 0.06 – 0.50, respectively. Prior to this peak, our data exhibited an 85% probability that calving rates were increasing (mean estimate = 7% per year); following this peak, calving rates have been in decline (-9% per year, 82% probability). The probabilities of increase and decline reported here are compelling early indicators of a possible shift in regional humpback whale demographic rates. The early increase in calving rate we observed in the first 9 years of our study is consistent with population increases that have been concomitantly observed in NBC and elsewhere in the north Pacific. Conversely, the decline we have begun to observe in NBC, which mirrors the 2018 reports from Glacier Bay, may represent a recent change in reproductive rates or calf survival prior to the mother being sampled on the feeding grounds.

Blending science and conservation with science fiction to reach a shiny new audience.

Wright, Andrew[1]; Wurche, Bettina[2]

Corresponding Author: marinebrit@gmail.com

Many in science and conservation expressed frustration recently when the Nortre Dame fire generated a global outpouring of grief and over a $billion overnight, while many species are quietly going extinct. While conservation issues may never attract such extensive impromptu funding, much can be achieved without serious funding if people are passionate and involved. Unfortunately, scientists and conservationists often struggle to engage with the public, failing to inspire them into relevant conservation action.

Focused outreach is crucial to connecting with target audiences, but requires carefully pairing your message to that audience. Science fiction fans are one audience worth exploring as they often go to extreme lengths and personal cost to support their fandom. For example, the Western Space Drama series 'Firefly' premiered on the U.S. Fox network in September 2002, but was quickly cancelled despite averaging 4.7 million viewers per episode by mid-December. Calling themselves 'Browncoats,' a reference to the show's protagonists, angry fans quickly mobilised enough pressure for closure to force an unprecedented rebirth in the form of the movie 'Serenity' in 2005.

To explore if such passion could be harnessed for conservation, the Facebook page "Vaquita Are Browncoats" was started in June 2014 to connect Firefly fans with the plight of the vaquita, a critically endangered cetacean that had been languishing in relative obscurity. With practically no financial resources, the resulting community grew slowly both on Facebook and Twitter. Although the page could not influence the drastic decline in vaquita numbers due to illegal fishing that unexpectedly resurfaced in 2015, it successfully boosted attention, ultimately being featured at the Sci-Fi convention, FedCon, in Bonn in May 2018. We will review this approach and offer suggestions for possible improvements in other such efforts that may arise in the future.

Habitat and distribution of cetaceans from the first comprehensive survey of coastal and offshore waters in the Canadian Pacific.

Many cetacean species were depleted in Canadian Pacific waters by commercial whaling, which ended in 1967. Although some populations have since shown evidence of recovery, there is limited information about current abundance and geographic distribution, particularly in difficult-to-access offshore regions. This lack of baseline data hampers conservation status assessments, including estimating population-level impacts of anthropogenic activities. From July to September 2018, we conducted ship-based surveys throughout the coastal and offshore waters of British Columbia, Canada to assess the abundance and distribution of cetacean species. In addition to visual observations, we employed complementary acoustic techniques such as sonobuoy deployments and a towed hydrophone array to locate cryptic and deep-diving species that are frequently missed by conventional surveys (e.g. sperm and beaked whales). The most common mysticetes were humpback whales (n=1164 individuals) and fin whales (n=378), while the most common small cetaceans were Dall's porpoise (n=868) and harbour porpoise (n=405). Six sightings and numerous acoustic detections of sei whales yielded new information about how this species is using Canadian Pacific waters again following its extirpation from the area. Density surface modelling was employed to analyze the distributions of species throughout the surveyed habitat. We found that baleen whales showed partitioning of habitat use, with fin, sei and blue whales populating the offshore region and humpbacks associating with continental shelf and coastal areas. Our results can be compared with historic whaling catch data to determine the extent of recovery of previously harvested populations, which will have important ecosystem-level implications as these predators return to habitats from which they were previously extirpated. Survey results will also inform management decisions such as Potential Biological Removal limits for fisheries bycatch and entanglement mortality, and will improve the effectiveness of Marine Protected Areas as tools for cetacean conservation.

Rapid sea-ice loss results in shifting distributions of Arctic and sub-Arctic marine mammals: Evidence from passive acoustic data in the eastern Bering seascape.

Wright, Dana[1]; Woodrich, Daniel[2]; Brewer, Arial[3]; Berchok, Catherine[4]
(1) Duke University Marine Laboratory, Beaufort, NC
(2) 2. Joint Institute for the Study of the Atmosphere and Oceans, Univ. of Washington, Seattle, WA

(4) Marine Mammal Laboratory, Seattle, WA
Corresponding Author: dana.wright@duke.edu

Rapid sea-ice loss in the Arctic has resulted in extended open water periods, which provide an opportunity to test hypotheses about the effects of environmental drivers, such as sea-ice onsent and retreat, on species occurence. To gain inference into the effect of these drivers, we manually analyzed 103,010 hours of data from nine passive acoustic recorders stationed along the eastern Bering shelf from 2012-2017 (~30% duty cycle) for the presence of four marine mammal. Migratory timing and extent of range of bowhead whales (*Balaena mysticetus*) and Pacific walrus (*Odobenus rosmarus divergens*) coincided with the onset and cessation of sea-ice over the shelf regardless of date of ice formation or retreat, resulting in abbreviated occurences in reduced ice-years. Walrus calls were absent from stations without ice, regardless of detections at those stations in prior years, supporting the conclusion that the walrus is as an ice-obligate species. In contrast, bowheads were detected annually at stations in the Northern and mid-Bering regions regardless of ice presence, suggesting a decoupling of ice and bowhead presence early in the season. Nevertheless, calling was brief at mid-Bering stations in reduced or ice-free years, suggesting that bowheads overwintered in ice-associated waters in the Northern Bering. Detections of humpback (*Megaptera novaeangliae*) and critically endangered right whales (*Eubalaena japonica*) spanned open water periods until ice formation. Additional brief and intermittent detection of humpback whales at southern stations during winter months of reduced/absent ice years suggest possible overwintering. Furthermore, overlap of humpback and bowhead whale detections increased at one Northern Bering station to 44 days in 2015 compared with 8-23 days in prior years. Taken together, these observations indicate that important shifts in the spatial extent and seasonal occurence of Arctic and sub-Arctic marine mammals have occured during a period of rapid sea-ice loss.

Computational fluid dynamics analysis of gliding North Atlantic right whale models with variable body shapes.

The streamlined body shapes of cetaceans delay the separation of flow, create lower drag when they swim, and therefore decrease their locomotor cost in terms of energetics. However, previous studies show that body shape of the North Atlantic right whale (Eubalaena glacialis; hereafter right whale) changes with life stages, reproduction status, nutritive conditions, and the effects of entanglement. In addition, results from our previous work indicate that drag on right whale varies with position due to its irregular outline. Accordingly, in this study, we aimed to investigate the changes in drag on right whales with variances in body shapes and estimate any associated kinematic costs. Based on our results, we hypothesized that emaciated right whales, which have a less-streamlined body configuration such as having concavity in the post nuchal area, suffer higher drag when swimming and consequently need longer time to recover from previous encounter with fishing gear or replenish their energy reserves. This fact is likewise crucial for pregnant females because their energy budget for migrating to breeding grounds may increase due to having an enlarged girth for their abdomen. To obtain measurements of drag over right whales under various body conditions, we undertook computational fluid dynamics (CFD) simulations on several static right whale models reflecting different body fitness (e.g., normal condition, emaciation due to entanglement or low prey availability, and pregnancy, etc.) and measured multiple fluid dynamics parameters such as characteristics of boundary layer, drag, drag coefficients, and other forces on the animals. Our results reveal that drag on right whales fluctuates across its body and is higher at positions facing incoming flow, suggesting that the kinematic energy expenditure of right whales is indeed affected by its body shape and that the body shape of right whale should be measured and analyzed carefully when assessing their health conditions.

A low-order model of dolphin swimming dynamics: Fluke flexibility and energetics.

This work presents a physics-based, low-order model of the swimming dynamics of a bottlenose dolphin, which captures critical features such as body posture, fluke flexibility, and delayed fluke stalls (Fish & Rohr 1999). The model integrates data and findings from previous research on odontocete cetaceans, including body morphometry, fluke morphology and elasticity (Fish et al. 2006; Fish et al. 2007; Gough et al. 2018), flipper hydrodynamics (Weber et al. 2009), and swimming gait and stability (Fish et al. 2003; Rohr & Fish 2004).

The modeling framework is based on a mixed Newtonian-Lagrangian formulation, first proposed for the modeling of aircraft with uni-dimensional flexible elements (Avanzini et al. 2014), and brings together tools and concepts from multi-body dynamics, plate theory, hydroelasticity, and unsteady hydrodynamics. The head, torso, caudal peduncle, and pectoral fins are modeled as a set of interconnected rigid bodies, with the peduncle elements being subject to a prescribed gait profile relative to the torso. The fluke, on the other hand, is modeled as a flexible plate, whose deformation evolves in response to the fluke's hydrodynamic, elastic, and inertial forces. Because hydrodynamic loading over the fluke is in turn affected by its deformation state, the model incorporates results from unsteady thin-airfoil theory and unsteady lifting-line theory to predict lift, drag, and pitching-moment distributions over the deforming fluke.

This model represents a versatile tool to investigate marine mammal biomechanics and swimming energetics. Here, we present a set of comparative studies that examine the impact of fluke flexibility and unsteady hydrodynamics on thrust generation and swimming efficiency. We also analyze active mechanisms for body and rostrum stability during swimming. We expect that the knowledge gained from this modeling effort will inform and support the development of algorithms for the reliable estimation of locomotion costs from bio-logging tag data.

Comparison analysis of color patterns between two subspecies of common minke whales (Balaenoptera acutorostrata).
Yagi, Genfu; Nakamura, Gen
Tokyo University of Marine Science and Technology, Shiraoka
Corresponding Author: yagigenfu@gmail.com

We compared color pattern differences between two subspecies of common minke whale (*Balaenoptera acutorostrata)*: North Atlantic minke whale (*B. a. acutorostrata*) and North Pacific minke whale (*B. a. scammoni*). The aims of this study were to clarify color pattern differences between these two subspecies and contribute to the phylogenetic knowledge. We used 18 North Atlantic specimens and 84 North Pacific specimens collected from offshore waters near Norway and Japan. We observed sexually mature females only. Observation points were the head, flipper, lateral field, peduncle field, and caudal fin. In terms of the flipper, we measured three points and only the left flipper was used. We used photographs to analyze the other observation points. On the head, dark throat patches and dark dorsal fields extending to the ventral grooves were observed in all individuals in both specimens. On the flipper, the mean angle between the tip of the flipper to the end of the articular process of the humerus and proximal boundary line of the white patch was larger in the North Atlantic specimens. The proximal boundary lines of flipper white patches were straight in the North Atlantic specimens but curved in North Pacific specimens. North Atlantic specimens showed streaks, eddy patterns in the lateral field, and counter shading with sharp distinctions. On the other hand, most of North Pacific specimens showed no streaks or eddy patterns, and gradual change in color. North Pacific specimens had double caudal chevrons but North Atlantic specimens showed one or zero chevrons in most individuals. North Atlantic minke whales also had concentric circular patterns on the caudal fin. Based on the color pattern differences observed in the two subspecies for this study, cladistic analysis would place the North Atlantic minke whale (*B. a. acutorostrata*) in the same clade as the dwarf minke whale (*B. a. subsp*.).

Helicobater pylori infection in South American sea-lions (Otaria byronia): High risk of human transmission.

Yaipen-LLanos, Carlos
Organization for Research and Conservation of Aquatic Animals - ORCA PERU, Lima
Corresponding Author: orcarlos@orca.org.pe

Gastro-enteric diseases are commonly associated to marine enteric zoonotic bacteremia, though transmission of anthropogenic diseases to marine life is poorly documented in Peru. *Helicobacter pylori* is the most common gastric bacteria reported in the human population of this country, considered an endemic disease. The objective of this presentation is to demonstrate the presence of *H. pylori* in South American sea-lions (*Otaria byronia*) as the closest marine species to a compromised human population. Live stranded sea-lions were admitted at the South Pacific Marine Mammal Center in Lima, gathering age class, gender, location and stranding cause. Blood samples were collected from specimens with clinical signs of gastroenteric disease (n=36) for immune-globulin reaction to *H. pylori* antigen: IgM for positive presence and IgG for previous exposure to the bacteria. Clinical signs in positive patients to *H. pylori* included abdominal discomfort, indigestion, high acidity, diarrhea, melena, hemorrhagic gastritis focalized in the pyloric region of the stomach, and severe anemia. Biopsies collected from patients positive to *H. pylori* were assessed using immune-histochemical stain. 87% of sampled cases were positive to *H. pylori.* Findings included necrosis of the gastric epithelium, local inflammatory reaction with high lymphocyte aggregation and loss of continuity solution in the shape of eroded elongated cavities in the pyloric mucous typical of this bacterial disease. Secondary gastritis is commonly associated to sea-lion strandings, though patient recovery requires a long-term antibiotic treatment for those positive to the bacteria. Lima is the largest coastal city in the country and risk of transmission to the local sea-lion population must be address on the epidemics of gastro-enteric diseases, and include public health campaigns. As part of an extensive health assessment of local marine mammal populations, *H. pylori* diagnose has been included in the regular admission protocol, becoming critical for live stranded individuals.

Peculiar morphology of the stomach of several beaked whale species known from the western North Pacific.

Morphology of the beaked whale stomach is intriguingly specific. Mead (2007), in his extensive and explicit study, proposed a classification of the beaked whale stomachs consisting of three types; 1) generalized (1 main stomach and 1 pyloric stomach), 2) derived stomach type I (2 main stomachs and 2 serial pyloric stomachs), and 3) derived stomach type II (2 main stomachs and 2 pyloric stomachs; PP&PA). We made gross morphological observations on the stomachs of 4 species of beaked whales of 3 genera

(*Berardius*,*Indopacetus*and *Mesoplodon*) that were not included or only briefly described in Mead (2007). Histological observations were also made on a very fresh individual of *M. carlhubbsi*. As a result, stomachs of the species observed in the present study are classified into: type II (*Berardius*sp. with 8 connecting chambers (CC) and *Mesoplodon ginkgodens*with 11 CC); 1 main plus 2 serial pyloric stomachs (*I. pacificus*with 5 CC); and modified type II (*M. carlhubbsi* with 10 CC). The stomach of *M. carlhubbssi*is very special, where the main stomach is faintly separated into two spaces (main stomach and accessory main stomach), and the distal portion of the accessory main stomach having a "cancellousstructure" separated by a network of interconnected trabeculae. Among 4 individuals of *M. carlhubbssi*, two were infants and their stomach structure was almost identical to that of the adult individuals.Histologically, both main stomachs are lined by a simple columnar mucus-secreting epithelium, with abundant parietal and chief cells in the mucosa. The epithelium of the connecting chambers through to the pyloric stomachs on the other hand, is continuous and constant with mucous cells organized into pyloric glands. The diversity of ziphiid stomachs may represent their phylogenetic background, and further comparative considerations with genetic phylogeny is necessary.

Target region selection for characterization of the microbiota of beluga (Delphinapterus leucas) by 16S MiSeq sequencing

Corresponding Author: jackywc@gmail.com

The taxonomic characterization of bacteria is usually based on amplification of 16S rRNA gene sequences. The Illumina MiSeq sequencing has extended the read length to 300 bp paired-end reads in a single run, enabling deep sequencing for plenty of samples. The V1–V3 region of 16S rRNA gene has been used as a genetic marker for bacteria, while more studies have used this technology for various microbiome studies targeting the 16S rRNA V3–V4 hypervariable region. However, there is no study on the selection of appropriate 16S target amplicons for cetacean microbiota. The aim of this study was to test the experimental applicability of V1–V3 and V3–V4 primer pairs by comparison of taxonomic coverage and target specificity in cetacean studies. Fecal and blowhole samples from 18 sampling in captive beluga whales (*Delphinapterus leucas*) were used for analysis using MiSeq platform. It shows that the V1–V3 presents higher species richness (Chao1 and observed species) than the V3–V4, but there was no significant difference between them in specie evenness (Shannon and Simpson). In blowhole samples, the V1–V3 appeared to observe more *Flavobacterium*than V3–V4. The V3–V4 appeared to contain more *Varibaculum*and *Taylorella*than found in V1–V3 region. In Fecal samples, the V1–V3 appeared to contain more *Lachnoclostridium*than found in V3–V4. It is therefore important to use primers targeted to these two regions of the 16S rRNA gene in all deep-sequencing efforts to obtain representational characterization of microbial communities.

A late-season survey reveals large numbers of humpback whales in the Northwestern Hawaiian Islands.

In April 2019, the NOAA Pacific Islands Fisheries Science Center and Hawaiian Islands Humpback Whale National Marine Sanctuary conducted a collaborative exploratory ship-based survey for humpback whales (*Megaptera novaeangliae*) in the Northwestern Hawaiian Islands. The 6-day effort surveyed shallow atolls and banks extending from Middle Bank (north of Kauai) to St. Rogatien Banks (north of French Frigate Shoals) and included visual observations and passive acoustic monitoring. Acoustic methods included the deployment of sonobuoys for detection of singing whales in shallow waters and use of a towed hydrophone array for detection between islands and atoll areas and during nighttime transits. We sighted approximately 180 humpback whales, primarily in waters less than 100 m depth, and acoustically detected many singers in shallow waters and during nighttime transits. Whales were also observed transiting between banks. Encounters included at least 13 calves, with several competitive groups at each of the surveyed areas. When feasible, whales were approached for the collection of individual identification photos and biopsy samples. At least 47 individuals were identified with fluke images and 10 biopsy samples

were collected from adults (including 3 pairs of samples from mom-calf-escort triads). This survey builds upon a 2007 visual and passive acoustic ship-based survey and other extensive passive acoustic data that indicated humpback whales use this portion of the archipelago. Our effort resulted in a much higher encounter rate than the previous survey, as well as the collection of adequate photo-ID and tissue samples to examine connectivity of whales in the Northwestern Hawaiian Islands with those in the main Hawaiian Islands and other breeding and feeding locations in the North Pacific.

Receiving sensitivity about the amplitude and frequency of the hydrophones attached to acrylic plate ― Towards simplification of dolphin sound study at aquariums, 2 ―

Yoshida, Yayoi M[1]; Morisaka, Tadamichi[2]; Nakahara, Fumio[3]; Senga, Yasuhiro

Sound recording system for captive aquatic animals, especially dolphins, in a tank needs to give care to the environmental enrichment. Recently it is improved that small hydrophones are attached outside on the acrylic glass of the tank (AQH100k-DTP, AquaSoundCo.). Here we evaluated about the sound transmission loss and modulation characteristics of the acrylic plates for three different thicknesses (15, 20 and 30 mm) at source frequency in range between 3 and 130 kHz. The amplitude of the output from the attached hydrophone was measured by an oscilloscope (TBS1064) and simultaneously recorded in an audio-recorder (EZ7510, Sampling-rate 500 kHz). The modulation was analyzed by an audio-software (Audition6.0). The frequency spectrum was calculated for the recorded signals by the FFT (size: 1024, Hamming window), after was taken noise-reduction at once. Results show no significant correlations between acrylic plate thickness and the sound transmission loss for every frequency. In addition, the loss increased at 3-40kHz, while it shows negative values between 50-130kHz regardless of the plate thickness. The former increased loss is due to the negative reflection at the interface between water and air. The latter gain is due to the sensitivity enhancement of the hydrophone's mechanical Q value. Results also show no significant correlations between acrylic plate thickness and the frequency modulation for every frequency. In addition, the frequency modulation appeared at the region 3-10 kHz, 80-130 kHz, while it was not recognized at 13-70kHz for any plate thickness. The maximum amplitudes appeared at 90kHz at any plate thickness and source frequency. The frequency modulation is affected by the mechanical noise of the recorder. The frequency ranged 3-10 kHz and 80-130 kHz is strongly affected by the high-noise regardless of the plate thickness. It needs careful analysis on transmission loss for recorded aquatic animal sounds by using the outside-attached hydrophone.

A whale of a tale: A 3-year study of metals in Gulf of Maine whales.

The Gulf of Maine is an important body of water for both humans and marine life, located on the Eastern seaboards of the United States and Canada. It is an important marine nursery, feeding ground and sanctuary, with over 3,000 marine species living there. At the same time, the Gulf of Maine is an area with heavy coastal development, industry, and marine traffic, all of which contribute environmental chemicals to the Gulf resulting in chronic exposures of the people, animals and ecosystem that depend on the Gulf of Maine. The whales in the Gulf of Maine are a valuable sentinel species for pollution in the Gulf as they integrate all possible exposure routes and are key species integral to the health of the people, ecosystem and economies of the region. We collected whale skin biopsies for three seasons (2010-2012) and measured the levels of 25 essential and non-essential metals in three whale species: humpback whales (*Megaptera novaeangliae*), fin whales (*Balaenoptera physalus*), and a minke whale (*Balaenoptera acutorostrata*). Overall, the general pattern of metal accumulation was consistent across species. As expected, we found the levels of the essential metals iron (Fe), magnesium (Mg) and zinc (Zn) to be among the highest levels for the metals we observed. Some metals of public health concern, aluminum (Al), nickel (Ni) and chromium

(Cr), were also among the highest levels, while others, arsenic (As), cadmium (Cd), cobalt (Co), lead (Pb), mercury (Hg) and uranium (U) were comparatively low. Comparisons with similar species from other regions indicate humpback whales have levels of genotoxic metals (i.e. DNA damaging) that are among the highest in the world. These data indicate metal exposure may be a significant health concern for the Gulf of Maine ecosystem. This work was supported by NIEHS grant ES016893 (J.P.W.).

Changes in harbor porpoise nutrition during an ocean warming event

n 2013, a mass of unusually warm water, known as "The Blob" was detected along the Pacific Coast of North America and persisted into 2016. The phenomenon dissipated later that year, but a new marine heatwave was detected in June of 2019. The effects of the Blob on local fauna are still being studied, and the population of harbor porpoises (*Phocoena phocoena*) off the coast of California is an ideal candidate for further investigation. Since they are non-migratory, their trophic history can offer insight into how feeding opportunities and trophic composition changed during the warming event. I will document changes in the foraging ecology of harbor porpoises that stranded from 2011-2018 along the coast of California using stable isotope analysis and nutrition characteristics. A better understanding of the foraging histories of cryptic cetaceans preceding, during, and after an extreme event could help managers gain insight into these events in the future.

Behavioural responses to human disturbances at a recently-established designated Atlantic grey seals haul-out site (Halichoerus grypus)

The Ythan estuary was recently included as a designated haul-out site for grey seals on the East coast of Scotland. This followed rapid growth in the number of seals utilising the site year-round. The Ythan estuary is also a favoured destination for recreation and leisure – as well as being directly below the take-off and landing path for helicopters navigating between Aberdeen airport and the offshore oil and gas installations. We need to understand how these human activities influence seal haul-outs to appropriately manage the important site.

This study sampled the behaviour of focal individual grey seals hauled out at the Ythan site during the post-breeding season (July–September 2017, n=420) and during the moult (January-March 2019, n=454) using ad-libitum sampling of behavioural events associated with responses to disturbances.

Grey seals were more likely to scan during post-breeding. In all cases, scanning was increased in the presence of dogs. Vigilance depending on the number of people on the beach also changed during weekends and school holidays. Seals at the back of the group, and those orientated away from the public were more likely to be disturbed – and this occurrence increased with increasing numbers of people and dogs. Interestingly, there was little effect of helicopter presence – except for juvenile seals.

Seals were rarely flushed into the water and this was more likely when people approached the seals from the closed beach area or when dogs entered the water. Human activities affect seal behaviour at this site, this despite those human activities pre-existing the site colonisation by seals. The physiological impacts of flushing during the moult are non-trivial. In addition, the variation in behavioural response between the two periods shows that those responses do incur a cost that may be harder to meet during the moult when seals are energetically constrained.

Global marine mammal bycatch in fisheries: Dispelling the myths and identifying the challenges in implementing the Marine Mammal Protection Act Import Provisions.

Young, Nina[1]; Fields, Lauren[2]; Roberts, Glynnis[3]; Confair, Rachael[3]

The United States' Marine Mammal Protection Act (MMPA) states that the United States shall ban the importation of foreign commercial fish or fish products which have been caught with commercial fishing technology which results in the incidental kill or incidental serious injury of marine mammals in excess of United States standards, or of any fish or fish product that was produced in a fishery that intentionally kills marine mammals in the course of those fishery operations. Under this regulation, NOAA Fisheries, in consultation with foreign trading partners assembled a List of Foreign Fisheries (LOFF). This LOFF contains global fisheries information for fisheries that export seafood products to the United States, including the target catch, gear type used, number of vessels or participants, area of operation of the fishery, and data regarding incidents of marine mammal interaction in the course of commercial fishing operations. Based on the fisheries on the LOFF, in July 2019, nations submitted Progress Reports outlining the steps they are taking to develop regulatory programs to mitigate marine mammal bycatch in their export fisheries. This information was submitted through the NOAA Fisheries International Affairs Information Capture and Reporting System data portal. Now, nearly three years into the implementation of the MMPA Import Provisions we have identified the fishing areas and gear types with the highest marine mammal bycatch. Stationary gear such as gillnets, set nets, and pound nets disproportionally entangle and kill marine mammals more than actively fished gear types. Areas with high marine mammal bycatch are more likely to be those with high gillnet use. Stationary gear represents the greatest challenge for bycatch mitigation while longline, purse seine, and trawl gear is more amenable to safe handling and release standards and best practices, all of which can reduce bycatch. High-seas pelagic fisheries represent a lower bycatch risk

Investigation of habitat preference of Risso's dolphins by using maximum entropy modeling in Eastern Taiwan

The information of spatial distribution and habitat preference of a wildlife species is the fundamental information for conservation and predicting its possible response toward environmental changes or anthropogenic threats. Although Risso's dolphin (*Grampus griseus*) is one of the most common cetacean species off the eastern coast of Taiwan, the knowledge on its distribution pattern is still limited. In this study, we took whale-watching sighting records during the years of 1998-2014 at two areas in the eastern coast of Taiwan. We used ecological niche modelling (Maxent) to analyze the habitat preference of Risso's dolphins with topographic and climatic features (depth, slope, the distance from coast , the distance from river mouth, and SST). Our results suggest that Risso's dolphins frequently occurred in deep water habitats along the edge of continental shelf in the study area. The important variables associated with their distribution include water depth, the distance from river mouth and sea surface temperature. This preference for steep and warm waters is consistent with other studies of the same species off California, in the Mediterranean Sea and the Gulf of Mexico, and may related with their food sources of squids. This study reveals that data from citizen science is able to provide useful information on cetacean spatial ecology.

What's with all the buzzing? – Propagation and potential function of short burst pulses produced by resident-type killer whales (Orcinus orca).

Yurk, Harald[1]; O'Neill, Caitlin[2]; Pilkington, James[3]

Corresponding Author: hayurk@gmail.com

Killer whales in many parts of the world produce pulsed calls that are characterized by stereotypical component structures allowing listeners to distinguish different call types. Due to their high pulse repetition rates some components become tonal. Tonal components often produce distinct frequency contours in spectrograms and therefore have been considered important in social communication. Call components with lower pulse rates or '*buzzes'* have received less attention than their tonal counterparts. Buzzes often occur at the beginning of calls and have been described as introductory notes that may capture the attention of a receiver who then can tune into the information that follows. Alternatively, buzzes may be means to prepare or tune the pulse generating apparatus to produce sounds with high pulse repetition rates that have a tonal quality. Some calls, however, can occur either with or without initial buzz components, while the types and order of the tonal components remains unchanged. On the other hand, buzzes can occur independently without being followed by tonal components. Also, the spectral composition of buzzes shows distinct variations in

sound energy across the frequency domain of these broadband signals. The variation is structured and recurring peaks at increasing sound frequencies are present. We tested the propagation of buzzes produced by a pod of *resident* killer whales in waters off British Columbia during field experiments and found them to travel considerably further than tonal sounds contained in the same sequence of calls in various ambient noise conditions. Buzzes may allow killer whales to stay in contact over greater distances, especially in noisy environments and may play a distinct role in social communication different from that of the tonal components of calls. The occurrence of buzzes at the beginning of calls may underline their role as markers of an important transmission.

Threatened coastal dolphins in southern Brazil: Expert elicitation as a tool for area-based marine conservation.

The coastline of southern Brazil harbours an extremely rich biodiversity, recognised by the presence of a natural World Heritage Site. Even though this area holds many crucial habitats for marine megafauna, it is also being threatened by a wide array of coastal anthropogenic activities that inevitably impact marine ecosystems. Among the present marine megafauna, top predators such as coastal cetaceans play a crucial role in the ecosystem functioning and health. Resident populations of small cetaceans depend on the coastal habitats for reproduction, nursing and foraging throughout their entire lifecycle. Some of these coastal dolphins are considered critically endangered and vulnerable within Brazil, such as Franciscana (*Pontoporia blainvillei*) and Guiana dolphin (*Sotalia guianensis*) respectively. Even though ecological and biological data about these populations exist, there is still a severe lack of spatial data for conservation strategies. In order to fill this knowledge gap, spatial rapid assessment has been conducted through expert elicitation, placing existing ecological data in space, integrating this with layers of anthropogenic activities, and thus exposing potential cumulative impacts and critical areas. Therefore, a workshop series is being organised to identify and map distribution of both dolphins and anthropogenic activities along southern Brazil. A first pilot workshop organised in November 2018, highlighted novel ecological data, such as dolphin occurrences on the coastal shelf, and over 20 anthropogenic stressors were listed. These workshop results are being complemented by a vulnerability assessment collected through an online survey, forming the baseline information for a second workshop in May 2019, which will be conducted with experts. Until December 2019, these results will provide a broader perspective on ecological issues and vulnerability of these dolphins, highlighting priority areas for conservation, and supporting future spatial planning efforts.

Trace element concentration in blubber biopsies of Humpback whales (Megaptera nevaeanglae) from Madagascar: Gender differences and correlation between different elements.

Contaminants monitoring in wild, large cetaceans may be performed using internal organs of stranded animals. Although extremely valuable, data obtained from dead animals can be biased by poor health conditions, modifying the concentrations of pollutants. Blubber biopsies represent the most feasible sampling technique from free ranging Mysticetes but are little used for trace elements quantification. Blubber biopsies from humpback whales (*Megaptera novaeangliae*) have been used to quantify most relevant trace elements (Hg, Cd, Pb, As). Samples were collected during the months of July and August 2014 in the North East of Madagascar, near the Island Sainte-Marie. Sex of the animals were genetically determined. For trace

elements quantification, samples were microwave digested and analyzed using an Inductively Coupled Plasma-Optic Emission Spectroscopy. Obtained data underline a reduced exposure to contaminants, which is not surprising considering the trophic level of humpback whales. Some sex-related differences (T-test, $p<0.05$) were observed for Hg and Cd, with males presenting double amounts of both elements than females (0.088 mg/kg vs 0.047 mg/kg and 0.005 mg/kg vs 0.002 mg/kg respectively). This result is comparable to what can be observed with persistent, organic compounds, and can be explained by element release during lactation. Concentrations of Hg, Pb and As are correlated between individuals in males, whereas As and Hg are not in females. The concentration of Cd is not correlated to the 3 other elements, in both males and females. This can reflect either different exposures to the elements or different accumulation and elimination pathways. We think that analyzing the accumulation of trace elements in humpback whale blubbers may represents a very relevant proxy for monitoring the health status of the population, likely correlated to migration routes and to feeding area localization. Our results will therefore have impacts both in terms of humpback whale ecology and conservation.

Measuring wild cetacean body temperature via blowholes using infrared thermal imaging from a drone

Body temperature is a key health indicator for terrestrial mammals. Thermal measurements of cetaceans have only been done in captivity or with stranded individuals. Internal blowhole temperature of captive dolphins has been shown to be a reliable method for monitoring internal body temperature, but this has not been verified with large, wild cetaceans. We investigated whether drone-based infrared thermography can be used measure internal body temperature of large wild whales by aiming a thermal camera straight down the blowhole apertures from a height of 10 m or higher. We flew an Inspire 1 with a FLIR Zenmuse XT to shoot thermal still images and a Matrice 210 with a FLIR Zenmuse XT2 to shoot thermal video. 48 flights were flown to collect thermographic measurements of relative body temperature in humpback whales (*Megaptera novaeangliae*) on Stellwagen Bank, Massachusetts in 2018 / 2019. FLIR Tools were used to measure a thermal window (>10 x 10 pixels) of the blowholes. Preliminary analysis indicates that looking straight down into a whale's blowholes with a thermal camera may represent an effective and non-invasive method for determining the internal body temperature of cetaceans. However, high variability in measured temperatures indicates a need for extensive flights and trials with different thermal systems to validate the precision of this method. Measurements may not represent true internal body temperature (accuracy depending on limits of imaging sensor up to ±5C) but can be used to measure and compare relative temperatures. The accuracy on internal body temperature measurements may be influenced by atmospheric conditions like cold air cooling the nasal mucosa membrane. These findings help validate the use of drone-based thermal imaging for *in situ* measurements of body temperature of large whales and provides incentive to further explore the uses of aerial thermal imaging for marine mammal health assessments.

Marine animal prosthetics design challenge: Using marine mammals to engage non-traditional audiences in science, technology, engineering, and math.

Zagzebski, Kathryn[1]; Ryack-Bell, Sandra[2]; Sperber, Sara[3]

Women are often underrepresented in science, technology, engineering, and math (STEM) fields in the United States and elsewhere around the world. At the same time, appreciation of animals cuts across gender and socioeconomic boundaries. Therefore, subject matter involving animals can be used to attract and involve many students that might not otherwise be interested in STEM.

The National Marine Life Center (NMLC) uses marine mammal topics to engage students, including girls and other underrepresented audiences, in STEM. Lessons involving marine mammals aren't limited to the biological sciences. Using marine mammals as subject material, we address topics ranging from science to technology, engineering to math, as well as art and language arts. Marine Animal Prosthetics: An Engineering

Design Challenge is a lesson plan that NMLC developed to excite students about engineering. Designed to meet the U.S. Next Generation Science Standards, the lesson connects disciplinary core ideas – life sciences, earth sciences, physical sciences – with technology and engineering. Additionally, the lesson offers opportunities to connect issues of marine mammal science with art and culture will also be addressed. The lesson was piloted to teachers who participated in a Wade Institute for Science Education Summer Professional Development Institute and refined through an Engineering Day event at public elementary schools in Bourne, Massachusetts. The program is now implemented as part of NMLC's regular educational programming.

Contribution to knowledge of ecology of cetaceans in the Black Sea.

The cetaceans are at the top of the food chain in the Black Sea and as the largest predators their populations can be a good indicator of the overall condition of the marine environment. Three species of Odontocetes (dolphins and porpoise) occur in the Black Sea – Black Sea Common Dolphin (*Delphinus delphis* ssp. *ponticus*), Black Sea Bottlenose Dolphin (*Tursiops truncatus* ssp. *ponticus*) and Black Sea Harbour Porpoise (*Phocoena phocoena* ssp. *relicta*). Cetaceans are vulnerable to various factors such as water pollution, food shortages, microbial contamination, habitat loss, interactions with fisheries. Against the backdrop of global changes, significant pressures from human activity contribute to the deterioration of living conditions for marine ecosystems. The cetaceans' conservation is seen as a significant challenge worldwide, especially in isolated water basins as the Black Sea. In this regard, we present an attempt to gather comprehensive data on the biotic and abiotic environment in the Bulgarian Black Sea. Through the application of different scientific methods we present a preliminary data on the ecology of cetaceans, their interactions with fisheries, assessment of the trophic state of the environment in model areas and the pressure of some pollutants. A set of particular data on potential and direct negative impacts on the cetaceans in the Black Sea including toxic pollutants accumulation in sediments, food chains and mammals themselves are presented. Data are discussed in regard with conservation ecology aspect.

Can Important Marine Mammal Areas (IMMAs) be used to assist in identifying areas of "high risk" for ship strikes mitigation?

Important Marine Mammal Areas (IMMAs) are a place-based conservation tool identifying discrete portions of habitat, important to marine mammal species, that have the potential to be delineated and managed for conservation.

Ship strikes involving odontocetes and mysticetes are reported globally, causing both temporary and lethal wounds. Fin whales are the species most often struck by vessels throughout the world's oceans, and there are concerns about the high collision rates for the isolated sub-populations of fin and sperm whales in the Mediterranean.

There is currently no universal technological solution to prevent ship strikes, and the most effective overall mitigation measures are to avoid high risk areas (defined as whale suitable habitat/high density areas interested by high traffic levels) and/or to restrict speed to 10 knots or less to reduce fatal collisions with large whales.

Efforts are being undertaken to assess whether IMMAs can be used as management tools to better delineate high density whale areas for the evaluation of the potential high risk areas for ship strikes.

In particular, IMMAs that contain species or populations vulnerable to ship strikes, and that are transited by significant shipping, could be "flagged" for further investigation of ship strikes events. These include the evaluation of strandings, ship traffic density analyses, and of the potential to

implement mitigation through avoidance or speed reduction.

The IMMA workshop organized in 2016 in collaboration with ACCOBAMS in the Mediterranean Region identified a total of 26 IMMAs, of which eight with large whales as primary species. These IMMAs can be used as tests to evaluate this methodology, by overlapping shipping routes to indicate areas with higher likelihood of ship strikes events. These areas can enhance conservation efforts on marine biodiversity and ecosystem health, leading *inter alia* to mitigation of human impacts and threats to large whales, through appropriate IMO measures.

Studio Porpoise, a novelty for science and tourism.

In 2017 Studio Porpoise was installed at the jetty of Zierikzee in the former Dutch Eastern Scheldt estuary. This area, in which about 50 harbour porpoises (*Phocoena phocoena*) live, is now semi-enclosed by a storm surge barrier.

One study shows that this water contains 5 relatively deep areas (50-60m) where the chance to find porpoises and its prey is above average, 'caused by the tidal turbulence and the abundancy of nutrients'. At one of these hotspot locations, a buoy with a hydrophone and transmitter were placed 200m from the jetty. On the jetty a pillar containing a sound receiver, data recorder and speakers were placed. This unique novelty serves two purposes. One is to show the public the uniqueness of having a cetacean species in the Netherlands, which can be observed simultaneously by ear and eye. Since the installation, 1000's of people have been listening here to the sound of porpoises. The studio's uniqueness was reason for the International Whaling Commission to make it a case study in their recently issued IWC handbook.

The other purpose is to learn more about the species itself. The effect of abiotic and biotic factors on the presence of the harbour porpoise has been studied. The recorded acoustic data, by using Pamguard software, shows that not only the currents are important for attracting prey for the porpoises, but the ship movements of local boats nearby may also be of importance. For now, we notice that most porpoise activity is almost absent here, possibly due to the sound disturbance in the morning. In the afternoon when boats are less present and, in the evening, even absent, the occurrence of porpoises increases. This is now further investigated in order to see if porpoises are affected by sound disturbance even when the prey abundancy is high.

Shedding light on common minke whales in the Gulf of St. Lawrence, Canada: Photo identification, effects of biopsy sampling and exposure to contaminants.

The common minke whale (*Balaenoptera acutorostrata*) is the most abundant mysticete in the St. Lawrence Estuary and its gulf and a seasonal visitor in this important feeding area at the East Coast of Canada. Our knowledge about the structure and size of this population as well as its exposure to environmental contaminants is very limited. Since 2001, we have been conducting a long-term study on minke whales of the St. Lawrence Estuary. A catalogue that currently contains 249 individuals has been established using state-of-the-art photo identification software, and biopsy samples are carried out annually since 2015 using a low-powered crossbow and adapted biopsy darts. In order to assess the short- and medium-term impacts of this biopsy sampling method, multiple behavioral focal animal observations were conducted before and after each biopsy sampling. These biopsies of skin and blubber were analyzed for a series of potentially toxic PBDEs and emerging halogenated flame retardants in order to better understand their bioaccumulation. Transcriptomic analyses were also conducted to investigate on potential effects of these contaminants on this population. Results of our focal animal monitoring suggest that biopsy sampling using a minimally invasive crossbow-dart technique has only short term effects on minke whales. Chemical analyses indicated elevated concentrations of PBDEs and certain emerging halogenated flame retardants in blubber of minke

whales. In addition, gene transcripts involved in the regulation of steroid hormone pathways were associated with several xenobiotics. To our knowledge, this is the first study to investigate the linkages between concentrations of any contaminants and genomic markers of endocrine regulation in this highly contaminant-exposed cetacean population. Although the minke whale population of the St. Lawrence Estuary is not currently at risk, exposure to environmental contaminants could ultimately have a significant impact on the state of health and reproduction of this population.

Understanding vocal behavior of right whale mother-calf pairs to inform passive acoustic density estimation.

A baseline understanding of vocal behavior in baleen whales is a vital first step for passive acoustic density estimation. Here we describe call type and call rate variability for southern right whale (*Eubalaena australis*) mother-calf pairs and characterize the probability of acoustic detection on the calving grounds. The southern right whale is a valuable model system because concurrent visual and acoustic observations of multiple mother-calf pairs can be conducted close to shore. In particular, this has implications for monitoring mother-calf pairs in the Southern Atlantic. Additionally, southern right whales can be used as a proxy for understanding the behavior of highly endangered North Atlantic right whales. For this study, we deployed four suction cup tags and moored hydrophones for 32 days of acoustic recording, as well as used a theodolite to collect 28 days of visual survey data concurrent with acoustic recordings in the Right Whale Environmental Protection Area in Ribanceira Bay, Santa Catarina, Brazil. Using these data, we modeled sound propagation in this environment and compared visual estimates of abundance with recorded calls. Additionally, we report on variation in call types and rates within the bay. These data can be used to inform acoustic density estimation parameters. Over the course of the field study, we recorded abundance estimates from visual surveys of 9 to 21 groups (mother-calf pairs or lone individuals) in the bay each day. The understanding of call rate and how it varies with whale abundance will provide important insight necessary for robust estimations of density using passive acoustic data.

Acoustic presence of bottlenose dolphins (T. truncatus) around a fish farm in the Gulf of Trieste, northern Adriatic Sea.

Common bottlenose dolphins (*T. truncatus)* inhabiting the Gulf of Trieste and adjacent waters of the northern Adriatic Sea have been the focus of a long-term study since 2002, primarily through boat-based and land-based surveys, focal follows and photo-identification. This population is relatively well studied, but its nocturnal occurrence and behavior patterns remain poorly understood. Passive acoustic monitoring methods help us to better understand such patterns when visual observations are limited by weather, daylight or other conditions. Between January 2015 and March 2016 we used a passive acoustic instrument C-POD to monitor dolphin occurrence at a fish farm in Piran Bay, Slovenia, to better understand potential interactions between dolphins and local aquaculture. The KERNO classification algorithm within the CPOD.exe software was used to classify dolphin click trains. Only high and moderate quality click trains were used for further analyses. We used negative binomial generalised additive models (GAMs) in software R to study the relationship between dolphin occurrence and potential covariates such as water temperature, noise, angle of the C-POD, hour of day and month. The C-POD recorded for a total of 17216 hours, including 2280 dolphin detection positive minutes (DPM), which represented 4.53% of all recorded minutes. Most dolphin detections occurred in September 2015 with a total of 648 DPM, while the lowest detection rate was in October with no DPM. The final GAM model included water temperature, hour and angle, and explained 18.8% of deviance, with water temperature being the most important explanatory variable of dolphin presence. Since the area is also a popular summer destination, the follow-up of this study will also help us to better

understand the impacts of tourism and maritime traffic on dolphins in this area.

Growing up with the cool kids – How population density, age and body condition relate to behavior of young Galapagos sea lions.

Living in the demanding waters near the equator, Galápagos sea lions (*Zalophus wollebaeki*) are increasingly confronted with additional challenging factors ranging from overfishing to climate change. To help improve conservation efforts, it is crucial to understand how this endangered marine predator is affected by such changes. Since an individual's behavior is a key component of the immediate response to an environment, studying its diversity, mechanisms and consequences in a population is a prerequisite for a better understanding of a species and its ecology. However, due to methodological constrains of fieldwork, most behavioral research is done under artificial conditions, making it difficult to transfer those findings to natural circumstances. The island tameness of Galápagos sea lions provides the opportunity to gather high-resolution behavioral observations of individuals in combination with physiological measurements and standardized behavioral response-tests. We present the first results of the most in-depth study of natural behavior of Galápagos sea lions, following a three-step approach. We developed (1) a detailed ethogram representing the most comprehensive description of behavior for this species. With help of this ethogram, we (2) studied and found an influence of population density, habitat, age and body condition, on the behavior of twenty pups, which paved the way to (3) look at consistent individual differences in the behavior of those pups, correlating their natural behavior with their behavioral responses toward different personality tests. This project is part of a long-term study, which gives the opportunity to follow individuals for years, observe the ontogeny of their behavior into adulthood, and see the consequences of early experiences on later life success. This study, thereby, will extend our knowledge on the development and adaptation of behavior in general, but will also provide information to better understand and hopefully protect this species of iconic status.

Assessing the recovery of an Antarctic predator from historical exploitation.

The recovery of whale populations from centuries of exploitation will likely have management and ecological implications due to greater exposure to anthropogenic threats and increasing competition with human and other predators for prey resources. A Bayesian population dynamics model that integrates catch data, estimates of absolute and relative abundance, and information on genetics and biology is used to assess the recovery of western South Atlantic (WSA) humpback whales (*Megaptera novaeangliae*). Modeling scenarios are used to evaluate the sensitivity of model outputs resulting from the use of different data, different model assumptions, uncertainty in the allocation of catches, and whales struck and lost. Model-averaged estimates of quantities of interest indicate that a long period of exploitation in the 19th and early 20th centuries drove WSA humpback whales to the brink of extinction. They declined from an estimated 27,200 individuals in 1830 (95% probability interval [PI] = 22,800-33,600) to only 450 whales (95%PI = 200-1,400) in the mid-1950s. Protection in the 1960s led to a strong recovery and the current population (24,900 individuals, 95% PI = 22,400-27,000) is estimated to be at 93% of its pre-exploitation size (95% PI = 73-100%). Results show that previous assessment models that ignored pre-modern whaling catches and whales struck but lost at sea resulted in positive bias in estimates of recent status and time to recover to pre-exploitation abundance. The current WSA humpback whale population likely annually removes 1.52-2.68 million tons of their primary prey, Antarctic krill (*Euphausia superba*), and has the potential to modify the community structure in their feeding grounds. Continued monitoring is needed to understand how these whales will interact with krill and other krill-dependent predators, and how they will respond to modern threats and to climate-driven changes to their habitats.

Do environmental variables affect harbor and gray seal haul out frequency at an offshore haul out site, Mount Desert Rock Marine Research

This work summarizes the trends in harbor seal and gray seal abundance at an offshore haul out site, studying the effect of environmental conditions on daily seal counts for the summers of 2016 through 2019. Allied Whale's field station at Mount Desert Rock (MDR), a small rock formation 25 miles offshore, is a regular haul out site for gray seals (*Halichoerus grypus*) and harbor seals (*Phoca vitulina*) in the northern Gulf of Maine. Seal haul out ledges are used throughout the year at all hours, but the number of seals using these ledges increase significantly during low tides. Daily seal counts across the island of MDR have been conducted regularly for decades at both high and low tides. On average, harbor seal counts are doubled in frequency than gray seal counts; high tide seal counts are markedly dominated by harbor seals with an average of 11 times the number of gray seals hauled out. Environmental variables during summer seasons 2016 - 2019 measured and analyzed include nearshore water temperature and air temperature measured regularly with a HOBO TidbiT data logger, cloud cover, and weather state. The daily seal counts, conducted from June to August, were correlated against regularly collected environmental variables to study the effect of temperature and weather conditions on the number of seals hauling out at MDR. These data are useful for understanding pinniped haul out behavior in the face of environmental variables at an important feeding haul out site in the northern Gulf of Maine.

Sarcocystis neurona Type II and Type VI genotypes associated with fatal polyphasic rhabdomyositis in stranded California sea lions

Protozoal tissue-encysting parasites (e.g. *Sarcocystis neurona*, *Toxoplasma gondii*) are emerging pathogens in marine mammal populations, including several listed or endangered species. Despite their significance, the extent to which these parasites contribute to pathology in these populations is not fully characterized. As part of a continuous surveillance effort, 165 marine mammals (representing three otariid species, two phocid species and four odontocete species) stranding between February 2016 and July 2017 along the California coastline were necropsied and assessed for protozoal infection using PCR-DNA sequencing. A high prevalence (n=61, 37.0%) of protozoal infection was detected, including *Toxoplasma gondii* (n=41), *Neospora caninum* (n=2), and *Sarcocystis neurona* (n=20), with four coinfected animals and two animals infected with novel protozoan species. In most marine mammals, fatal protozoal infection results from meningoencephalitis. Bivariate analyses between cause of death, sample population characteristics (i.e. sex and age), and protozoal infection status incorporating all 165 necropsied animals found only *S. neurona* infection associated with fatal polyphasic rhabdomyositis in the absence of neurologic disease as significant (p=0.007). When parsed using California Sea Lions (CSL) only, the association remained significant (p=0.01), but with a lower statistical power (alpha = 0.05). *S. neurona* infected CSL dying of myositis-related causes were predominantly subadult or younger animals. No other associations were found. Multilocus genotyping of *S. neurona* infected animals using high resolution surface antigen and microsatellite biomarkers revealed a preponderance of Type II and Type VI strains, two strains commonly found associated with causing neurologic disease in circulating marine mammal populations along the Eastern Pacific coast of the United States. This study confirms a significant association between *S. neurona* strains and a novel myositis in CSLs. What remains unknown is why this novel disease presentation has emerged only in one host species.

River bank habitat assessment of the Yangtze finless porpoise in main stem of the middle and lower reaches of Yangtze River
Zhang, Jinxiu; Chen, Mao; Han, Yi[1]; Lei, Peiyu[2]; Wang, Kexiong; Zhigang, Mei[1]; Wang, Ding[2]

Habitat quality can directly affect population abundance and distribution of the Yangtze finless porpoise; however, current habitat status for the Yangtze finless porpoise in the Yangtze River remains unclear. In this study we investigated habitat status of both south and north banks of the main stem of the Yangtze River by taking high-resolution digital photos systematically during the 2017 Yangtze Freshwater Dolphin Expedition from November 10th to December 17th, 2017. The survey area covers the entire middle and lower reaches of the Yangtze River from Yichang to Shanghai (1669km in length) and a total of 794 photo samples were collected. In the meanwhile, we recorded 318 sightings with 631 individuals of the Yangtze finless porpoise. We conducted a Chi-squared goodness of fit test showing that proportions of observed frequency are significantly higher than the expected frequency in natural river banks (χ^2=69.81, P<0.001). Whereas the result is opposite in the semi-natural and solidified river banks (χ^2=39.26, P<0.001; χ^2=12.15, P<0.001), which indicating the natural river banks were the preferred habitat of the Yangtze finless porpoise. The results also showed that the length of the semi-natural river and solidified banks accounted for 45.47% of the total length of the river bank and their patches intermingled with the patches of the natural river banks. These results suggested that the natural habitat preferred by the Yangtze finless porpoise was severely degraded and highly fragmented, which could be the primary reason leading to the fragmented distribution pattern of this species in the Yangtze River. Our study suggested that habitat degradation and fragmentation pose a significant threat to the survival of the Yangtze finless porpoise. Future conservation research and practice should focus on habitat restoration of the solidified river banks to reestablish and enhance habitat connectivity.

Dentine stable isotopes reveal weaning age and variation in diet among narwhals (Monodon monoceros) harvested 30 years apart.

Zhao, Shu-Ting[1]; Matthews, Cory[2]; Ferguson, Steven[3]; Watt, Cortney[2]

Corresponding Author: zhaost@myumanitoba.ca

Changing food webs in the Arctic will alter prey dynamics and may lead to diet shifts for predators. This can have energetic consequences for individuals and impact nursing duration, which may be prolonged or shortened depending on prey availability. Monitoring diet and nursing is difficult for Arctic marine mammals; however, it is made possible by employing stable isotope analysis (SIA) of dentine in teeth/tusks. Dentine is metabolically inert and accumulates as annual growth layer groups (GLGs) in marine mammal teeth. SIA of sequential dentine GLGs can provide a lifetime record of individual diet and be applied to infer weaning, the time at which nursing comes to an end and calves switch from milk to solid food. We used SIA of dentine from narwhal embedded tusks to investigate whether narwhal weaning, and post-weaning diet differ between sexes and among individuals over a 30-year time period. Embedded tusks from both sexes were collected near Pond Inlet, Nunavut, from 1982 – 1983 (n=12) and 2015 – 2017 (n=14). Weaning age was estimated through a ~ 1‰ decline in $d^{15}N$ over the first few GLGs. Ontogenetic $d^{13}C$ and $d^{15}N$ profiles and an isotopic niche breadth were constructed for each individual to compare feeding habits among narwhals. Fifteen narwhals sampled weaned by age one, while 11 were nursed into their second and up-to fourth year. Weaning age did not differ between sexes or time periods. Post-weaning, narwhals showed varied degrees of dietary overlap between individuals ranging from 0 – 100%, suggesting diverged feeding strategies were adopted by different whales. Variation in isotopic niche breadths among narwhals indicates some whales have a more specialized diet than others. This study provides insight on how narwhals have been impacted by climate-induced resource shifts, and the potential for narwhals to adapt to food web changes in the future.

Inbreeding and inbreeding avoidance in Yangtze finless porpoise

Zheng, Yang[1]; Zheng, Jinsong; Hao, Yujiang[1]; Zhigang, Mei[2]; Wang, Kexiong; Wang, Ding[1]

Recent population survey indicates that the Tian'e-Zhou *ex situ* conserved Yangtze Finless Porpoise (YFP, *Neophocaena asiaeorientalis asiaeorientalis*) population has been increasing stably and fast in the past few years. This breeding population now consists of more than sixty individuals that the sex ratio is very close to 1:1. The reproduction occurred within limited number of founders and genes circulated in the relatively closed exchanging pool leads to serious inbreeding risks in such a booming population. Therefore the potential level of inbreeding and the possible existing inbreeding avoidance mechanism are attempting for us to investigate which never been studied in this species. This research

documented the development of a 60-individual pedigree of YFP population. Their relationships were determined by genetic information over four generations in 2015. Mating system and inbreeding rate were studied by parentage-based pedigree analyses using 21 microsatellite loci and a 597 bp segment of the mitochondrial DNA control region. This study identified 37 potential mother-offspring pairs and 38 potential father-offspring pairs (including 32 potential parents-offspring pairs). Among them five maternal multigenerational families were uncovered. It is the largest and most complicated pedigrees ever constructed. The result indicate that the YFP exhibits matrilineal society that characterized with polygamous and male-biased dispersal that is a common way to avoid inbreeding. One case of inbreeding between father and daughter was uncovered and one case of inbreeding happened between halfblooded sibs who share the same father but different mothers. Conversely, we find no case of inbreeding between relatives in the same matrilineal family. This suggests a kind of active inbreeding avoidance strategy also exist to promote avoidance of inbreeding. The ability to recognize maternal relatives, primarily by individual or group-specific vocalizations, may play an important role in inbreeding avoidance.

Tracking the Yangtze finless porpoise by using the non-invasive radio system

Zhigang, Mei[1]; Wang, Ding[2]; Wang, Kexiong

Corresponding Author: meizhigang@ihb.ac.cn

Using tags to track animals can provide insight into their ecology ranging from insects to whales. However, we face great challenge of deploying tracking devices on small toothed whales without the dorsal fin. In June 2018, we tracked two Yangtze finless porpoise in the Poyang Lake by using a newly developed tracking vest to protect tracking tags. The vest has a great elasticity with dense holes to ensure water permeability. In addition, keels were designed to prevent the vest from curling together. Radio tags (designed to lasted for 2 months, 120g, 110*52*12 mm) were made with a transmit frequency of 433 MHz. The receiving base stations were deployed on navigation buoys to collect and transmit real time locations automatically. One of the two tags failed to work immediately after it was released. Observations and photos showed that after released, the two animals stayed together and had integrated into the surrounding porpoise groups. A total of 22,940 minutes tracking with 100,980 surface behaviors were recorded. After released, they moved to a bunker (~2km in length) 10km downstream and stayed there for two days. Then, with the water level rising, they moved to the bunker (~5km in length) 30km downstream and stayed there for 12 days. These records indicate that the porpoise may stay in the bunkers for a long time during the dry seasons, and the fluctuation of the water level is one of the factors driving them to move. After the signal disappeared, we searched for a month in the surrounding waters and found no porpoise or corpse wearing a vest which implies that the vests have been safely detached. This is the first successful long-term tracking of the movements of the Yangtze finless porpoise and the tracking vest provides a new non-invasive way to safely track small toothed whales.

The underwater noise impact on the Yangtze Finless Porpoises (Neophocaena asiaeorientalis asiaeorientalis) in the downstream of Nanjing of Yangtze River of China

Zhou, Lu; Wang, Zhitao; Wang, Kexiong
Institute of Hydrobiology, Chinese Academy of Sciences
Corresponding Author: zhoulu@ihb.ac.cn

The research on how the underwater noise influences the endemic and endangered Yangtze Finless Porpoises (YFP) inhabiting the lower reaches of Yangtze River is extremely limited and indispensable for their conservation. Passive acoustic monitoring in three different points spreading in the lower Nanjing range of the Yangtze River of China was continuously conducted for 14 days in July 2018. The non-parametric test and correlation analysis were utilized to analyze the data. The number of click trains, acoustic witness, and witness duration show uncorrelation to root-mean-square sound pressure level (SPL*rm*) and peak sound pressure level (SPL*p-p*), while they are significantly related to the variance of SPL*p-p*. This indicates that the appearance of porpoises and the duration of their stay probably not be influenced by the mean level of noise, however, they are affected more by the fluctuation of peak level of the noise. Additionally, there is a significant pertinence between the number of buzzes (related to predation) and the variance of SPL*p-p*. It reveals that the stronger the peak level of the noise fluctuates is, the less the porpoises prey. It is claimed that sound environment with drastic undulation of peak level is disadvantageous to the porpoises' predation. Furthermore, the limit of lower frequency of porpoises signals has significant positive correlation with the increase of SPL*rm* and SPL*p-p*, since the SPL*rm* decreases when the noise frequency goes up based on the 1/3 octave band

sound pressure level analysis. And porpoises are easier to discriminate their echolocation signals from higher frequency noise with lower SPL*rm*. To compromise this higher noise level, the lifting of lower limit of signal frequency might cost porpoises more energy. The results inspire us to consider both the fluctuation of peak level of noise and the average noise level when determine the conservation strategy for YFP.

Let sleeping dolphins swim: Characterizing sleep behaviour of wild Indo-Pacific bottlenose dolphins (Tursiops aduncus) in the Northern Red Sea, Egypt.

Undoubtedly, sleep is an essential part of life. While all animal studied to date sleep, cetaceans are among the few that exhibit unihemispherical sleep, where only half of the brain displays typical signs of sleeping due to their continual need for breathing and movement. Most sleeping studies in cetaceans so far have been conducted in captivity, but suggest certain behaviours such as circular swimming are associated with sleeping in cetaceans. However, little is known about sleep behaviours in the wild. Since 2012 *ad libitum* boat-based and underwater SCUBA-based behavioural data (videos/photos) of the Indo-Pacific bottlenose dolphin (*Tursiops aduncus*) have been collected off Hurghada, Egypt. This record provides a unique opportunity to define and study behavioural characteristics of sleeping in the wild, defined here as a period where an individual has at least one eye closed. These videos provide confirmed observations of tight group movement during sleeping in wild cetaceans, and reveal that sleeping is further influenced by social factors and habitat selection, such as reef sites. Hence, this study provides a greater understanding of factors that affect sleep behaviour in wild Indo-Pacific bottlenose dolphins. Particularly, the high association of sleeping behaviour with reef sites suggests that this habitat type is essential for the resident dolphin population. Such an understanding, in turn, enables an effective management for conservation as particularly the Egyptian Northern Red Sea is facing increased pressure of touristic activities.

Clear movement responses by bottlenose dolphins to whistle playbacks

Experimentally testing animal communication theories using field playback experiments with free-swimming cetaceans remains notoriously challenging, as animals are seldom in view when exposed to playbacks. To examine responses of wild bottlenose dolphins to signature whistles of familiar and unfamiliar dolphins, we performed 16 whistle playbacks to 13 individual dolphins in the resident Sarasota Bay, Florida, community, while they were wearing digital acoustic tags (DTAGs). We examined whether movement responses were discernible on the tag accelerometers. Each dolphin was exposed to two playbacks, each of which consisted of two whistles separated by 3 seconds of silence. One stimulus was from a dolphin from a geographically separated population (unfamiliar signature) and the other was from a highly associated dolphin (familiar signature). Clear motion responses were evident in every case, with varying degrees of intensity and duration. Two young males showed short-lived responses (less than 10 seconds), whereas three mothers with dependent calves showed stronger and more prolonged responses (exceeding 1 minute). Two adult males traveling together also showed strong and prolonged (about 1 minute) reactions. Surprisingly, whether the stimulus was a signature whistle of a familiar or unfamiliar dolphin did not appear to affect the magnitude or duration of the response. Although more data are needed, especially from young animals, our preliminary results indicate that older (greater than 4 years) dolphins show stronger responses to whistle playbacks than younger (independent) animals. Further research is needed to determine whether and to what degree social context, behavioral state

and playback design (e.g., stimulus features, post-tagging effects) may have influenced these responses.

Structural and biophysical characterization of the Cetacean morbillivirus haemagglutinin.

Cetacean morbillivirus (CeMV) is an enveloped, non-segmented, negative-stranded RNA virus that infects marine mammals and spreads between species, causing lethal disease outbreaks worldwide. Among the eight proteins encoded by the CeMV genome, the haemagglutinin (H) is responsible for the virus binding to cellular receptors, thereby enabling its entry into the host cell. As a determinant of virulence and pathogenesis, CeMV H represents an attractive target for antiviral and diagnostic research. Yet the elucidation of the molecular mechanisms underlying its role in infection and inter-species transmission has been hampered so far due to the unavailability of a recombinant version of the protein. Here we present the cloning, expression and purification of the recombinant CeMV H ectodomain in a heterologous system, providing a molecular view of its structural organization by means of biochemical (sodium dodecyl sulphate - polyacrylamide gel electrophoresis (SDS-PAGE), Western blot (WB) – periodic acid Schiff (PAS), blue native (BN)-PAGE, liquid chromatography mass spectrometry (LC-MS)), biophysical techniques (size exclusion chromatography - multiangle light scattering (SEC-MALS), miniaturized differential scanning fluorimetry (nano-DSF)) and negative stain three-dimensional electron microscopy (3D-EM) single particle analysis. Results show that the recombinant CeMV H ectodomain is natively glycosylated, globularly folded and thermally stable. Moreover, CeMV H exists in solution in the oligomeric states of dimers and multiple of dimers. Furthermore, the low-resolution density map obtained by 3D-EM represents the first experimental model for the delineation of the CeMV H molecular architecture. Paving the way for future investigations at atomic level, the structural insights here presented serve as a fundamental framework towards an understanding of the CeMV H function.

Scaling the laws of marine mammal detection using thermal imaging

Marine mammals are under growing pressure as anthropogenic use of the ocean increases. Ship-strikes of large whales and loud underwater sound sources including airguns for marine geophysical prospecting and naval mid-frequency sonar are criticized for their possible negative effects on marine mammals. Competent authorities regularly require the implementation of mitigation measures, including vessel speed reductions or shut-down of acoustic sources if marine mammals are sighted in sensitive areas or in predefined exclusion zones around a vessel. To ensure successful mitigation, reliable at-sea detection of animals is crucial. To date, ship-based marine mammal observers are the most commonly implemented detection method, however thermal (IR) imaging based automatic detection systems have been used in recent years. We evaluated thermal imaging-based automatic whale detection technology for its use across different oceans. During six field experiments between 2014 and 2017 in Australian, US and Canadian waters we assessed the performance of this technology and characterized it with respect to environmental conditions with and without use of an automatic detection algorithm for whale blows. We show that the technology can detect whales in polar, temperate and subtropical ocean regimes over distances of up to several kilometers and in some situations outperforms marine mammal observers in probability of whales detected. We present dual platform performance comparison of real-time marine mammal detections by the thermal imaging system and traditional marine mammal observers. Our results show that thermal imaging technology can be used to assist in providing protection for marine mammals against ship-strike and acoustic impact across the world's oceans and provides a hitherto unique night-time ability to detect whales at the surface.

Results of visual observer aerial surveys for six large whale species in the New York bight

Abundance, seasonality, and density of large whale species in the New York Bight have not been intensively studied to date. Assessing impacts from potential future development in the NY Offshore Planning Area requires current and comprehensive data on these species. This longitudinal multi-year study is investigating 6 large whale species (North Atlantic right whale, blue, fin, sei, humpback, and sperm whale) by conducting monthly visual aerial surveys. Survey transects run from the south shore of Long Island, NY to beyond the continental shelf break (total survey area of 43,449 km^2). Aerial line-transect methods are being used to allow estimation of density and abundance using distance sampling techniques. Data from the first 2 years have been analyzed. In Year 1 (Y1), 73 sightings were recorded while in Year 2 (Y2) 143 sightings were recorded. Combined density of the 6 whale species in Y2 was 0.00235 individuals/km^2 and total abundance was 102 (CV = 21.11%), representing improved accuracy over Y1 density estimates, which were based on a smaller sample size. Density estimates (individuals/1,000 km^2) were highest for humpback (Y1=0.483; Y2=1.513) and fin (Y1=0.506; Y2=0.658) whales in both years. Sei whales were only seen in Y2 (0.011) and blue whales only in Y1 (0.046). Sighting rates varied seasonally; in both years fin whale sighting rates were highest in spring and humpback whale sighting rates were highest from summer through winter. North Atlantic right whales were seen during 5 months in Y1 in fall, winter, and spring and 3 months in Y2 in winter and spring. Photographs of right whales in Y1 and Y2 were submitted to the New England Aquarium, resulting in the identification of 6 individual right whales, including 2 whales new to the catalogue. Surveys will continue through February of 2020 for a total of 3 years of data collection.

Distribution and resource division of the two coastal dolphins inhabiting the southern Israeli Mediterranean coast

The southeastern continental shelf of the Levantine Basin was recently announced by IUCN's Marine Mammal Protected Areas Task Force as an Important Marine Mammal Area (https://www.marinemammalhabitat.org/portfolio-item/coastal-shelf-waters-southeast-levantine-sea) on account of both the common bottlenose dolphin (CBD; *Tursiops truncatus*) and the common dolphin (CD; *Delphinus delphis*) inhabiting the area. During the last decade, both species are sighted year round, with CBD maintaining a presence along the entire Israeli coast and CD being confined to its southern portion. In order to establish science-based conservation measures, a thorough understanding of the level of geographical and ecological overlap of the two species off the southern coast is required, together with the degree of distributional overlap with putative anthropogenic threats (e.g. gas industry & fishing) and conservation measures (e.g. marine protected areas). In other areas around the world, the two species' overlap is possible due to different diets, with CBD being mainly a benthonic predator and CD feeding on epipelagic and mesopelagic schooling prey (the latter while upward migrating at night). In Israel, stomach content analysis suggests that both species are exploiting trawlers as a food source, with partial diet overlap. In the case of CD, this may enable presence during seasons when its typical prey is at low supply. This research will deploy technologies aimed at expanding the knowledge about distribution (boat and unmanned aerial surveys), daily habitat utilization (moored passive acoustic recorders coupled with the development of dedicated CBD-CD species-classification software), resource sharing/division (stomach contents and stable isotope analysis) and interaction with trawlers (net-attached underwater cameras). Preliminary mapping results show CD sightings during daylight hours not to extend beyond 10 km from shore and rarely beyond the 50 m isobath. The proposed first stage of the Avtach Marine Protected area (70 km^2) covers roughly 6% of CD's daylight area of occupancy.

Follow the leader or take a vote? Long-finned pilot whales choose democracy for their day-to-day diving decisions.

Long-finned pilot whales (*Globicephala melas*) are a gregarious, social species of cetacean that live in long-term stable matrilines. Their common name – pilot – refers to assumptions that an individual leads the group, but how they make their day-to-day decisions is still a mystery. Theoretical models predict that most social-living organisms would be expected to use shared consensus decision-making processes, as this leads to greater expected fitness gains at both a group and individual level unless there is significant asymmetry in ecological knowledge among group members. In this study we used drone-collected footage of long-finned pilot whales summering off Cape Breton Island, Nova Scotia, to look at whether group decision-making events, such as deep dives or turns, showed evidence of leadership or shared consensus processes. Preliminary analyses used 239 minutes of aerial video footage of long-finned pilot whales (N=136) from 11 independent groups to look at transitions from a shallow diving pattern to a deeper, longer dive where all whales dove out of sight for periods of over 45 seconds. In these cases, the interval between the 1stand 2nd dive (median 0.7s) was similar to that between subsequent pairs of dives: 0.9s between the 2ndand 3rd, 1.1s between the 3rdand 4th, 0.6s between the 4thand 5th, and so forth. This suggests that pilot whale dive decisions are generally consensual. However, in two of the groups the first individual to dive had a substantial lead over subsequent dives (3.0s and 14.6s respectively), which may indicate attempted leadership. Determining how long-finned pilot whales achieve consensus is important for learning more about their within-group behavioural structure and dynamics, which are poorly understood.
